Journal of the Physical Society of Japan

Published monthly by the Physical Society of Japan and devoted to original papers in physics and related fields which materially contribute to the progress of physics

BOARD OF EDITORS (1959-1960)

T. Kato (Chief Editor), S. Asaka, M. Hatoyama, H. Horie, I. Imai, T. Inui, E. Ishiguro, K. Ishiguro, K. Kinosita, G. Kuwabara, S. Miyahara, T. Nagamiya, S. Ono, S. Ogawa, K. Senda, T. Suzuki, S. Suwa, H. Takahasi, T. Tanaka, E. Tatsumoto, M. Toda, Y. Tomono, S. Tomotika, R. Uyeda.

SUGGESTIONS TO OVERSEAS CONTRIBUTORS

Manuscript should be addressed to the Office of the Physical Society of Japan, Room No. 342, Physics Building, Faculty of Science, University of Tokyo, Bunkyo-ku, Tokyo.

Each manuscript should be prepared as concisely as possible. Its organization should conform to the following: title, author's name, name and address of the author's institution, synopsis of about 100 words, body of the paper, list of references, tables and figures. The textual material should be typewritten, double-spaced on white bond paper of letter size. The original copy is required. Literature reference should be numbered consecutively. Figures and photographs will be printed in any of the following sizes (at the choice of the author): 3 cm, 6 cm, 12 cm in breadth, less than 18 cm in height. The original should be 2.5 to 3 times as large as the size in print. The drawing should be a very neatly prepared original with lettering, in Indian ink. Self-explanatory titles to figures and photographs are essential.

Short Note Section is provided for brief reports which need prompt publication. The manuscript of a Short Note should follow the same style and form as that required for a full paper with the exception that it needs no synopsis. The available space for a Short Note is one page of the Journal (about 800 words).

Galley proof only will be sent to the author. Proof should be carefully corrected and returned as soon as possible to the Office of the Society. For prompt publication, proof of the Short Note will sometimes be read by the Editor in place of the author.

Reprints may be ordered in lots of 50. The author or the author's institution is requested to pay charges according to the following formulae:

$\$\,(2.00+0.10p^2+(1.50+0.01x)p+3A)$ for full paper, $\$\,(3.00+0.01x)$ for Short Note.
Here p stands for the number of printed pages of the paper, x for the number of copies required, and A for the number of sheets of art paper if any.

SUBSCRIPTION

Subscription orders as well as related inquiries should be addressed to the Office of the Society or to one of the following agents:

Gamma Rays from Several Elements Bombarded by 10 and 14 MeV Protons.

By Tetsuo WAKATSUKI, Yasuo HIRAO, Eiji OKADA, Iwao MIURA,
Kenzo SUGIMOTO and Akira MIZOBUCHI

Department of Physics and the Laboratory of Nuclear Studies,
Faculty of Science, Osaka University, Osaka

(Received December 14, 1959)

Gamma ray spectra and intensities from C, O, Mg, Al, Si, Ca, Ti, Cr, Fe, Ni, Cu, Ag, Cd, Sn, Pt, Au and Pb bombarded by 10 and 14 MeV protons have been studied.

For C, O, Mg, Si and Ca, most of the gamma rays could be attributed to the inelastic scattering. New levels at 7.08 and 8.13 MeV are suggested in ^{40}Ca.

§ 1. Introduction

The analysis of gamma rays from the excited states of nuclei gives valuable informations on the properties of nuclei. Detailed investigations have been carried out for many nuclear levels following the decays of radioactive nuclides and for nuclear levels of nuclides formed by proton or neutron capture. Compared to these investigations, excitations of nuclear levels by the inelastic scattering of protons has the advantage that it can be applied for most of the nuclei and is especially suitable for studying relatively lower levels. Gamma rays resulting from inelastic scattering of protons have been studied only for few elements at relatively low proton energies. We have investigated the gamma rays due to inelastic scattering of protons using proton energies up to 5.7 MeV for some light elements[1]. In this paper, we shall report the results of similar investigations in which we employ 10 and 14 MeV protons in an attempt to observe gamma rays from higher excited states. In this case, however, due to higher proton energies, gamma rays following (p, n), $(p, \alpha)\cdots$ reactions pile up upon those due to inelastic scattering for most elements.

For C, O, Mg, Si and Ca, the gamma ray spectra could be resolved and identified for the most part as coming from various levels excited by the inelastic scattering of protons. For the other elements investigated (Al, Ti, Cr, Fe, Ni, Cu, Ag, Cd, Sn, Pt, Au and Pb) the spectra could not be fully resolved. In these cases, a survey on the energy spectra was made including higher energy spectra following capture of protons.

§ 2. Experimental Arrangements

The proton beam from 63 in. variable energy cyclotron of the Institute for Nuclear Study of the University of Tokyo was used. The general arrangements are shown in Fig. 1.

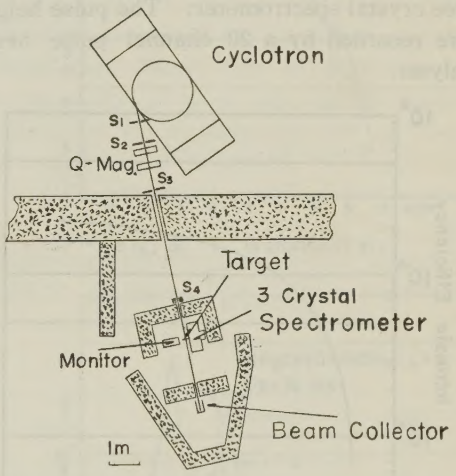

Fig. 1. T. Wakatsuki etc.

To avoid background due to neutrons, the protons were collimated to a narrow beam by slits S_1 (6 mm × 6 mm), S_2 (7 mm width) and S_3 (7 mm height) in the cyclotoron room so that no proton hit the wall of the beam duct. S_4 is a slit 6 mm wide and 10 mm high in front of the target. All those slits were made of graphite and a lead block of 10 cm thickness with a hole of size 8 mm × 12 mm was placed just behind the slit S_4 to absorb the gamma rays emitted from graphite along the beam duct. The targets used were all thin foils and protons after traversing the target were collected in a Faraday cup placed 2.7 m

1155'' 63 / 10

away from the target and measured by a current integrater. The size of the beam, as measured by colouration of a glass plate at the position of the target, was 2 mm in width and 14 mm in height. The target, detecter and Faraday cup were shielded by surrounding with concrete blocks as shown in Fig. 1.

The detectors for gamma rays were single crystal spectrometer with NaI (Tl) 3 in. in diameter and length, and a three crystal scintillation pair spectrometer with a center crystal of 1½ in. diameter and 4 in. long. The side crystals were 3 in. in diameter and length. The gamma ray to the three crystal pair spectrometer was collimated by a lead block with a hole 2.5 cm in diameter and 10 cm in length. Scintillation crystals were shielded by 10 cm thick lead blocks. The distance from the target to the surface of the scintillation crystal was 12 cm for the single crystal spectrometer and 18 cm for the center crystal of three crystal spectrometer. The pulse heights were recorded by a 20 channel pulse height analyzer.

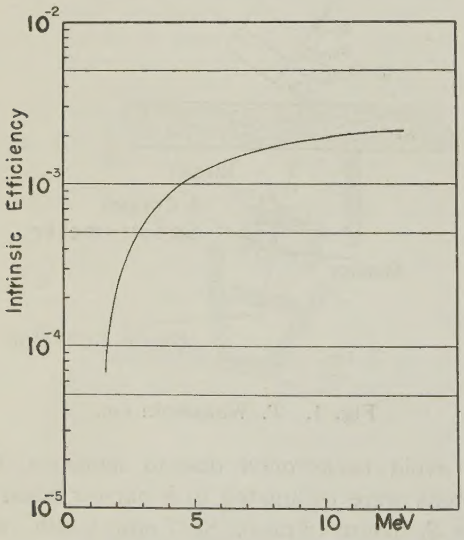

Fig. 2. Calculated efficiency of the three crystal spectrometer for the gamma ray incident on the center crystal surface.

To determine the cross sections we used a calculated efficiency curve for our three crystal spectrometer shown in Fig. 2. The absolute value was normalized at 4.43 MeV gamma rays produced by $^{12}C(p, p'\gamma)$ reaction at proton energy of 14 MeV for which inelastic cross section has been determined by Peelle at 14.0 MeV[2]. For a single crystal spectrometer, efficiency curves obtained by Lazer et al. were utilized[3]. The spectrometer was calibrated for gamma ray energies by ^{60}Co(1.17 and 1.33 MeV), ThC″(2.62 MeV) and $^{12}C(p, p'\gamma)$ (4.43 MeV). The energy resolution of our three crystal spectrometer was 13.8% at 2.62 MeV and 9.7% at 4.43 MeV. The resolution of the single crystal spectrometer was 6.3% at 2.62 MeV.

§ 3. Results and Discussions

1) C

Three crystal pair spectra of gamma rays from polyethylene target 4.3 mg/cm² thick bombarded by 14 and 10 MeV protons are shown in Fig. 3 and Fig. 4, respectively. Besides the intense 4.43 MeV gamma ray from the first excited state of ^{12}C, there appear weaker gamma rays of energy between 6 and 8 MeV. The ratio of the intensity to that of 4.43 MeV is about 1/300 for both 14 and 10 MeV protons considering the detector efficiency. The second excited state of ^{12}C at 7.66 MeV has been investigated by authors[4] and its spin is assigned as 0^+, which decays to ^{8}Be and α particle and no ground state gamma transition can be expected. From the above value of the ratio of gamma rays we may calculate the upper limit of Γ_γ/Γ for

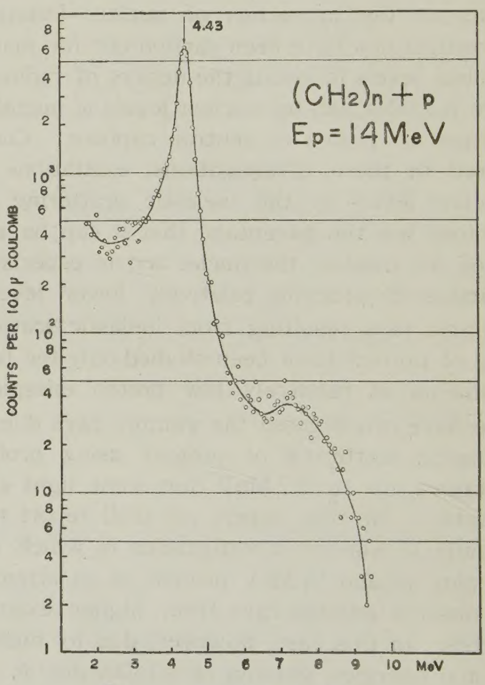

Fig. 3. T. Wakatsuki etc.

7.66 MeV level if the ratio of cross sections for inelastic scattering leading to 7.66 and 4.43 MeV level is known. As the cross sections for 14.0 MeV protons are not available, we used the cross sections at 16.7 MeV[2] and obtained the result $\Gamma_\gamma/\Gamma<10\%$. The value of upper limit 10% is consistent 1.4% obtained by Moak et al.[5]

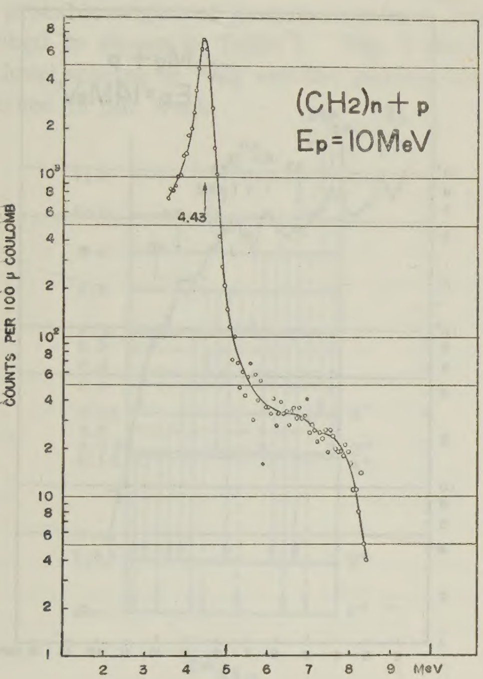

Fig. 4. T. Wakatsuki etc.

To see if the gamma rays between 6 and 8 MeV comes from the capture of protons by ^{12}C, we measured the gamma ray spectra under similar conditions using 5.5 MeV protons from 44 in. cyclotron at Osaka University. Though the capture gamma rays are expected to increase compared to 4.43 MeV inelastic gamma rays at lower bombarding energies, the intensity of higher energy gamma ray was observed not to exceed the intensity (compared to 4.43 MeV gamma rays) at proton energy of 14 MeV. Therefore, the origins of the higher energy gamma rays at 6∼8 MeV observed in the present experiment are perhaps ^{13}C$(p, p'\gamma)$ reaction but some part may be the results of ^{13}C$(p, n\gamma)$ reaction and pile up of 4.43 MeV gamma rays.

2) O

Self supporting film of polyvinylacetate $-CH_2CH(O\cdot CO\cdot DH_3)-$ 2.8 mg/cm² thick was bombarded by 14 and 10 MeV protons. Three crystal pair spectra are shown in Fig. 5 and Fig. 6. Besides 4.43 MeV gamma rays from ^{12}C, intense gamma rays from the excited states of ^{16}O at 6.13, 6.19 and 7.10 MeV were observed for both proton energies. Moreover, for proton energy of 14 MeV, 8.87 and 5.65

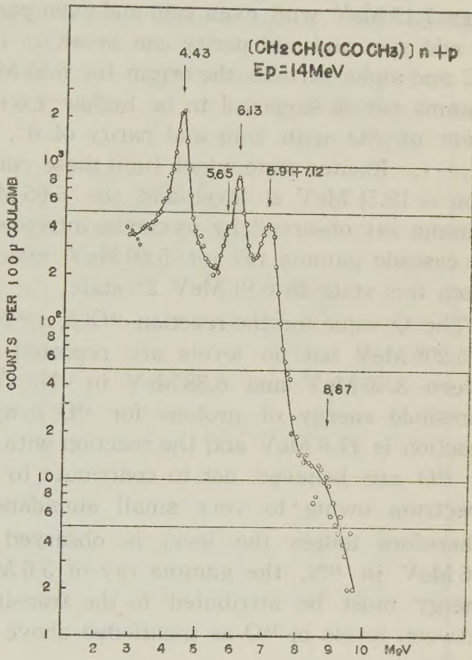

Fig. 5. T. Wakatsuki etc.

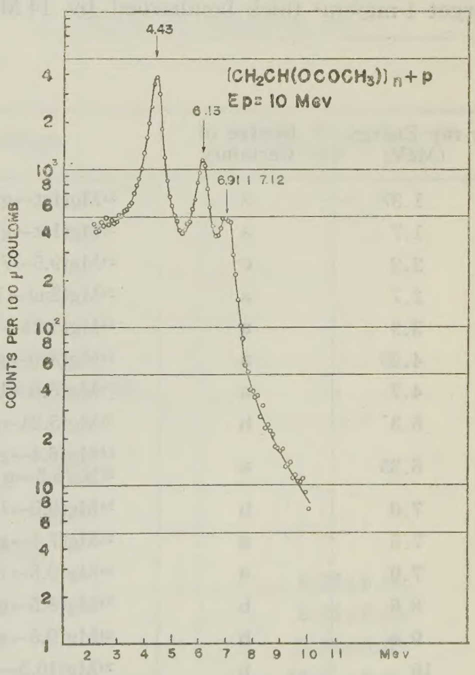

Fig. 6. T. Wakatsuki etc.

MeV gamma rays were observed. The former comes from 8.87 MeV state of ^{16}O and the latter, not observed for proton energy of 10 MeV and observed also from SiO_2 bombarded by 14 MeV protons (Fig. 9) can be interpreted as cascade gamma ray from higher excited state of ^{16}O. As the excited state of ^{16}O higher than 7.15 MeV with even spin and even parity or odd spin and odd parity can break up into ^{12}C and alpha particle, the origin for 5.65 MeV gamma ray is supposed to be higher excited state of ^{16}O with spin and parity of 0^-, 1^+, 2^-, $\cdots$. Excited state which fulfil these condition is 12.51 MeV 2^- level and the 5.65 MeV gamma ray observed by us can be interpreted as cascade gamma ray (of 5.60 MeV energy) from this state to 6.91 MeV 2^+ state.

The Q value for the reaction $^{16}O(p, \alpha)^{13}N$ is -5.208 MeV but no levels are reported between 3.56 MeV and 6.38 MeV in ^{13}N. The threshold energy of protons for $^{16}O(p, n)^{16}F$ reaction is 17.8 MeV and the reaction with ^{17}O or ^{18}O are believed not to contribute to the spectrum owing to very small abundances. Therefore unless the level is observed at 5.6 MeV in ^{13}N, the gamma ray of 5.6 MeV energy must be attributed to the transition between levels in ^{16}O as mentioned above.

3) Mg

A gamma ray spectrum from magnesium target 1 mg/cm² thick bombarded by 14 MeV protons is shown in Fig. 7. Q values for $^{24}Mg(p, n)^{24}Al$, $^{25}Mg(p, n)^{25}Al$ and $^{26}Mg(p, n)^{26}Al$ are -14.8, -5.02 and -4.5 MeV, respectively. Q values for $^{24}Mg(p, \alpha)^{21}Na$, $^{25}Mg(p, \alpha)^{22}Na$ and $^{26}Mg(p, \alpha)^{23}Na$ are -6.880, -3.161, -1.848 MeV, respectively. Q values for $^{24}Mg(p, \alpha)^{21}Na$, $^{25}Mg(p, \alpha)^{22}Na$ and $^{26}Mg(p, \alpha)^{23}Na$ are -6.880, -3.161 and -1.848 MeV,

7.9	a	^{24}Mg(9.5→1.37)
8.6	b	^{24}Mg(8.5→g)
9.4	b	^{24}Mg(9.5→g)
10	b	^{24}Mg(10.5→g; 11.5→1.37)

respectively. Matsuda, Oda and others measured energy spectra of scattered protons from magnesium using 14 MeV protons[7]. They have found scattered protons from 1.37, 4.2 (4.12, 4.24), 5.24, 6.0, 7.4, 8.5 and 9.5 MeV levels of ^{24}Mg. Considering these results and Q values for (p, n) and (p, α) reactions as well as the previous works with magnesium[1),6)] the probable origins of gamma rays have been ascribed as shown in Table I. Fig. 8 shows the level scheme of ^{24}Mg and the gamma rays observed in our work.

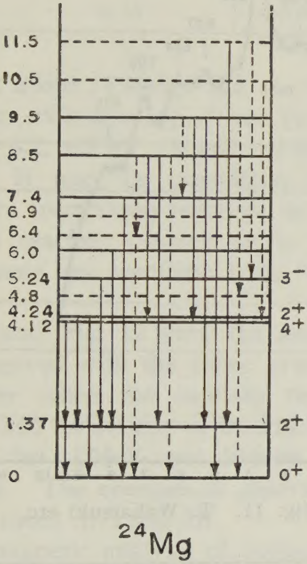

Fig. 8. T. Wakatsuki etc.

4) Si

A thin target of SiO$_2$ of 1.5 mg/cm^2 in thickness was used. The Q values of (p, n) and (p, d) reactions for ^{28}Si and ^{16}O are negative and larger than about 14 MeV. For (p, α) reactions, these values are −7.71 and −5.20 MeV for ^{28}Si and ^{16}O, respectively. But considering barrier penetrabilities, high energy

8.44	a	^{28}Si(8.3→g)	8.28±0.04
8.89	b	^{28}Si(8.6→g)	8.75±0.04
9.41	c	^{28}Si(9.3→g)	9.45±0.08
10.8	b	^{28}Si(10.03(10.7)→g)	10.7 ±0.2

gamma rays from these reactions are considered to be less intense than from the (p, p') reactions.

The Q values for $^{29}Si(p, n)$, (p, d) and (p, α) reactions are −5.75, −6.25 and −4.82 MeV, respectively. These values for ^{30}Si are −5.05, −8.3 and −2.38 MeV, respectively. These reactions may occur, but the gamma ray intensities from these reactions may be also weaker than from inelastic scattering by ^{28}Si, ^{29}Si and ^{30}Si even in the low energy region, considering the abundance ratio and barrier penetrabilities.

Fig. 9 shows the gamma ray spectrum observed with the three crystal spectrometer when the SiO_2 target was bombarded by 14 MeV protons. The energies of the gamma rays were determined from this spectrum and other spectrum of single crystal spectrometer. These results were listed in Table II. Bent et al.[8] measured the gamma ray energies from $^{27}Al(d, n\gamma)$ ^{28}Si reaction with a magnetic pair spectrometer. These results agree fairly well with the present results for the gamma rays above 8 MeV. But we can not compare the lower energy gamma rays, because of the presence of intense 6 and 7 MeV gamma rays from $^{16}O(p, p'\gamma)$ reaction. Fig. 10 shows the decay scheme of ^{28}Si.

5) Ca

For calcium targets, we used two metalic calcium foil targets of different thickness, one of which was 0.8 mg/cm² and the other was 2.0 mg/cm² in thickness, in order to estimate the effect of oxygen impurity on the surface of the foil. This effect could not be observed. The isotopic abundance of ^{40}Ca is 97% and that of ^{44}Ca is 2%. The Q values of $^{40}Ca(p, n)$ and (p, d) reactions are also negative and

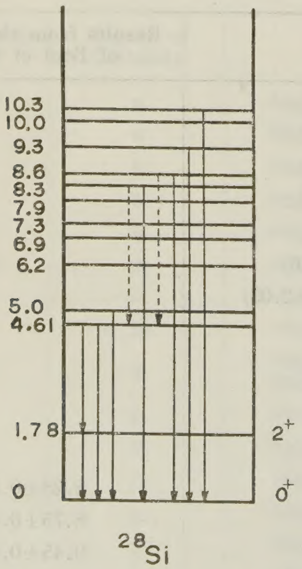

Fig. 10. T. Wakatsuki etc.

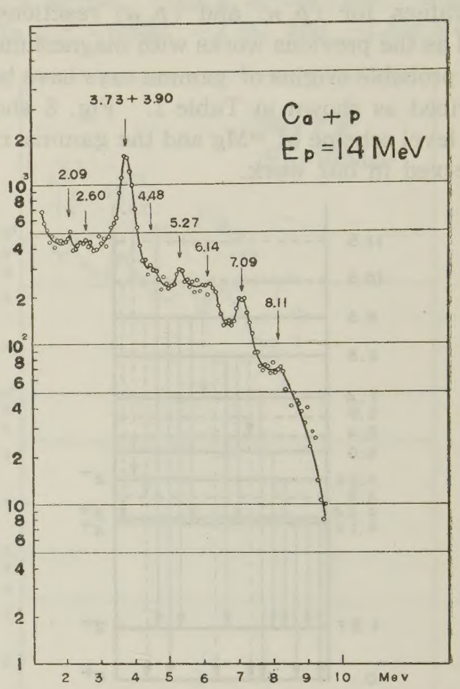

Fig. 11. T. Wakatsuki etc.

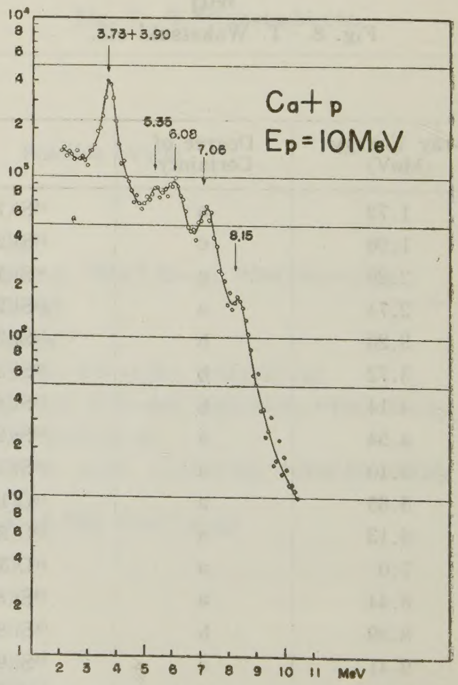

Fig. 12. T. Wakatsuki etc.

Table III.

γ-ray Energy (MeV)			Degree of Certainty	Possible Origin
E_p=10 MeV	E_p=14 MeV	Mean Value		
—	2.09	2.09	b	^{40}Ca(6.03→3.90)
2.57	2.60	2.59	b	^{40}Ca(6.03→3.35; 7.09→4.48)
3.73	3.73	3.73	a	^{40}Ca(3.73→g)
3.90	3.90	3.90	(not resolved)	^{40}Ca(3.90→g)
4.90	4.48	4.70	b	^{40}Ca(4.48→g)
5.35	5.27	5.31	a	^{40}Ca(5.27→g)
6.08	6.14	6.11	a	^{40}Ca(6.03→g)
7.06	7.09	7.08	a	^{40}Ca(7.08→g)
8.15	8.11	8.13	a	^{40}Ca(8.13→g)

larger than about 14 MeV. But the Q values of ^{40}Ca(p, α), ^{44}Ca(p, n), (p, d) and (p, α) reactions are −5.2, −3.65, −9 and −1 MeV, respectively. It may be considered that the gamma rays from these reactions as well as ^{44}Ca($p, p'\gamma$) reaction overlap on to the low energy gamma ray spectrum from ^{40}Ca(p, p') reaction.

Fig. 11 and Fig. 12 show the gamma ray spectra observed with the three crystal pair spectrometer when the calcium targets of 0.8 mg/cm^2 and 2.0 mg/cm^2 in thicknesses were bombarded by 14 MeV and 10 MeV protons, respectively. The energies of observed gamrays were listed in Table III.

By the magnetic analysis of inelastic scattering of 6 to 8 MeV protons by ^{40}Ca, the level energies have been determined up to 6 MeV. The levels above 9 MeV have been studied by ^{39}K(p, γ) reaction[6]. But any information for levels in the region from 6 to 9 MeV have not been reported. The gamma rays observed in the present work in the energy range from 2.09 to 6.11 MeV can be expected from the results of the magnetic analysis of the inelastic scattering. But two gamma rays of 7.08 and 8.13 MeV are both newly found gamma rays and can not be explained as cascade gamma rays between well established states. It is also impossible to consider that these gamma rays result from other reactions or ^{44}Ca, considering the intensites of both gamma ray spectra by 14 and 10 MeV protons, Q values, barrier penetrabilities and abundance. We concluded, therefore, that ^{40}Ca have the levels at 7.08 and these two gamma rays are of the direct ground state trasitions. Shook[9] reports a 8.4 MeV level in ^{40}Ca by the observation of α particle groups from the inelastic scattering of 43 MeV α particles. This level may be the same one as the 8.13 MeV level above mentioned. Fig. 13 shows the levels and gamma rays in ^{40}Ca.

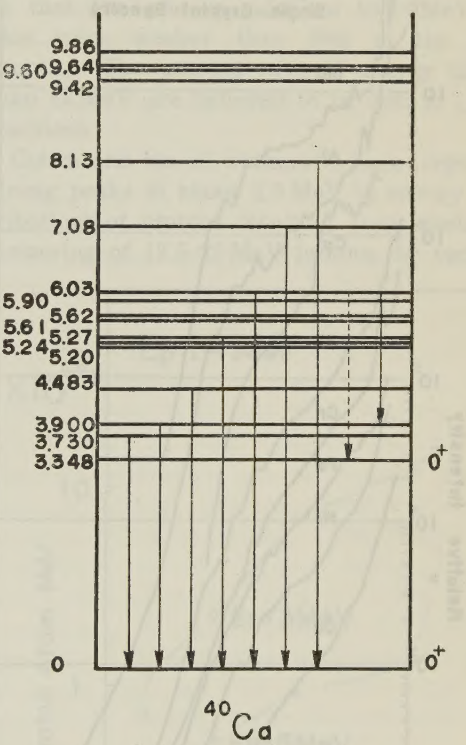

Fig. 13. T. Wakatsuki etc.

6) Other elements

A survey was made on the energy spectra of gamma rays from natural Al, Ti, Cr, Fe, Ni, Cu, Ag, Cd, Sn, Pt, Au and Pb bombarded by 14 MeV protons. The targets used were thin metal foils and most measurements were made with the single crystal spectrometer. In the cases of Al, Cu, Sn, Pt and Pb, these gamma ray energy spectra were also measured with the three crystal spectrometer.

The proton energy of 14 MeV is larger than the threshold energy for (*p*, *n*) reactions of these targets. (*p*, *pn*), (*p*, 2*n*) and (*p*, *α*) reactions are also possible for some nuclei, but proton energy of 14 MeV is not sufficiently higher than the threshold of (*p*, *pn*) and (*p*, 2*n*) reactions for most of these elements. Therefore the gamma rays following (*p*, *pn*), (*p*, 2*n*) and (*p*, *α*) reactions may be weaker than the gamma rays following (*p*, *p′*) and (*p*, *n*) reactions for most of these elements.

Neutrons arising from (*p*, *n*), (*p*, *pn*) and (*p*, 2*n*) reactions in the targets pass through the NaI (T1) scintillation crystal, and gamma rays following neutron nonelastic scattering in scintillation crystal and neighboring matters overlap on the gamma ray spectra. But the intensities of gamma rays following neutron scattering are estimated to be weaker than

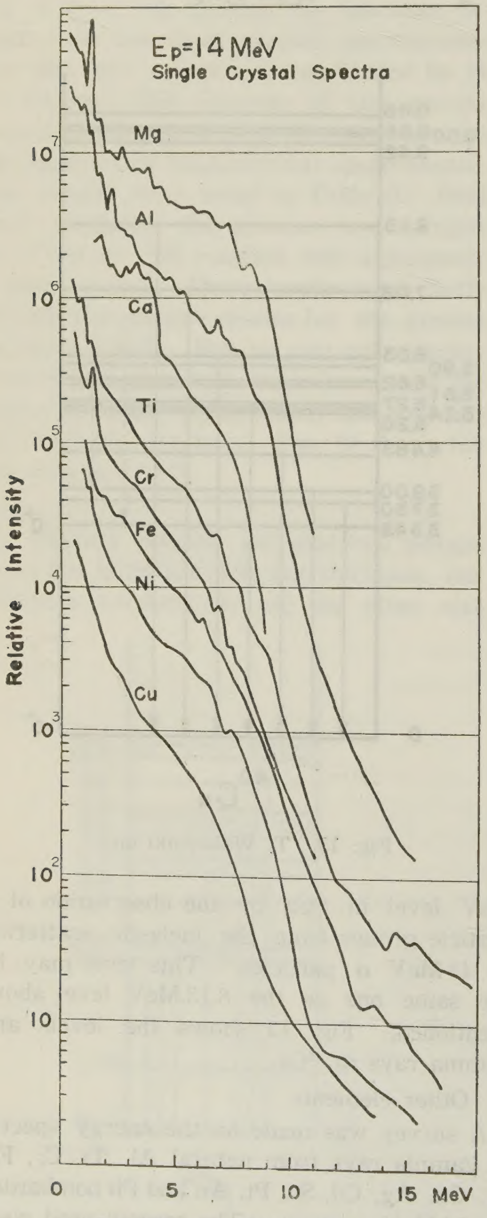

Fig. 14. T. Wakatsuki etc.

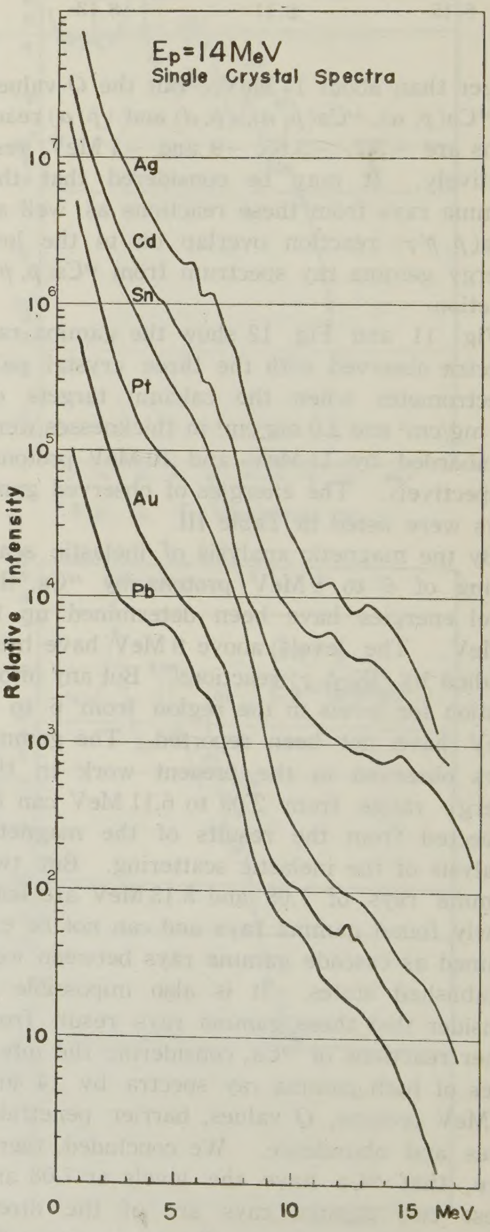

Fig. 15. T. Wakatsuki etc.

10% of the gamma rays from the targets.

The single crystal spectra and the three crystal spectra of the gamma rays from 14 MeV proton bombardments of several targets are shown in Fig. 14, 15 and 16, respectively.

For the gamma ray spectra of Al, many peaks were observed and the origin of 1.37 MeV, 2.21 MeV and 3.0 MeV gamma ray may be assigned to (3rd→1st), (3rd→gnd) and (5th or 6th→gnd) transitions, respectively.

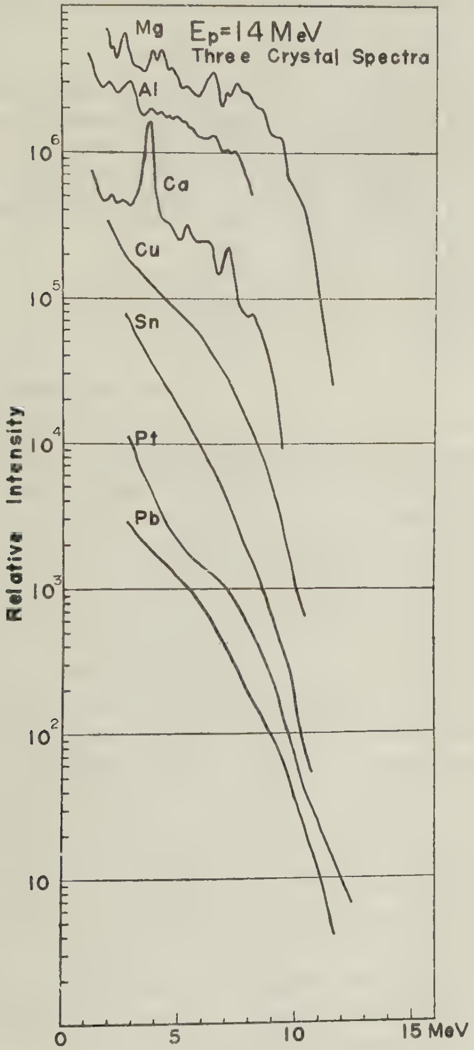

Fig. 16. T. Wakatsuki etc.

For Ti, Cr, Fe, Ni, Cu, Ag, Cd, Sn, Pt, Au and Pb, gamma ray spectra are almost continuous, but gamma rays from the 1st excited states of ^{48}Ti, ^{52}Cr, and ^{58}Ni could be resolved and broad peaks were observed at about 7 MeV and 13 MeV for some elements.

Almost all the intense gamma rays up to about 8 MeV may be the gamma rays following (p, p') and (p, n) reactions for most elements. As shown in Fig. 14, 15 and 16, the declivity of the gamma ray spectra up to about 8 MeV increases with atomic number. This behavior of gamma ray spectra is reasonable since the level densities of the residual states for gamma ray emissions increase with the atomic numbers.

The gamma ray intensities decrease suddenly at about 8 MeV, and the intensity ratios of about 1 MeV and about 12 MeV gamma rays are about 10^3: 1, correcting for the detector efficiency. The counting rates were kept low, so that the pile up pulses of 10–14 MeV region were weaker than 10% of the true counts. The gamma rays of energy larger than 12 MeV are believed to be due to (p, γ) reactions.

Cohen and his co-workers[10] have reported strong peaks at about 2.5 MeV in energy distributions of protons resulting from inelastic scattering of 12.5–23 MeV protons by various

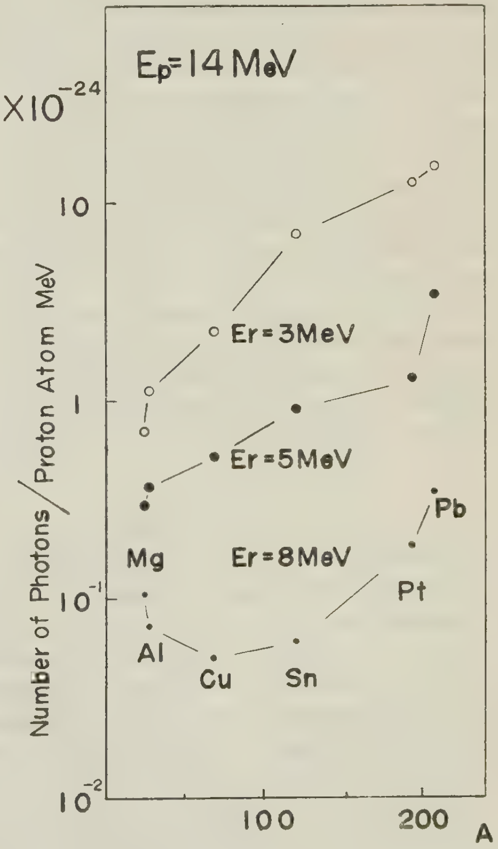

Fig. 17. T. Wakatsuki etc.

medium weignt and heavy nuclei. In this experiments, no peaks were observed at about 2.5 MeV on the gamma ray spectra for 14 MeV proton bombardments of various nuclei.

The yields of 3 MeV, 5 MeV and 8 MeV gamma rays for 14 MeV proton bombardments of Mg, Al, Cu, Sn, Pt and Pb are calculated from the three crystal spectra and are shown in Fig. 17.

The yields of 3 MeV and 5 MeV gamma rays and yield ratios of 3 MeV gamma rays to 5 MeV and to 8 MeV gamma rays increase with the atomic numbers. These behaviors of the gamma ray yields are also reasonable considering the increase of level densities with atomic numbers and excitation energies.

The authors wish to thanks cyclotron crew of the Institute for Nuclear Study for the operation of the cyclotron and for kind assistances throughout the work.

(Received February 4, 1960)

Angular and energy dependence of the elastic and the inelastic scattering of protons from nickel isotopes, Ni^{58} and Ni^{60}, were investigated in the energy range from 7.0 MeV to 15.3 MeV. Angular distributions in the high energy region ($E_p \geq 10$ MeV) showed small difference between both isotopes. Energy dependence of the differential cross sections in the low energy region (7 MeV $< E_p <$ 9 MeV) showed some fluctuations both for the elastic and the inelastic scattering. The inelastic yield for Ni^{58} was larger than that for Ni^{60} in the low energy region ($E_p \leq 9$ MeV). These yields decreased gradually as the incident energy increased. The results of present work are compared with our previous one and with the investigations of Thirion et al., Greenlees et al., and Seward.

§1. Introduction

The angular distribution for inelastic scattering of protons leaving the target nucleus to a definite excited state of medium weight nuclei ($A>40$) was investigated by Schrank, Gugelot and Dayton1), who bombarded the natural iron target by protons of 17 MeV. Sherr2) also reported the result of the angular correlation measurements for Fe. These results obtained at Princeton suggested the so-called "direct process" for the mechanism of inelastic scattering of protons leaving the target nucleus to the lowlying excited state. Experiments with separated isotopes have been done by several authors at proton energies of about 10 MeV. Hintz et al.3) used Fe^{54}, Fe^{56}, Cu^{65}, Ni^{58} and Zn^{66}, Thirion et al.4) used Zn^{64}, Zn^{66} and Zn^{68}, Greenlees and Rolph5) used Ni^{58} as targets.**** At lower incident energies, Seward6) investigated the angular distribution of inelastic protons from Ti and Cr, the angular correlation between protons and de-exitation gamma rays from Cr, and the energy dependence of the cross section of inelastic scattering at 90° from Ti, Cr and Fe. We9),10) investigated the angular dependence of elastic and the inelastic scattering for the medium weight nuclei (Ti, Cr, Fe, Ni and Zn) with their natural isotopic abundances at several incident energies of protons from 8 MeV to 14 MeV. The results of our previous work led us to a similar investigation with separated isotropes. The work reported here is very similar to the recent measurement done by Greenlees and Rolph. Both nuclei, Ni^{58} and Ni^{60}, however, were investigated in a wider energy range of incident protons.

§2. Experimental

Proton beam was obtained from the INS (Tokyo) variable energy cyclotron.11) The beam focusing system and the scattering chamber used in this experiment were described elsewhere.9),11),12) However, the experimental procedure was different from the previous works in the following point. We used fifteen scintilation counters at the same time, which were attached to the side windows of the large scattering chamber. Seventeen windows open at each ten degrees from

**** We must also mention the works of B. L. Cohen and his colaborators,7) and experiments of the inelastic scattering of alpha particles.8)

10° to 170° on one half of the side wall of the chamber, and sixteen from −15° to −165° on the other half of the wall.

The foil targets of separated nickel isotope which were obtained from A.E.R.E. (Harwell), were set at the centre of the scattering chamber making an angle of 45° to the incident beam. The angles of detection in the laboratory system were 25°, 30°, 40°, 50°, 60°, 70°, 80°, 90°, 105°, 115°, 125°, 135°, 145°, 155° and 165°. High voltage was fed always to each counter and the signals from each counter were always sent to the measuring room through a cathode follower and coaxial cable. We used five sets of linear amplifiers and multi-channel pulse height analysers; thus we could measure the yields at five angles simultaneously. When we introduced the signal from another five counters to the five sets of electronics, we could measure the yields at the next five angles. For the investigation of energy dependence we could measured the yields at 30°, 60°, 90° 125° and 165°, at the same time. For the investigation of the angular dependence, we always measured the yield at 90° as the monitor of the system. Only four sets of such measurements gave us the angular dependence at one incident energy. This method gave us very reliable data on the angular distribution especially at the region region where the yields change remarkably with the incident energy. The solid angles subtended by the detectors at the forward angles were made smaller than those by other counters, as the diameters of the defining apertures, which were 505 mm apart from the centre, were 3 mm, 5 mm, and 10 mm at 25°, 30°–50° and 60°–165° respectively. These different solid angles made the counts from each counter to be of the same order. The slit edge effect and the correction for the multiple scattering, however, were neglected in the analysis of the data.

The thicknesses of the foils of Ni^{58} and Ni^{60} were informed by A.E.R.E. to be 2.62 mg/cm^2 and 2.42 mg/cm^2, respectively. We used these values for the determination of the absolute cross sections. From the observed cross sections at 14.3 MeV for both isotopes, we calculated the average cross sections of the elastic scattering and the inelastic scattering, corresponding to the natural nickel element; $1/4\cdot\{3(d\sigma/d\Omega)_{Ni^{58}}+(d\sigma/d\Omega)_{Ni^{60}}\}$, and compared these values with our previous data.[9] The agreement was fairly good as shown in Fig. 1(a) and (b), the errors being about ±5%.

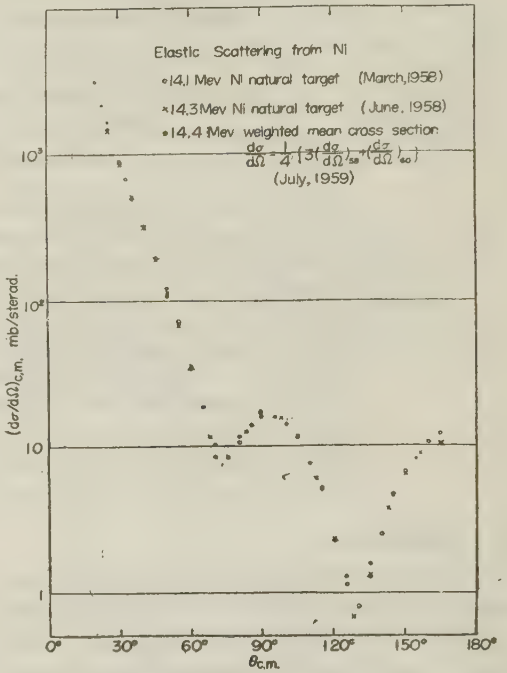

Fig. 1(a). Comparison among the results of the elastic scattering from Ni in our laboratory.

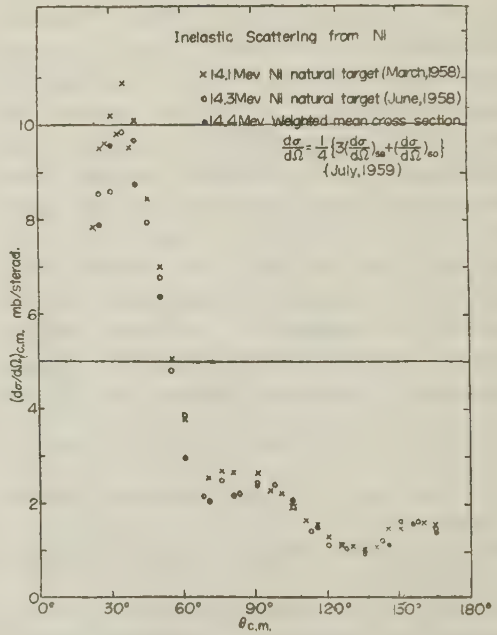

Fig. 1(b). Comparison among the results of the inelastic scattering from Ni in our laboratory.

The energy spread of the cyclotron beam cannot be precisely determined. This spread was not always constant during a long run, and in some cases it would be about 0.5% but in other cases it would be near 1%.

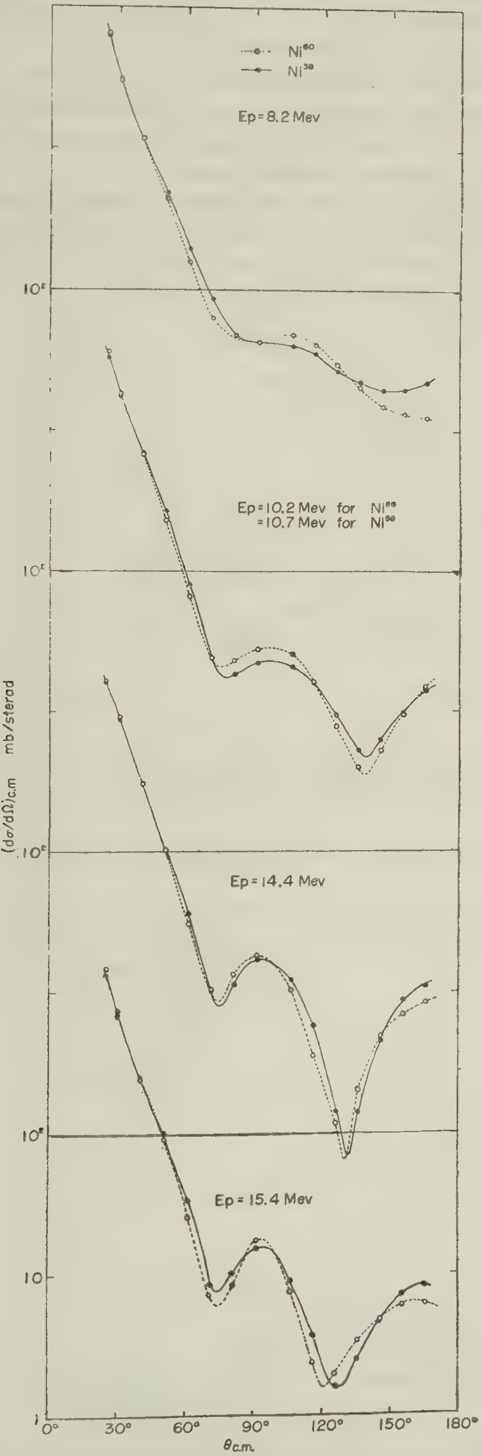

Fig. 2. Angular distributions of the elastic scattering from Ni^{58} and Ni^{60}.

§ 3. Results

Fig. 2 shows the angular distribution of

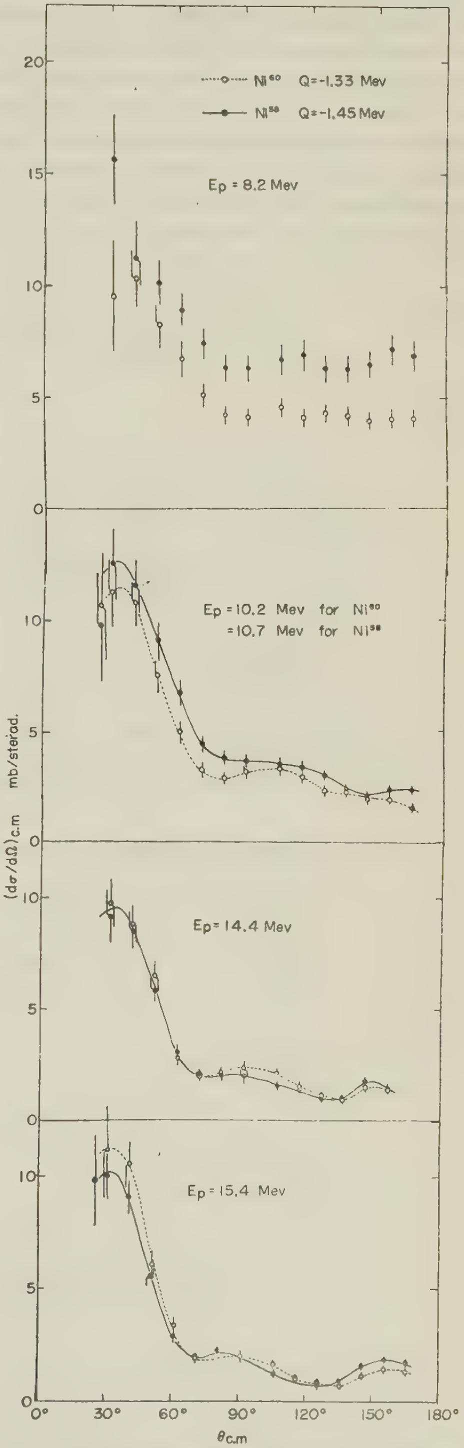

Fig. 3. Angular distributions of the inelastic scattering from Ni^{58} and Ni^{60}.

the elastic scattering at 15.3 MeV, 14.3 MeV, 10 MeV and 8.1 MeV. The angular distributions from these two isotopes are similar. Especially at forward angles, the cross sections agree with each other within the experimental errors at four incident energies. The cross sections for both isotopes at large angles ($\geq 60°$) differ a little from each other over the whole range of the incident energy. Errors of the absolute values of elastic cross sections appear to be less than 10% as mentioned above.

Fig. 3 shows the angular distribution of the inelastic scattering. In some cases, the angular distribution of inelastic scattering differ between Ni^{58} and Ni^{60} as follows:

1) the larger cross sections for Ni^{58} than for Ni^{60} at 8.1 MeV;

2) the presence of small differences of the angular distribution at high incident energies. As indicated in the figure, the errors were not small at forward angles.

Fig. 4 and Fig. 5 show the energy dependences of the cross sections for Ni^{58} and Ni^{60}

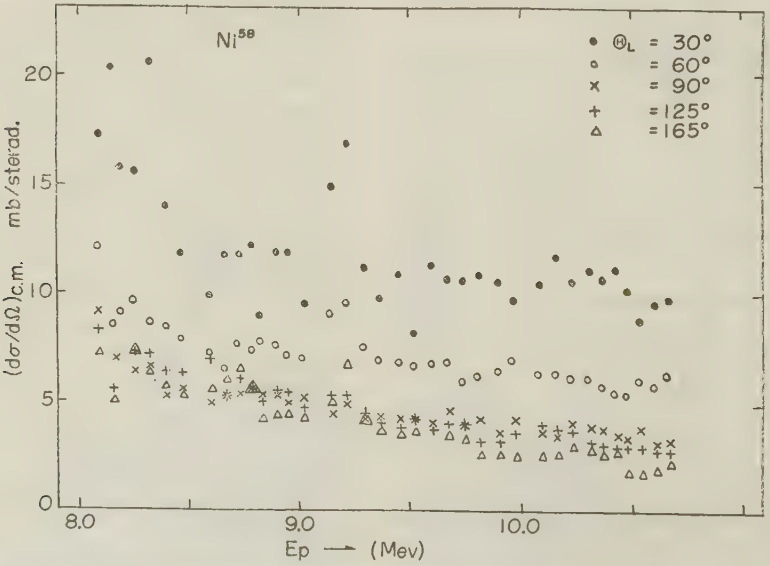

Fig. 4(b). Energy dependence of differential cross sections of the inelastic scattering ($Q = -1.45$MeV) from Ni^{58}.

respectively. For the elastic scattering, the ratio of $(d\sigma/d\Omega)_{cm}$ to the cross section of the Rutherford scattering is represented on the figures. The energy dependence of the inelastic scattering at $\theta_L=30°$ for Ni^{60} was also measured but the experimental errors seemed too large for the energy dependence to be precisely discussed; so we omitted the details and showed only the average behavior of the 30° cross section in the energy range. There exist some energy-dependent fluctuations both in the elastic and in the inelastic cross sections. In some cases, for example, at 9.2 MeV for Ni^{58}, the energy dependence in inelastic scattering shows a resonance-like behaviour, which is believed to correspond to the anomaly found at 9.3 MeV our previous work.[7]* Such an anomaly in the differential cross section does not necessarily occur at the same incident energy in elastic and inelastic scattering. The energy dependence of the inelastic cross section is remarkable at forward and at backward angles, while that of the elastic cross section is not so remarkable at forward angles as at backward angles. The energy dependence of the elastic cross section is not so remarkable at forward an-

---

* The discrepancy of resonance energy between the two experiments is due to the difference of the range-energy relations used. We used that of reference 13 previously and used that of reference 14 in the present work.

gles as at backward angles. The energy dependence of the elastic cross section at 165° for N^{58} shows gross structure at a energy region larger than 9.6 MeV. The inelastic cross sections at more than 60° increase gradually as the incident energy decreases. The cross section for Ni^{60} fluctuates less than that for Ni^{58} and the absolute yields of inelastic scattering for Ni^{60} are less than those for Ni^{58} at the same energy region of incident protons. Total inelastic cross sections for the first excited state, estimated roughly from these values of differential cross sections at five angles, are showe in Fig. 6. It is to be noted that the energy dependence curve is more smooth in the total cross section.

§ 4. Discussion

1) No analysis by the optical model has yet been attempted to fit the present data of elastic scattering. The positions of the minima and maxima of the diffraction pattern seem to change regularly with atomic mass. The only exception is in the case of the first minimum at 15.3 MeV, where the present data do not give any definite conclusion, because the angular intervals of the observation were rather large.

2) The larger inelastic cross section for Ni^{58}, found in the energy region from 8 MeV, in comparison with that for Ni^{60}, may be caused by the high threshold energy of the $Ni^{58}(p, n)Cu^{58}$ reaction, or by the smaller level density of Ni^{58}. The last two factors diminish the number of the open channels and might make the contribution of the compound process to the inelastic scattering for Ni^{58} (for the first excited state) more predominant than for Ni^{60}.

3) Thirion et al. found rather large differences among the inelastic yields for zinc isotopes at 11 MeV. The results of our previous work with natural elements showed that there exist marked differences in the inelastic yield from different nuclide especially at forward angles. The results of the present work show that at the high incident energy these two particular isotopes of nickel give similar yields. We are now attempting to measure the cross section at forward angles more accurately by magnetic analysis. Present data cover the region investigated by Greenlees. Our results agree with his conclusion but the values of the cross sections do not agree with his within the estimated experimental errors.

4) The differential cross section of inelastic scattering at 90° increases as the incident energy decreases, and that for Ni^{60} reaches about 8 or 10 mb/sterad. near 7 MeV. These values can be compared to the results obtained by Seward, who measured the differential cross sections of the similar inelastic scattering for Ti, Cr and Fe in energy range from 3 MeV to 7 MeV. The cross sections measured by him at 7.0 MeV were about 9 or 10 mb /sterad. for these medium weight nuclei. Moreover, the cross sections obtained at five angles in the present work indicate that the angular dependence becomes more isotropic as the incident energy decreases. So, Seward's results that the angular distributions for nuclei of these atomic weights are nearly

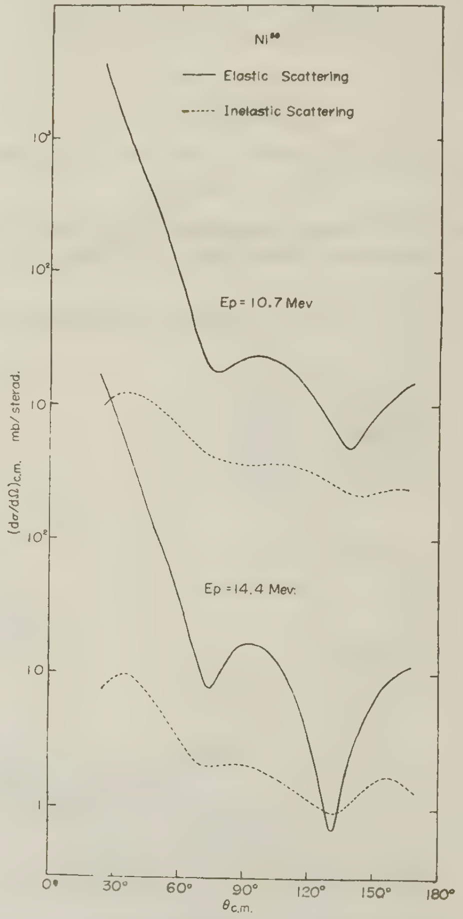

Fig. 7. In-phase relation between the elastic and the inelastic scattering.

isotropic below 7.0 MeV, can be smoothly connected to our results.

5) The total cross sections depend less on the incident energy than the differential cross sections do. The decrease of the total cross section with increasing energy is more gradual than that predicted by the theory of compound process and statistical level density. We can find some anomalies in the excitation curves of the total cross section. Those at E_p=8.2 MeV and at E_p=9.1 MeV for Ni^{58} are evident, which correspond to the excitation energies of 11.7 MeV and 12.5 MeV for Cu^{59}, respectively.

6) Fig. 7 shows the angular distributions of elastic and inelastic scattering from Ni^{58}. We can see from this figure that there exists an "in-phase" relation between them. This in-phase relation does not agree with the calculation proposed by Blair[15] for the scattering of alpha particles. This inphase relation which is found in inelastic scattering leaving the target nucleus to the first excited state at such a mass number region generally,[9] may be accidentally due to the distortion of the proton wave; nevertheless the fact, that the angular frequencies of the diffraction patterns are similar for the elastic and the inelastic scattering, seems to suggest us some under-lying similarity between these two phenomena.

The authors thank to Professor S. Kikuchi, who encouraged them through-out their experiments and gave them many valuable suggestions during his presidency of our laboratory. Particularly, the design of the scattering chamber with many side windows was suggested by him, and they used many counter systems according to his recommendation. They also with to thank Professor I. Nonaka for his kind encouragement. They are to say thanks to Messrs. T. Karasawa, A. Suzuki, H. Ogawa and other numbers of the cyclotron crew.

Elastic and Inelastic Scattering of Alpha Particles by Carbon

By Takashi MIKUMO, Hisashi YAMAGUCHI, Itaru NONAKA,
Masatoshi ODERA*, Yoshio HASHIMOTO**,
Motoo KONDO* and Takashi MAKI***

Institute for Nuclear Study, University of Tokyo,
Tanashi-machi, Kitatama-gun, Tokyo,

(Received February 5, 1960)

Angular distributions of alpha particles scattered elastically and inelastically ($Q=-4.43$ MeV) by carbon nucleus were measured with incident alpha energies of 28.4, 31.0 and 33.6 MeV.

Angular distributions of inelastic alpha groups corresponding to $Q=-7.66$ and -9.63 MeV and a broad alpha group with $Q\simeq 12.7$ MeV were also obtained at $E_\alpha=28.4$ MeV. The data were compared with Blair's diffraction scattering model and fairly good agreements were obtained for both elastic and inelastic ($Q=-4.43$ MeV) angular distributions for forward angles for three energies. The rises of cross sections at back angles, however, seem to occur from other mechanisms. Spin and parity assignments were tried for 7.66 and 9.63 MeV levels of carbon.

§ 1. Introduction

Angular distributions of elastic scattering of alpha particles in the energy range of 20- to 50-MeV were widely investigated in recent years. Some of the data were analyzed in the light of the optical model[1),2)] especially for heavy and intermediate nuclei.

Elastic scattering by heavy nuclei were fairly well fitted also with the semi-classical model proposed by J. S. Blair[3),4)]. This simple model, however, does not apply well to the data obtained with light nuclei as does to heavy nuclei.

On account of short mean free paths of alpha particles in the nucleus, several attempts[5)–8)] were made to fit the data with conventional diffraction model taking the nucleus to be black.

These theories described above were all based on the assumption that the nuclear matter was opaque or black against the alpha particles. But this is in contrast with the success in fitting the data of inelastic alpha scattering with simple direct interaction model, in which the incident and final unbound particles were assumed to be well represented by plane waves[9)–11)].

Recently J. S. Blair[12)] suggested a diffraction model to overcome the paradox mentioned above. He extended the diffraction theory introduced by S. I. Drozdov[13)] and E. V. Inopin[14)] to scattering of alpha particles or deuterons by "black" nuclei. These theories discussed inelastic scattering through either excitation of rotational states of ellipsoidally deformed nuclei or excitation of quadrupole vibrational states introducing either deformation parameter β_l or surface tension C_l defined by A. Bohr et al.[15)].

In the present situation, however, it is desirable to obtain more experimental facts which cover wide range of atomic numbers of target nuclei and energies of incident alpha particles to have a correct understanding of the mechanism of elastic and inelastic scattering of alpha particles by nuclei. Especially, the variations of angular distributions with the energies of incident alpha particles are considered to be the most important factor to be investigated. We planned, therefore, to measure the angular distributions of elastic and inelastic scattering as a function of the energy of incident alpha particle around 30 MeV.

As the first step of this plan we selected carbon as the target because the low lying levels of this nucleus are widely spaced and it is easy to separate experimentally the elastic and inelastic groups one another. Angular distributions of elastic and inelastic scattering of alpha particles by C^{12} were measured by F. J. Vaughn[16] at 48 MeV, by Igo, Wegner and Eisberg[17] at 40 MeV, by H. J. Watters[6] at 31.5 MeV, by Hu, Kato, Oda and Takeda[7] at 22 MeV, and by A. I. Yavin and G. W. Farwell[8] at 40 and 41 MeV. All of these data show more or less sharp diffraction patterns for both elastic and inelastic scatterings, but the patterns are quite different in shape and in size as the bombarding energy changes.

---

* Tokyo Institute of Technology.

** Faculty of Science, University of Tokyo.

*** Faculty of Science, Kyushu University.

In the present experiment, angular distributions were measured at three values of energies of incident alpha particles, 28.4, 31.0 and 33.6 MeV respectively, but more data will be taken at many other energies in near future.

§ 2. Experimental Procedure

We have made measurements of elastic and inelastic scattering of alpha particles by carbon with the 160 cm INS (Tokyo) variable energy cyclotron, from which alpha particles of energy from 27 to 43 MeV are obtained. Details of the cyclotron and the scattering chamber system are reported previously[18]. At the centre of the 100 cm scattering chamber was placed a self-supporting carbon foil of 2.38 mg/cm² in thickness, making an angle of 45° to the alpha particle beam. The target was prepared by the same method as that used in the course of $C^{12}(\alpha, p)N^{15}$ experiment[17]. Two proportional counter-CsI(Tl) scintillation counter telescopes 180° apart were placed on a turn table in the scattering chamber. Linearly amplified pulses from scintillation counters were gated by those from proportional counters which were biased at adequate voltages. By this procedure the discrimination of alpha particles against singly charged particles were performed without difficulty. The energies of alpha particles incident to the target were measured at the end of each energy run using aluminium absorbers and an ionization chamber, and were known to be 28.7_5, 31.3_0 and 33.9_0 MeV respectively. The average energies in the target were $E_\alpha=28.4$, 31.0 and 33.6 MeV, respectively.

Fig. 1 shows a typical histogram obtained at 30° at $E_\alpha=28.4$ MeV using three 20 channel and two 10 channel pulse height analyzers. Widths of elastic peaks at half-maximum were 3 to 4 per cent for "forward" counter, but they were as broad as 20 to 30 per cent for "backward" counter which caught reflected particles.

Elastic angular distributions and inelastic angular distributions corresponding to $Q=-4.43$ MeV were measured at all these three energies, at angular interval of 1° to 2.5°. Angular distributions of inelastic groups corresponding to $Q=-7.66$ and -9.63 and a broad peak around $Q\cong-12.7$ MeV were measured only at $E_\alpha=28.4$ MeV (owing to the limitation of machine time).

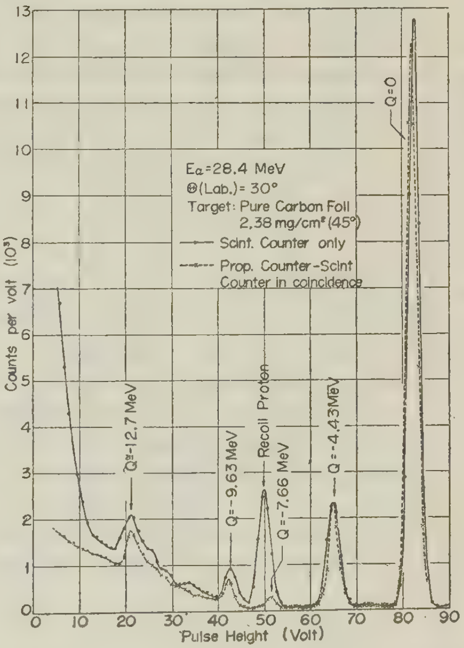

Fig. 1. Typical pulse height distribution obtained at $\Theta_{lab}=30°$ and $E_\alpha=28.4$ MeV with and without proportional counter.

The errors are considered to arise from the following sources; i) Inhomogeneity of target foil <20%; ii) Beam energy fluctuation <1%; But owing to the steepness of diffraction pattern in angular distributions and to the remarkable changes of cross sections with energy, a small energy change might influence the magnitude of cross sections considerably; iii) Errors in values of scattering angles: <0.15°; iv) Counting loss: at $\Theta_{lab}\leq 30°$ it was necessary to make the beam intensity as small as possible, otherwise the loss reached as high as 30%. The data shown in the figures are expected to have losses of less than 5%; v) Statistical errors: concerning the elastic group and inelastic group for $Q=-4.43$ MeV, these errors are very small except for several angles at which angular distributions show steep minima; vi) Background subtraction: This source of errors is the most serious one in particular at large angles and for inelastic groups corresponding to $Q=-7.66$, -9.63 and $\cong -12.7$ MeV. Errors from this source were estimated to be 10% at most.

§ 3. Results and Discussions

Angular distributions of elastic scattering as well as those of inelastic scattering to the 4.43 MeV state of C^{12} were obtained at $E_\alpha=28.4$, 31.0 and 33.6 MeV. Because of the energy losses of scattered alpha particles in the target and in the counter foils, the measurements were limited for backward angles to 110° to 130°.

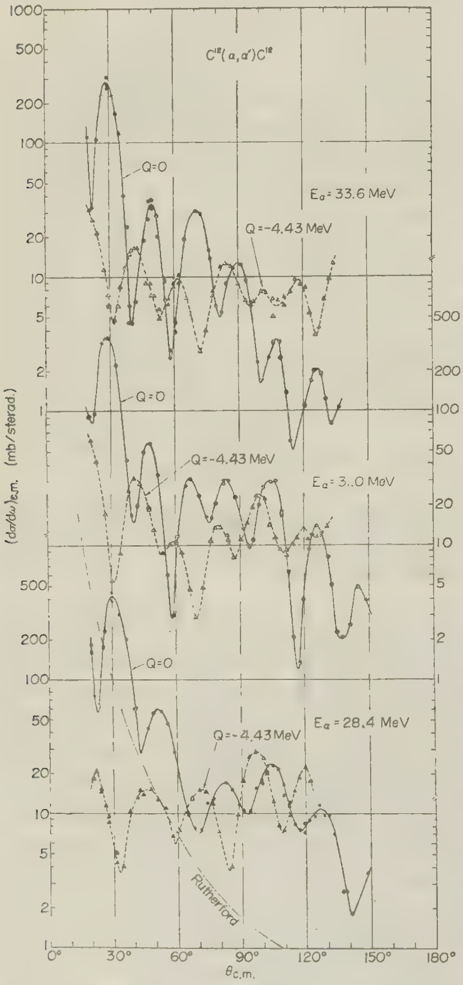

Fig. 2. Angular distributions of elastic scattering and inelastic scattering ($Q=-4.43$ MeV) obtained at three alpha particle energies.

Fig. 2 shows the angular distributions for both groups at these three energies.

Fig. 3 shows the results obtained for the groups corresponding to $Q=-7.65$, -9.76 and a broad peak at $Q\cong -12.7$ MeV at $E_\alpha=28.4$ MeV together with the elastic group.

We now discuss each group separately.

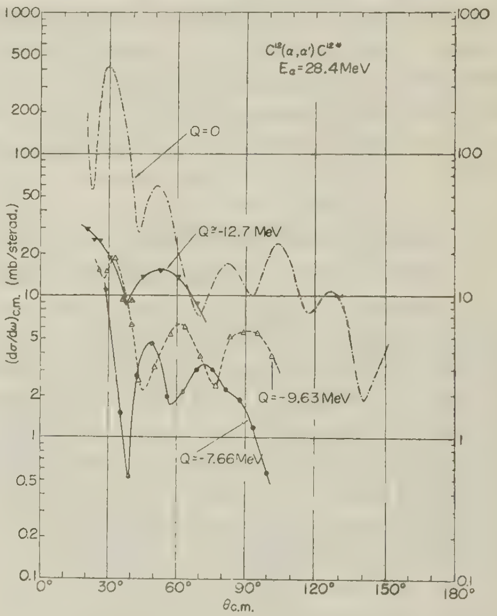

Fig. 3. Inelastic angular distributions at $E_\alpha=28.4$ MeV leaving the residual nucleus at higher excitations. For comparison, elastic angular distribution is also shown.

i) $C^{12}(\alpha, \alpha)C^{12}$, $Q=0$

As shown in Fig. 2, angular distributions of elastic groups at three different energies show pronounced diffraction patterns. Rutherford cross section for $E_\alpha=28.4$ MeV is also shown in Fig. 2. The observed cross sections are higher than the Rutherford cross sections except at very forward angles, and the ratios $\sigma(\theta)_{obs}/\sigma(\theta)_{Ruth}$ are especially high at backward angles. This behaviour is in contrast with the case of heavy elements and in agreement with the general trend found by Igo et al[1),17)]. There appears no systematic shift in diffraction patterns with energy, except at extremely forward angles ($\theta<40°$). At 31.0 MeV we have not observed the plateau around $60°\lesssim\theta\lesssim 75°$ reported by Watters[6)] at 31.5 MeV. His average energy at the target centre is not known because of the uncertainty of the target thickness, and it was probably somewhat less than our 31.0 MeV. The positions of maxima and minima of the angular distributions are nearly equidistant in θ rather than in $\sin(\theta/2)$, except for $E_\alpha=28.4$ MeV, where equidistance relation is largely violated for $\theta>60°$. These angular distributions were analyzed in terms of diffraction scattering formula. For small θ, absolute differential cross sections of elastic scattering are expressed by the formula

$$\frac{d\sigma(\theta)}{d\omega}=k^2R_0^4\left(\frac{J_1(kR_0\theta)}{kR_0\theta}\right)^2$$

where $k=k_i$ is the c.m. wave number of the incident particle, R_0 is the interaction radius between the target nucleus and the incident alpha particle, $J_1(x)$ is the first order Bessel function. We took the argument of $J_1(x)$ as $x=kR_0\theta$ instead of $x=2kR_0\sin(\theta/2)$ because of simplicity and of equidistancy in θ of the experimental results as mentioned above. Fig. 4 shows the results of the analyses. The values of R_0 were adjusted so that the best fits were obtained with the experimental data, at least for the positions of the first and the second maxima and minima. Values of R_0 thus obtained were

$(5.4\pm0.1)\times10^{-13}$ cm	for	$E_\alpha=28.4$ MeV
(5.5 ± 0.1)		$E_\alpha=31.0$
(5.2 ± 0.1)		$E_\alpha=33.6$

For $E_\alpha=31.0$ MeV the positions of maxima and minima were very well fitted even for the fourth maximum. As regards absolute values, the observed cross sections were twice or three times larger than the calculated ones, except at the second maximum for $E_\alpha=33.6$ MeV, where they were nearly equal. The origin of these discrepancies in absolute values are not yet very clear; Coulomb correction does not change the situation very much except at extreme forward angles*. It is interesting to compare the values of R_0 with those obtained by other authors**. In Fig. 5 values of R_0 are plotted against E_α between 22 and 48 MeV. As can be readily seen R_0 decreases as E_α increases. The reason of this fact is not clear at present.

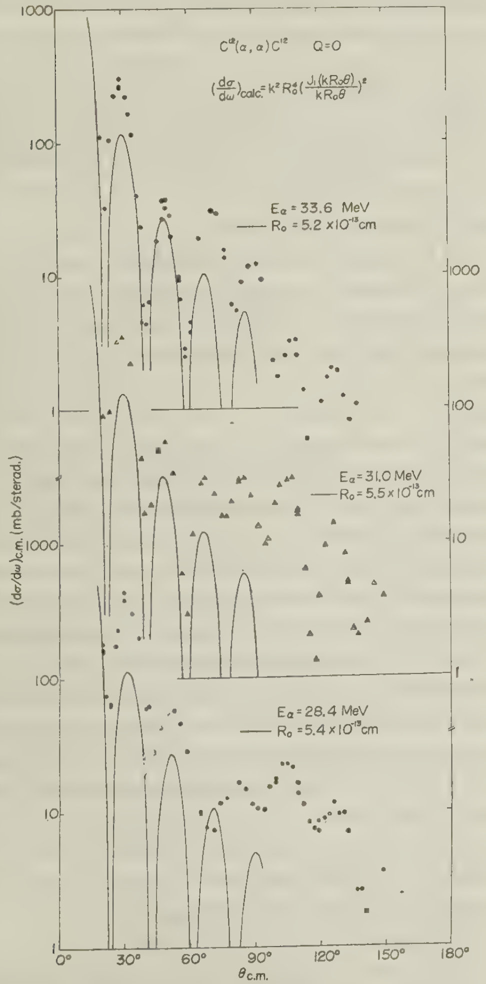

Fig. 4. Comparison of calculated elastic angular distributions based on diffraction model with observed ones.

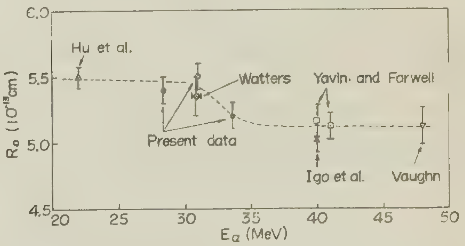

Fig. 5. Relations between R_0 and E_α for elastic scattering of alpha particles by carbon, obtained by the diffraction model. Values of R_0 are recalculated by the present authors so as to fit the positions of experimental first or/and second maxima.

---

* According to Blair, diffraction scattering and Coulomb scattering (with finite nuclear size) are out of phase, and both cross sections can be added to give differential cross section at each angle.

** The values of R_0 were recalculated by the present authors so as to fit the experimental data for the first and/or second maxima.

ii) $C^{12}(\alpha, \alpha')C^{12*}$, $Q=-4.43$ MeV

As are readily seen in Fig. 2 these angular distributions also show pronounced diffraction patterns, and they are "out of phase" with those of corresponding elastic alphas. This indicates, according to Blair's diffraction theory, that the parity of 4.43 MeV state is the same as that of the ground state. Really the 4.43 MeV state of C^{12} is known to be 2+. Blair predicts the differential cross section for (0+→2+) transition for $k_f \simeq k_i \simeq k$ to be

$$\frac{d\sigma(\theta)}{d\omega}(0\rightarrow 2)=(kR_0)^2\frac{5}{4\pi}\frac{\hbar\omega_2}{2C_2}\times\left[\frac{1}{4}\{J_0(kR_0\theta)\}^2+\frac{3}{4}\{J_2(kR_0\theta)\}^2\right]$$

where R_0 is the interaction radius which gives the best fit with observed elastic angular distribution, $\hbar\omega_2=4.43$ MeV is excitation energy of the final nucleus and C_2 is a quantity corresponding to the surface tension, when C^{12} is assumed to be a spherical vibrational nucleus and 4.43 MeV states be excited through collective quadrupole vibration.

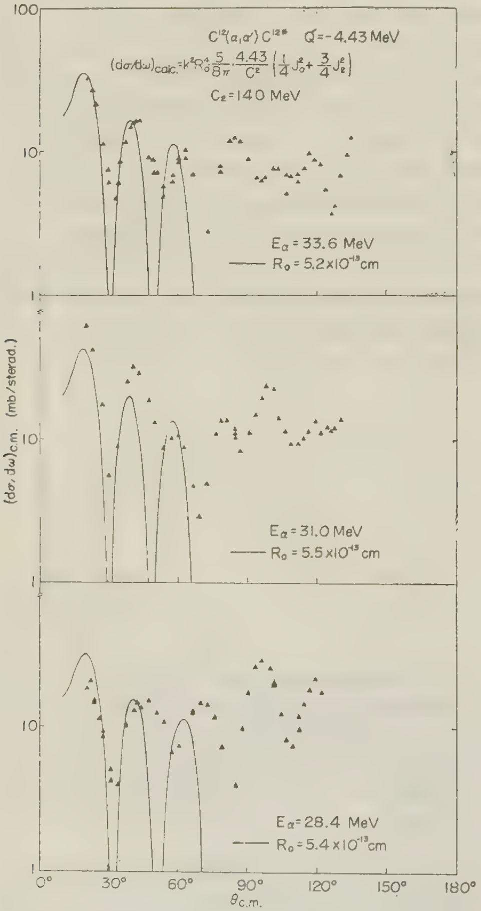

Fig. 6. Comparison of calculated inelastic angular distributions ($Q=-4.43$ MeV) based on diffraction model with observed ones. Values of R_0 are those which give the best fits with observed elastic angular distributions.

In Fig. 6 are shown comparisons between observed and calculated cross sections. Absolute values around the second maximum are only fitted by taking the values of C_2 to be around 140 MeV which is a value ten times larger than that given by Alder et al.[15], except for $E_\alpha=31.0$ MeV where a good fiit is obtained as to the positions of maxima but a value of about 90 MeV for C_2 must be taken to obtain a fit with the absolute values of cross sections. As is seen from Fig. 2, experimental cross sections do not decrease so remarkably as the theory predicts at large angles, showing even some rise at backward angles. It must be very interesting to get more data at large angles and compare them with the theory in order to elucidate scattering mechanism more clearly. Any theories are hoped for which could handle the angular distributions at large angles.

iii) $C^{12}(\alpha, \alpha')C^{12*}$, $Q=-7.66$ MeV

Fig. 3 shows inelastic angular distribution data obtained at $E_\alpha=28.4$ MeV leaving the residual nucleus in excitations of 7.66, 9.63 and about 12.7 MeV. For comparison, the angular distribution of the elastic scattering was shown together. For these data of inelastic scattering, no numerical analysis was made, because the conditions $\hbar\omega_i \ll E$, $k_f \simeq k_i$ are not satisfied in these cases. It seems, however, that the angular distribution corresponding to $Q=-7.66$ MeV is rather out of phase with the elastic angular distribution. This is in agreement with the current assignment of 0+ to this level. Unfortunately, it was not possible to take data at backward angles to obtain the ratio of the cross section for 7.66 MeV level to that for 4.43 MeV level $(\sigma(0+\rightarrow 0+)/\sigma(0+\rightarrow 2+))$. More extensive investigation of the inelastic scattering to this state at $E_\alpha=42$ MeV has recently been reported by Eccles and Bodansky[19].

iv) $C^{12}(\alpha, \alpha')C^{12*}$, $Q=-9.63$ MeV

As is seen from Fig. 3 the inelastic angular distribution corresponding to this state is rather out of phase with that to 7.66 MeV state, so that the former is in phase with the elastic scattering angular distribution. Therefore, though the excitation energy is too high to be compared with the theory, it seems probable that this state have odd parity. This is in contrast to the assignment of 0+ or 2+ to this state given by Yavin and Farwell[8], and in favor to 1− assignment as given in the table by Ajzenberg-Selove and Lauritsen[20].

v) $C^{12}(\alpha, \alpha')C^{12*}$, $Q \simeq 12.7$ MeV

This group consists of excitations to at least unresolved two states (12.73 and 13.30 MeV states[20]). The angular distribution obtained at $E_\alpha = 28.4$ MeV is given in Fig. 3. No analysis was yet made, but at $E_\alpha = 31.0$ MeV and 33.4 MeV this group seems to be excited much less strongly. It will be of interest to investigate the energy variation of cross sections with better resolution to elucidate the excitation mechanism of this group.

We are now intending to investigate the behaviour of the change of elastic and inelastic angular distributions with energies for C, in detail, and also for O, Ne, Mg, etc.

The authors are indebted to Dr. J. S. Blair for sending them his article before publication and to Dr. M. Sano for valuable discussions. They are very much grateful to the cyclotron technical staff of the Institute for Nuclear Study.

Note Added in Proof:

We have just made additional measurements of angular distributions of elastic and inelastic scattering ($Q = -4.43$ MeV) at eight more energies. We have reproduced Watters' plateau in the elastic angular distribution at $E_\alpha \cong 30.0$ MeV. There is a kind of very sharp resonance near this energy. Inelastic angular distributions are closely correlated to those of elastic scattering of the same energies even near this resonance. These results will be reported in near future.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 15, No. 7, JULY, 1960

Elastic and Inelastic Scattering of Protons by Oxygen in the Energy Region of 6.9 MeV to 15.6 MeV

By Shinsaku KOBAYASHI

Institute for Nuclear Study, University of Tokyo
Tanashi-machi, Kitatama-gun, Tokyo

(Received April 11, 1960)

Extensive experimental results are presented, showing the variation with energy of the absolute angular distributions for the elastic and inelastic scattering of medium energy protons on oxygen.

For the elastic scattering, angular distributions between 20 deg and 160 deg were obtained for twenty incident proton energies spaced between 6.87 MeV and 15.6 MeV. The absolute angular distributions for the inelastic proton groups, leading to the excitation of about 6 MeV (6.06 and 6.14 MeV) and 7 MeV (6.92 and 7.12 MeV) states of O^{16}, were measured at five energies from 11.9 MeV to 15.6 MeV. Although angular distributions vary remarkably with the incident energy, integrated cross section decreases monotonically as incident energy increases. In particular, at $E_p=15.6$ MeV the total inelastic scattering cross section was roughly measured to be 240±40 mb. From this result and the reported results for other reaction cross sections, we may deduce that O^{16} nucleus is considerably transparent even for this rather high incident energy, where the mean free path of nucleon in nuclear matter has nearly the minimum value in usual nuclei.

The excitation function for the elastic scattering shows appreciably sharp resonances at energies, 7.2, 10.6 and 14.7 MeV, and its gross structure has a large scale resonance of a width about 4 MeV, at incident energy of about 13 MeV. It appears that this resonance is the f-wave giant resonance expected from the shell model.

§ 1. Introduction

The elastic scattering of protons by oxygen has been investigated by many researchers[1)-10)], and some of their studies have thrown light on the low-lying levels of F^{17}. O^{16} contains 8 neutrons and 8 protons, and can be considered as a closed shell neucleus both in neutrons and protons. If this shell model of the nucleus is correct, the compound nucleus F^{17}, formed under bombardment of O^{16} by protons, will consist of one proton outside a closed shell. Therefore F^{17} is a single particle nucleus in the sense that it should show the states of a single particle moving in a central field. Of course levels due to the excitation of the O^{16} core should also appear. F^{17} should be constructed by the addition of an $s_{1/2}$, $d_{5/2}$ or $d_{3/2}$ proton to the O^{16} core and the states corresponding to these protons are expected. In fact, the ground state, the first excited state (at 0.500 MeV), and the state at about 4.7 MeV of F^{17} are believed to be single particle states and the spins and parities of these states are 5/2 +, 1/2+, and 3/2+ respectively. Possibly the level 7/2− (at 3.86 MeV) is not a single particle state of $f_{7/2}$, because this state has a small nucleon reduced width.

The energy region presented in this paper begins just above those of other works[1)-5)] and includes the bombarding energy in the work of Burcham et al.[6)]. The result of Burcham et al. was analyzed in terms of the optical model by Fujimoto et al.[11)], using complex square well potentials. They showed that the potential with small imaginary part ($V=36+2i$ MeV, $R=1.45\times10^{-13}A^{1/3}$ cm) gave the best fit to the experimental result. We may deduce from this fact[26)] that the deviations from the prediction of shell model are appreciably small at this somewhat high excitation energy ($E_p=9.5$ MeV). Therefore there is a possibility that a large scale resonance due to the f-state is detectable at energies higher than 10 MeV. This means that the states of F^{17} in this energy region are predominantly *f*-states and hence have a spin of 5/2 or 7/2, thereby showing that the intermediate coupling model due to Lane, Thomas and Wigner[26] should be in this case a sufficiently good approximation for explaining the energy states concerned.

Previously we measured the elastic scattering of protons by oxygen at energies 7.72, 9.64, 11.7 and 14.1 MeV, and showed that the angular distributions varied irregularly with the incident energy, contrary to the variations in the elastic scattering on medium weight nuclei[12]. More detailed investigation of variations is the aim of the present work.

§ 2. Apparatus

A. *Production of the Focused Proton Beam*

The proton beam is deflected by an A.C. deflector from the variable energy INS (Tokyo) cyclotron[13] and passing through a magnetic shielding channel, leaves the cyclotron chamber. Then it is focused by a pair of quadrupole magnets and is deflected by a sector magnet. The combined lens action of the quadrupole magnets and the sector magnet[14] produces a beam spot about 5 mm wide and 10 mm high, whose intensity can be changed stably from a few μA to 0.01 μA or less, before the collimator slits. The beam then passes through the collimator which has two defining apertures of graphite, 5 mm in diameter, spaced 80 cm apart. To remove slit-scattered protons from the beam, five graphite baffles, each 7.5 mm in diameter, are used.[15]

B. *Scattering chamber and gas target chamber*

Details of the scattering chamber were described elsewhere.[13],[15] It consists of a turn table, a target assembly and a vacuum can containing them. The vacuum can has an inner diameter of nearly 100 cm and a height of 40 cm, whose side wall has 32 windows. The side windows open at each ten degrees from 10° to 170° on one half of the side wall of the chamber and from $-15°$ to $-165°$ on the other half of the wall. These windows allow us each 5 degree observations, but in this work we used the windows of one half of the side wall.

Commercial tank oxygen was used as the target gas. Volumetric analysis showed that this gas consisted of 99.85% O_2 and 0.15% N_2, other impurities being negligible. The isotopic content of O^{16} is 99.76%. The gas was filled in a container, which was made of a brass cylinder of 9 cm in diameter and of 6 cm in height and had a window extending along an angle of more than 180° including the beam entrance and the beam exit. This window was sealed with a sheet of alminum foil 20 μ in thickness. The gas target chamber was located at the center of the scattering chamber. The pressure of the target gas was 40.6 cm Hg (at 27°C) which was measured with a mercury manometer.

The unscattered beam was collected in a Faraday cup. In order to reduce the effect of secondary electrons, the collector cup was equipped with a couple of magnets which produce magnetic fields of about 300 gausses. The collected charge was measured electronically by using 100% feed back type beam current integrator. At the bottom of the cup, an aperture of 3 mm in diameter was equipped, through which a part of the unscattered beam could be extracted from the vacuum and led into an ionization chamber for the beam energy measurement which was placed behind the cup. This aperture was closed with a small piece of permanent magnet during the cross section measurement and could be opened by changing the polarity of the Faraday cup magnet.

C. *Beam energy measurement*

The INS (Tokyo) cyclotron, with its wide range magnet and variable frequency oscillator system, can offer proton beams of energies from 7 MeV up to 16 MeV to the scattering chamber without appreciable change in intensity. In this work, proton beams of various energy were obtained mainly changing the cyclotron parameters, but the small energy changes ($\leq$200 kev) were performed by inserting Al absorbers before the beam collimator. At each energy studied, the energy of the incident beam was determined as follows. The unscattered proton beam entered into an argon-filled shallow parallel-plate ionization chamber, after passing through the small aperture prepared at the bottom of the Faraday cup. By changing the thickness of aluminum absorbers placed in front of the ionization chamber, one could obtain the Bragg curve, which determined the mean range of the incident beam.[16] Thus, using the range energy relation obtained by Bichsel, Mozley, and Aron,[17] the absolute value of the beam energy was determined. The energy spread of the incident proton was estimated to be about ±0.5%.

D. *Detector system*

We used sixteen scintillation counters in each measurement. Fifteen counters were attached to the side windows of the scattering chamber. A spare counter was set up on the turn table in the scattering chamber, and could be placed at any desired scattering angle. The side window counters were equipped at each ten degree from 20° to 160° on one half of the side wall of the chamber. (Fig. 1) Scintillation counters were similar to that used in our previous work.[15] Each consisted of a thallium-activated NaI scintillation crystal of about $20\times20\times1.5$ mm and a photomultiplier tube (mostly RCA 5819 and the remainder RCA 6342, 6655 and DuMont 6292). The energy resolution of these counters was about 2.3% at $E_p=15.6$ MeV. Each counter equipped with a defining slit system, which consisted of a vertical front slit and a circular rear aperture. The G-fractors of these counters were estimated using the equation of Silverstein,[18] including the correction for finite beam size. We found the higher order terms of the equation, including 1st order, negligible compared with the accuracy of the defining slit dimension (about ±0.5%).

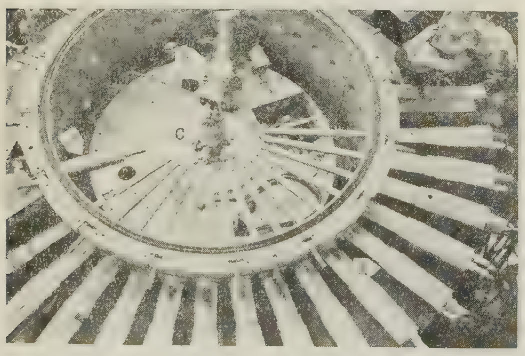

Fig. 1. A perspective view of the experimental apparatus. A: Scintilllation counters attached to the side windows of the scattering chamber. B: Spare counter set up on the turn table in the scattering chamber. C: Target chamber. D: Beam collimator. E: Defining slit system of detector. F: Faraday cup. G: Al absorbers for the beam energy measurement.

The G-factors of these counters were on the average as follows; for the side window counter, 2.26×10^{-4} cm (from 60° to 160°), 0.566×10^{-4} cm (from 30° to 50°), 0.204×10^{-4} cm (20°), and for the turn table counter, 6.06×10^{-4} cm.

The signal pulses, after passing through a cathode follower (White type), were sent to the counting room about 50 meters apart from the measuring room, through a coaxial cable (RG63U). And after amplified by a linear amplifier (Bell-Jordan type), the pulses were fed to a multi-channel pulse height analyzer (Joenstone type). We used five sets of linear amplifiers and multi-channel pulse height analyzers simultaneously. All the electronic equipments were constructed in the electronics division of our laboratory.

§ 3. Experimental Procedure

The angles of detection in the laboratory system range from 20° to 160° at intervals of ten degrees. In addition, a spare counter was set at 55° or 65° according to the incident proton energy. High voltages were supplied always to each counter and the signals from each one were always sent to the counting room. As described in § 2. D, we used simultaniously five sets of electric equipments, each of which includes a multichannel pulse height analyzer. When we connected the cables from the counters at five other scattering angles to the inputs of the five sets of electronic equipments, we could measure the yields at next new five scattering angles. The observation of the angular dependence at a given incident proton energy, needed only four times of such measurement. In a series of measurements at a given energy, we always measured the yield at 90° as the monitor of the system, to obtain important checks upon the operation of the current integrator and upon the conditions of target gas.

This method gave us more reliable data on the angular distribution especially at the region, where the yields change remarkably with the incident energy. The G-factors of the detector at forward angles were made smaller than at other angles, so that the statistical errors in the number of counts did not change markedly with the detection angle. The counting rate was so adjusted by controlling the beam intensity that the counting loss may be much less than 1%.

§ 4. Analysis of the Data

A. *Subtraction of background*

A typical pulse height distribution is shown in Fig. 2. The elastic peak was found to be always accompanied by a uniformly distributed low-pulse-height tail. The greater part of the tail seems to be due not to the low energy component of the incident beam, but due to the multiple scattering by the detector slit edges.[21] Therefore on determining the number of protons elastically scattered by the target gas we set the cutoff threshold just below the elastic peak and discarded all counts falling in the tail. The resolution of the detector being takes into account, this procedure is justified by Courant's calculation,[19] and eliminates the effect due to the slit edge penetration and scattering. The low-energy components of the incident beam were estimated to be less than 0.5%. Therefore we neglected this effect.

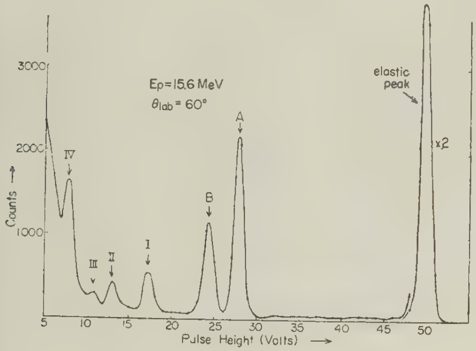

Fig. 2. Typical pulse height spectrum obtained with an NaI(Tl) detector for protons of 15.6 MeV incident energy scattered by oxygen gas at angle of 60°.

In the inelastic groups, ($Q \simeq -6.1$ MeV and -7.0 MeV), there is another background source due to γ rays, especially for the lower energy side, in addition to the above-mentioned origin. This fact made us to give up the measurement of the inelastic groups at the lower incident proton energies ($E_p \leq 10$ MeV). We followed the procedure for the background subtraction, described in our previous papers.[15] In each individual case, an estimated probable error is assigned to this background, commensurate with the extent to

which its value appeard uncertain.

B. *Discussion of errors*

(i) *Uncertainly in the cross sections*

The error in the collected charge, consisting of errors in calibration of the integrator including its zero drift, was ±1.5%.

The error coming from the target gas, such as the amounts of impurity and that in the measurement of density (pressure and temperature), was estimated to be ±1.0% or less.

Insufficient accuracy of the exact scattering geometry and the method of background subtraction were already described in § 2. D and

Table I (iv).

§4. A, respectively.

In addition, the loss in beam charge collection due to multiple scattering in the target gas and in the foils of the target chamber, should be allowed for. This was estimated, according to the treatment of Bethe for multiple scattering[20] and was corrected. The error after this correction is believed to be appreciably small. The effect of multiple scattering by Al foil and O_2 gas on the scattered particles to be detected was also estimated. It is considerably reduced by mutual compensation of the scattered-in and -out.[21] The deviation in this compensation was appreciably small (<1%) at over all detection angles in this work except at $\vartheta_{\rm lab}=20^\circ$ and 30°.

The various errors considered above, together with that due to the counting statistics, have been combined quadratically, although they are not all truly random, and are given in the bracket of Table I as estimated probable errors.

The largest parts of errors of the inelastic cross section come from the background subtraction, described in §4. A already.

The statistical error in the number of pulses counted was mostly of the order of 1%.

(ii) *Uncertainty in the scattering angle*

Uncertainty in the scattering angles (±0.15°) was mainly compounded from the following sources: the uncertainty in the zero-angle correction (±0.01° or less) and the error in the alignment of the defining slit in front of the scintillation detector.

(iii) *Uncertainty in the incident energy*

As is described in §2. C., uncertainty in the determination of incident energy is due to the error, in the measurement of Bragg curve and in the determination of the absolute thickness of Al absorber. The uncertainty in the beam energy at the target center was estimated to be ±0.5%. Of course, this depends on the range-energy relation based on the work of Bichsel, Mozly and Aron.[17]

§5. Results and Discussion

A. *Elastic scattering*

Table I gives the data obtained for elastic scattering at the twenty incident energies used. The differential cross sections for elastic scattering expressed as ratios to Rutherford cross sections, are shown in Fig. 3. The excitation function is given, as a function of incident energies at $\vartheta_{\rm lab}=140^\circ$, 150° and 160°, in Fig. 4, which also contains our pre-

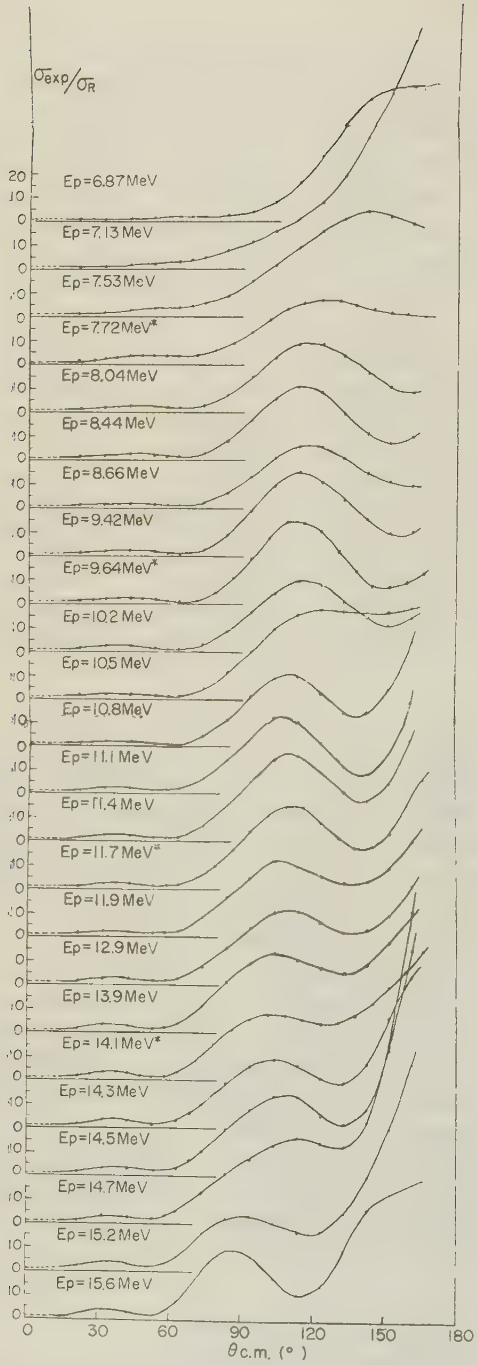

Fig. 3. Differential cross sections for the elastic scattering of protons by oxygen, in units of the Rutherford cross section. * our previous results (2).

vious data[12] and Burcham's data.[6]* The excitation function shows appreciable sharp resonances at energies 7.2, 10.6 and 14.7 MeV. The lowest resonance at 7.2 MeV continues to the Zürich data[3] qualitatively.

The excited states higher than 7 MeV, in F^{17} nucleus, have not been investigated. On the other hand, we know considerably well of the higher excited states in O^{17} nucleus,[22] which is the mirror nucleus of F^{17}, and the correspondence is appreciably good in lower excited states. The formula

$$\omega(E)=0.2\exp[2(0.5E)^{1/2}]/\mathrm{MeV}$$

agrees fairly well with the experimentally determined average level densities for O^{17} at 6.0 MeV and 8.0 MeV excitation,[22], and therefore it is used to estimate the average level densities for F^{17} nucleus. This formula gives $\omega\simeq 20$, and 50 levels per MeV at excitations 10 MeV and 15 MeV, respectively.** There-

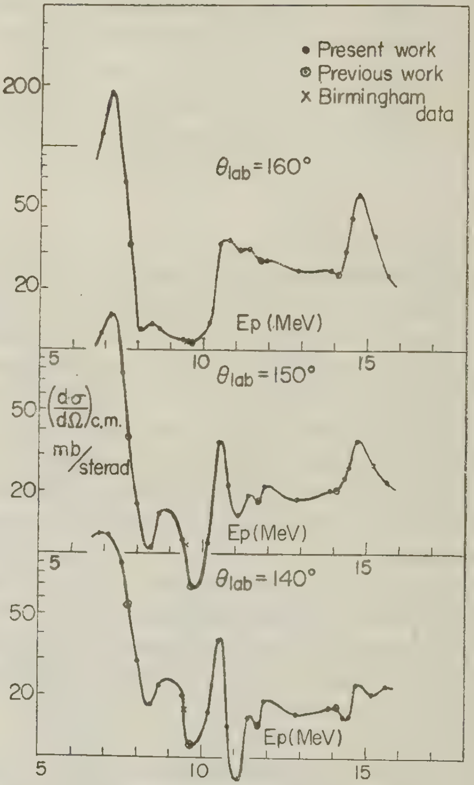

Fig. 4. Excitation curves of the elastic scattering on oxygen.

---

* Although a part of incident energy used by Kinsey and Stone[7] was included in our energy region, unfortunately they did not reported the data at backward scattering angles ($\vartheta \geq 130°$). Any comparison with their result has not been done.

** Excitation energy in F^{17} nucleus is given by $(16/17\cdot E_p+0.596)$ (MeV), where E_p is mean incident proton energy at the center of target in lab. system.

fore allowing for the beam energy spread used, we should not discuss the one level problem, but the gross structure problem or the average problem, at an incident energy higher than 10 MeV. The result of Burcham et al. at $E_p=9.5$ MeV[6] was analyzed in terms of the optical model by Fujimoto et al.[11] as was described in § 1. Following their procedure, we fitted our experimental result at $E_p=12.9$ MeV, using complex square well potentials. The result analyzed by the potential $V=35+2i$ MeV ($R=1.45\times10^{-13}A^{1/3}$ cm), agrees with the angular position of the first minimum and the value of the first maximum, of the experimental differential cross section, and is shown in Fig. 5.* In our energy region, the wavelength of the incident proton is of the same order as the radius of the nucleus and therefore the effect of the edge is not so serious as it is for higher energies. It should be noted that W_0 is considerably small. This fact means that the mean free path of the incident protons in nuclear matter is 16.1×10^{-13} cm, which is much larger than the radius of the target nucleus. This value is calculated from the relation[24]

$$1/\Lambda^2=2\left[\left\{\left(\frac{W_0}{E+V_0}\right)^2+1\right\}^{1/2}-1\right]K^2,$$

using the best value of V_0 and W_0. From the following reasons, we may understand such a small imaginary part of the optical model. The first is due to the high threshold of $(p,\ n)$ reaction (Eth$=17.3$ MeV), and so open channels except $(p,\ p')$ scattering are mainly $(p,\ \alpha)$ (Eth$=5.53$ MeV), $(p,\ \gamma)$ and $(p,\ d)$ reactions (Eth$=14.2$ MeV). The largest contribution except $(p,\ p')$ scattering is perhaps based on $(p,\ \alpha)$ reaction, the cross section of which is at most 50 mb.[28] Therefore the main part of proton induced reaction comes from inelastic scattering. This inelastic scattering does not open at $E_p\leq 6$ MeV in oxygen. So the level density of the lowlying level of O^{16} is relatively small. In our measurements, total cross section of $(p,\ p')$ scattering is roughly estimated to be 240 ± 40 mb at $E_p=15.6$ MeV. (See, Table II) The compound nucleus formation cross section σ_c was estimated from the continium theory[25] to be about 630 mb. Thus, $(p,\ p')+(p,\ \alpha)$ cross section is smaller than a half of σ_c, and this is consistent with the small imaginary part W_0. We cannot exclude, however, the contribution of the compound elastic scattering to σ_c to a considerable extent.

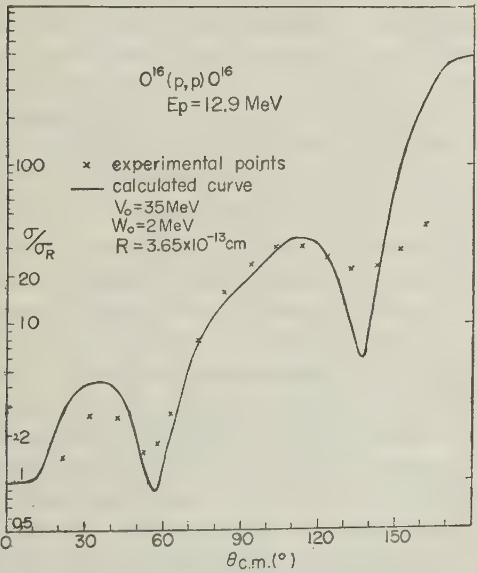

Fig. 5. Angular distribution of elastically scattered protons from Oxygen, with the calculated curve based upon the optical model. Ordinates are ratios to Rutherford cross-section.

Table II. Total integrated cross sections.

Group	$-Q$ (MeV)	σ_t (mb)	
		$E_p=15.6$ MeV	$E_p=19.0$ MeV
A	6.14	94 ± 10	59 ± 7
B	7.02	57 ± 6	34 ± 4
I	8.87	28 ± 5	28 ± 3
II	9.85	18 ± 4	8 ± 2
III	10.34	8 ± 2	8 ± 2
IV	11.08	30 ± 10	19 ± 3
V	11.51	—	11 ± 2
VI	12.02	—	6 ± 2
VII	12.53	—	11 ± 2

$E_p=15.6$ MeV (Present work)
$E_p=19.0$ MeV (Princeton dada).

The smallness of imaginary part W_0 leads us to the conclusion that the departure from the shell model is small at somewhat high energy, and thereby the sharp appearance of the large-scale resonance is predicted. From the above-mentioned analysis based on the optical model, it is seen that the maximum contribution to the scattering comes from proton waves of angular momentum $l=3$*. Namely, using the potential $V=35+2i$ MeV, we find an f-wave characteristic resonance ($N_3=-\Delta_3+\mathrm{Re}\,f_3=0$)[27] at energy about 13.5 MeV. The width of this resonance should be related to twice of the imaginary part.[26] Thus this width is expected to be about 4 MeV. In other usual nuclei, the imaginary part of optical potentical is much larger than that in O^{16} at $E_p \gtrsim 10$ MeV. Consequently the width of the giant resonance will appear to be broadened. Thus possibly, O^{16} appears to be one of the examples of such unusual nuclei, in which the giant resonance is clearly observed at $E_p \gtrsim 10$ MeV.

---

* Without an electronic computer, it is impracticable to study these results fully, and we have merely attempted to obtain approximate agreement.

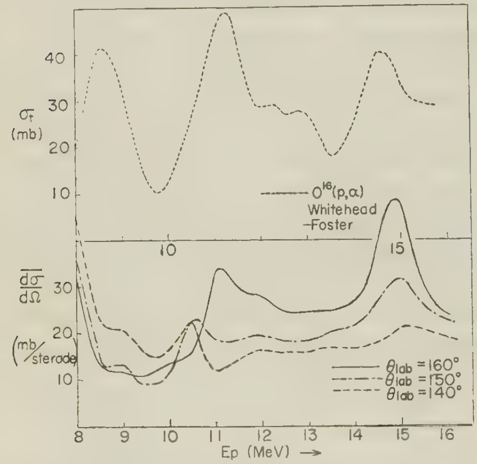

Fig. 6. The averaged excitation curves of the elastic scattering on Oxygen. The excitation function for $O^{16}(p, \alpha)$ reaction measured by Whitehead and Foster is also included.

In view of the gross structure problem, which we concern, we will average the experimental differential cross sections at energy interval ±500 kev. This magnitude of energy interval includes, on an average, about three measuring points. The average cross section is plotted in Fig. 6 as a function of the incident energy. Particularly the average excitation function of differential cross section at $\vartheta_{\mathrm{lab}}=160°$, has an apparent gross structure. In Fig. 6, the excitation function for O^{16} (p, α) reaction, which was measured by Whitehead et al.,[23] is also included, and the positions of this large scale resonance agree fairly well with each other. This seems to be the above-mentioned f-wave giant resonance from the following reasons. In the approximation based on the optical model, neglecting a spin-orbit coupling term, we expect that the f-wave resonance does not appear near $\vartheta_{\mathrm{lab}}=140°$, which is the zero point of the third order Legendre function. In fact, in Fig. 6, we cannot find the occurrence of the large-scale resonance in the excitation function at $\vartheta_{\mathrm{lab}}=140°$. This statement is also verified qualitatively by comparing our analysis based on the optical model with that of Fujimoto et al.; that is, at $\vartheta_{\mathrm{lab}} \cong 140°$ our result nearly equals to that of Fujimoto et al., while at $\vartheta_{\mathrm{lab}} \cong 160°$ our calculated result at $E_p=12.9$ MeV is much larger than theirs at $E_p=9.5$ MeV.

Therefore this suggests that the states of F^{17} in this characteristic resonance region are predominantly f states and hence have spins of 5/2 or 7/2, thereby showing that the intermediate coupling model due to Lane, Thomas and Wigner,[26] is in this case a sufficiently good approximation for explaining the energy states concerned. The result of the above-mentioned O^{16} (p, α) reaction[23] may also be explained as an f-wave resonance.

B. *Inelastic scattering*

The inelastic proton grouds, leading to the excitation of about 6 MeV (group A) and 7 MeV (group B) states of O^{16}, were observed at five energies from 11.9 MeV to 15.6 MeV together with the elastic proton group. Group A gives an energy excitation of the 3− level at 6.14 MeV in O^{16}. The group B corresponds to an energy of about 7.0 MeV states in O^{16} and appears to be the unresolved 6.91 and 7.12 MeV states. The resulting differential cross sections are shown in Fig. 7; a part of the angular distribution curves could not be measured because of the background and is excluded from Fig. 7. Although angular distributions vary remarkably with the incident energy, the integrated cross section decreases monotonically as incident energy increases. This is shown in Fig. 8, including the work of Hornyak and Sherr.[8] There appears a

---

* The calculated cross section for the formation of the compound nucleus (optical model) at energy 12.9 MeV was as follows. $\sigma_c = \sum_{l=0}^{4} \sigma_c^{(l)} \simeq 460$ mb.

	$l=0$	$l=1$	$l=2$	$l=3$	$l=4$	
$\sigma_c^{(l)}$	22	38	42	354	2	(mb)

shoulder at $E_p \simeq 14.7$ MeV for group A. Table II gives the total integrated cross section and was compared with Princeton data.[8] Any comparison with the theory of inelastic scattering has not been done.

The author is particulary indebted to Professors S. Kikuchi and I. Nonaka for their guidance and encouragement, and to Professor Y. Oda for helpful discussions held throughout the course of the work. The author wishes to express his deepest appreciation to Professor K. Matsuda. Without his active guidance and severe criticism, the present work, doubtlessly, would not have been completed. It is a distinct pleasure to thank Messrs N. Yamamuro and Y. Nagahara for their active participation in obtaining the data, Professor S. Suwa for his invaluable suggestion in the data analysis, Messrs T. Karasawa, A. Suzuki, H. Ogawa and the members of the INS (Tokyo) cyclotron crew for providing excellent cyclotron operation and Messrs M. Otsuka and N. Yoshimura for their maintenance and construction of the electronic equipments.

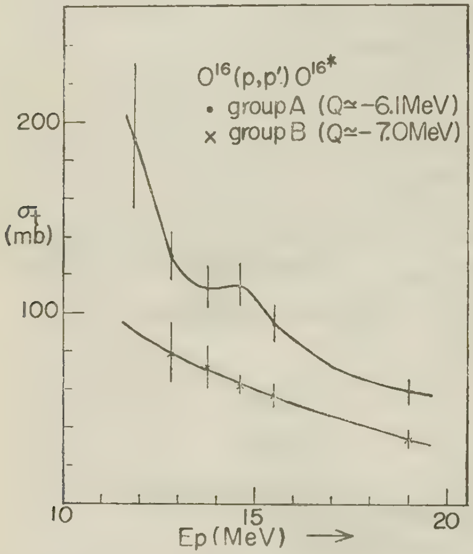

Fig. 8. Excitation functions for group A ($Q\simeq -6.1$ MeV) and group B ($Q\simeq -7.0$ MeV) in $O^{16}(p,p')O^{16*}$ scattering. Ordinates are integrated cross sections.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 15, No. 7, JULY, 1960

On the High Energy Soft Component Near Sea Level

By Tadashi KAMEDA

Department of Physics, Kobe University, Kobe

(Received February 9, 1960)

As the features of the high energy soft components of cosmic rays have not yet been thoroughly investigated, it is of great interest to study them at present day, especially in very high energy region (above BeV). To obtain the energy of such high energy electron or photon, the electromagnetic shower theory can be applied.

Using an experimental arrangement consisting of GM-counter hodoscopes and an ionization chamber with large area, the pulse height distribution of cosmic-ray showers produced by electrons or photons in lead and iron absorbers of different thickness was measured. The number of shower particles was estimated from the pulse height considering the angular spread of shower particles, and the energy of electrons or photons was obtained from the results of shower theory. The results of the present experiment show that, i) the differential energy spectra can be represented by a power law of the form $E^{-\gamma}$, with γ of 2.90 and 2.80 for electrons and photons of 2–20 BeV, respectively, ii) the zenith angle distribution of electrons is expressed by $\cos^2\theta$, and iii) upper limit of the ratio of the number of electrons to that of photons is 1.1. It is also found that the calculated results by Ivanenko are favorable to explain the observed results for lead and iron absorbers. The essential part of this investigation is to provide a classification of the incident electrons or photons by the GM-counter hodoscopes, that is, single incident particles, multiple incident ones, and those associated with EAS are separated in order to minimize the ambiguity involved in the results.

§1. Introduction

According to the generally accepted interpretation, cosmic-ray electrons and photons in the lower atmosphere are produced by decay and collision processes of μ-mesons, and by decay process of π^0-mesons resulting from nuclear interactions. It is of importance to obtain detailed information concerning the origin of the soft components, comparing the results of the observations at different altitudes with the suppositions based on the above-mentioned processes.

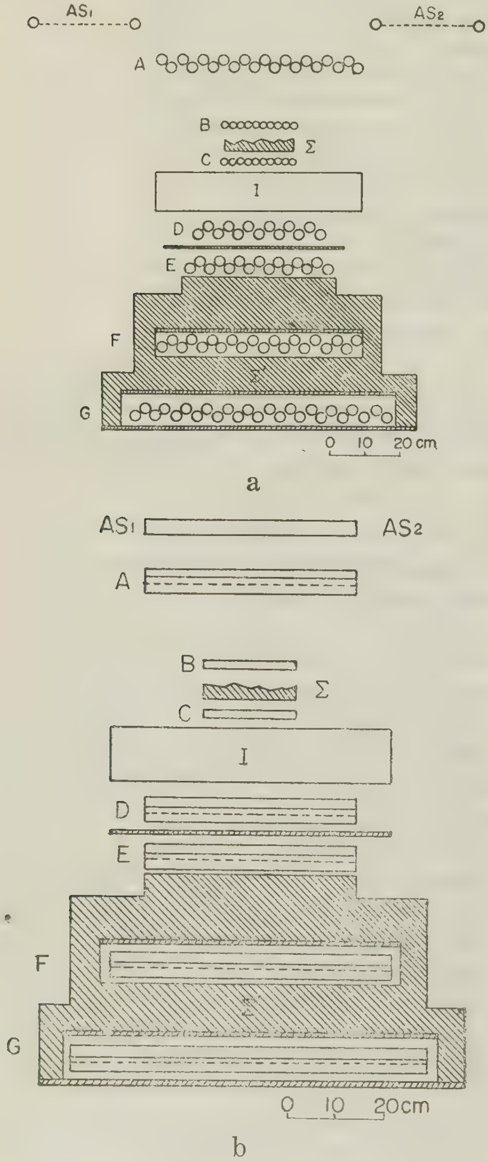
Experiments on the soft components have been performed hitherto by means of various methods, through which we have fairly accurate knowledge concerning the soft component of relatively low energy ($\leqslant$500 MeV),[1)–4)] but the observation in high energy region ($\geqslant$1 BeV) is not sufficient[2),4)].

The present experiment was planned to obtain energy spectra, absolute intensities, and zenith angle dependence of electrons and photons of very high energy. For this purpose, an ionization chamber of large area and counter hodoscopes were used. The ionization chamber is useful in the study of high energy electrons and photons as compared to the cloud chamber, because they produce so dense showers that individual tracks can not be identified separately in the latter case. Results obtained by experiments with ionization chambers, however, are apt to contain considerable uncertainties because of the variety of events giving rise to bursts. The uncertainties will be minimized under due caution, that is, if individual events associated with ionization bursts are identified by some auxiliary means. GM-counter hodoscopes in our experiment serve to select the events caused by electrons and photons. The events associated with extensive air showers are distinguished from unassociated ones by means of air shower trays. It is necessary to distinguish the events associated with EAS, because, if electrons and photons are associated with them, not only the particles initiating the cascade showers in absorber are not identified, but also the number of shower particles becomes uncertain because of large area of the ionization chamber. Further it is generally accepted that high energy electrons and photons in EAS have different energy spectra from those of single incoming particles[5].

In this paper we describe the method of experiments and the results otained near sea level. The observation at mountain altitude and the related discussion will be reported in the succeeding paper.

§ 2. Apparatus

Fig. 1 a and b show the experimental apparatus used in this experiment. The number of GM-counters in each tray and the effective area of each counters are listed in Table I.



a

b

Fig. 1. Arrangement of the apparatus.

Trays AS_1 and AS_2 are located 230 cm and 170 cm apart from the centre of Tray A respectively, lying immediately under the roof of the laboratory. All counters of the above trays are connected to neon lamps of the hodoscopes.

Table I.

Tray No.	Number of GM-counter	Effective Area of Each Counter	
A	20	2.8 cm	43.5 cm
B	10	2.0 cm	18.5 cm
C	10	〃	
D	13	2.8 cm	43.5 cm
E	15	〃	
F	20	2.8 cm	58.5 cm
G	25	2.8 cm	70.0 cm
AS_1	20	2.8 cm	43.5 cm
AS_2	20	〃	

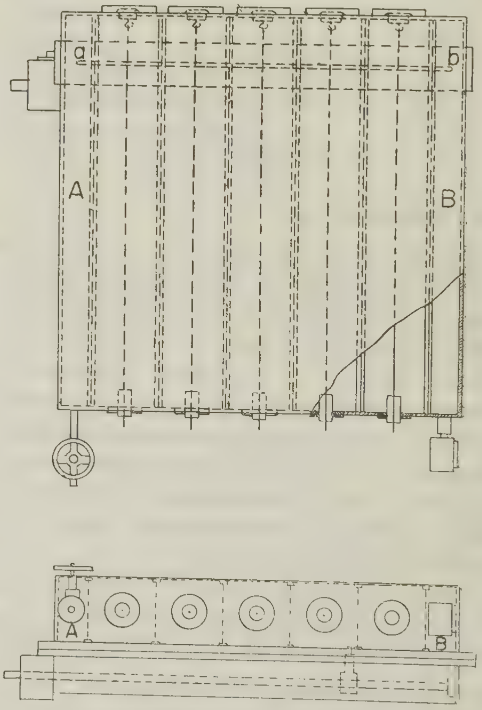


Fig. 2. Ionization chamber.

I in the Fig. 1 is the ionization chamber which was constructed in the form of rectangular parallelepiped of 10 cm height, 50 cm width and 50 cm length, and was filled with commercial argon of 99.9% purity at a pressure of 5.0 atmosphere (at 0°C). The top plate of the chamber is made of 3 mm thick iron, and the bottom and the sides are 5 mm thick iron plates. The chamber is divided into five compartments of 10 cm width by brass meshes as shown in Fig. 2, and dummy spaces of both sides (A and B in the Fig. 2) are provided against the effect of side walls. Each compartment has an effec tive volume of 10 cm × 10 cm × 50 cm, and a molybdenum wire of 1 mm diameter is stretched at the centre along the long axis. A polonium α source for calibration can be moved along the slit (ab in Fig. 2) of the bottom plate by the gear system, and in normal operation the source is placed within the dummary compartment.

Σ in Fig. 1 is a shower producer of lead or iron of 20 cm × 20 cm area, in which the electromagnetic showers, initiated by incident electron or photon, develop, and of different thickness, 0, 1, 2, 3, and 4 cm of lead, and 4 8 cm of iron.

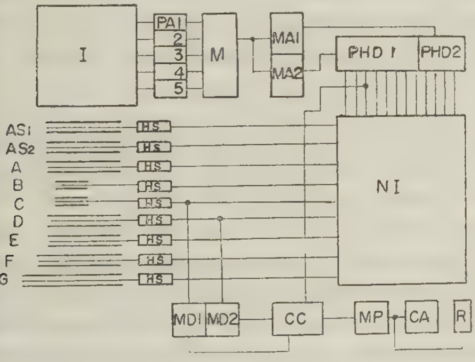

Fig. 3.
Block diagram

PA: preamplifier
M: mixer
MA: main amplifier
PHD: pulse height discriminator
HS: holdoscope circuits
NI: neon indicator
MD: mixing discrimimator
CC: coincidence circuits
MP: master pulse generator
CA: camera driver
R: register

The block diagram of the circuit is shown in Fig. 3. The amplifier for the ionization chamber is that of Jordan-Bell⁶⁾, and the output pulses of the amplifier are fed into a pulse height analyser of 12 channels, each channel being connected to a neon lamp. These neon indicators of pulse height and the GM-counter hodoscopes are photographed on the same film of 16 mm cine-camera.

The hodoscopes are triggered by a master pulse generated when an ionization pulse higher than the predetermined pulse height occured simultaneously with the discharges of any GM-counters in tray C, and the discharges of three or more GM-counters in tray D (hereafter we designate it for abbreviation as $C^{\geq 1}\ D^{\geq 3}\ I^{\geq x}$, where x is expressed by a pulse height of ionization measured in terms of unit of Po$-\alpha$).

Experiments were performed from spring to summer in 1956 in the hut on the university building (30 m a.s.l.), the roof of which has 0.7 g/cm² thickness of wood and zinc. counters and all circuits were checked daily, and if there was something wrong, the data after the previous check were omitted from the analysis*.

§ 3. Analysis of the Data

A) *Classification of events*

The photographic records were reproduced on drawings of the apparatus on a reduced scale of 0.1. These records were classified on the basis of the following criteria:

a) Association and non-association with EAS of density $\Delta \geqslant 4/\mathrm{m}^2$.

For this purpose, events were classified into two groups by the number of discharged GM-counters of trays AS_1 and AS_2. We designate the events in which none of trays AS_1 and AS_2 discharged as non associated events with EAS of $\Delta \geqslant 4/\mathrm{m}^2$, and the one in which the discharge of one or more counters in tray AS_1 and AS_2 occurred as associated events with EAS.

b) Electron (or photon) initiated showers and penetrating showers.

The showers in which none of the GM-counters in trays F and/or G discharged are regarded as electron (or photon) initiated showers, and those in which any GM-counters in trays F and/or G discharged as penetrating showers.

c) Single incident particle and multiple incident particles.

This classification was made by the number of discharged GM-counters in trays A and B. We regard the showers as those initiated by single incident particle, when one or two (adjoining) GM-counters in each of trays A and B discharged, and as showers initiated by multiple incident particles when three or more GM-counters in close proximity in trays A and B discharged. However, in the cases where 4 or less GM-counters in tray A discharged scatteringly and one or two (adjoining) GM-counters in tray B discharged, we regard these events also those initiated by single incident particles.

---

* Such cases were found five times during the experiments running for four months.

d) Electron initiated showers and photon initiated showers

When none of the GM-counters in tray A and B discharged and the first criterion in (b) is fulfilled, the shower is regarded as photon initiated showers. If the first criterion in (b) and in (c) are fulfilled respectively, we regard the showers as electron initiated showers.

e) Uncertain events

There were many pictures which satisfied the criteria a), b), and c), but not d); for example, pictures in which none of tray A but one or more GM-counters in tray B discharged or vice versa. There were also some pictures in which an electron (or photon) was incident with some penetrating particles in parallel, and these might be classified as penetrating showers according to b). We omitted these indistinct records when the energy spectra were concidered, but a part of them were adopted under due correction when intensities of electrons and photons were the subject of interest.

Some remarks are necessary for trays D and E. Appearance of the discharge plots of GM-counters in these trays was utilized to distinguish electron (or photon) initiated showers from nuclear disruptions which were initiated in gases or walls of the ionization chamber and produced some heavily ionizing particles and grey particles.

B) *Estimate of the number of shower particles*

The average number of shower particles traversing the ionization chamber is estimated by the following procedures:

a) The number of particles N_{10} corresponding to pulse height of 1 Po$-\alpha$, which traverse the ionization chamber vertically to the axis is obtained as usual by the equation

$$N_{10}=\frac{5.3\times10^6}{j\,W_0\delta lf}\,, \qquad (1)$$

where j is an average specific ionization in terms of ion-pairs per gram per square centimeter, W_0 an average energy to produce an ion pair, δ the density of gas, l the length of path in the chamber, and f the geometrical factor which is characteristic for the size of the ionization chamber. In our chamber, $f=0.93$ (obtained by a graphical calculation), $l=10$ cm, and for $j\,W$ we use $2.1\times10^6\,eV/g\,\text{cm}^2$. Thus we obtain for N_{10} the value 30.7.

b) If we measure the pulse height distribution of the ionization bursts caused by EAS at certain places where the density distribution of EAS is known by some other methods, N_{10} will be deduced comparing the pulse height and density distribution. Thus, the pulse height distribution of ionization bursts were measured at Mt. Norikura (2770 m a.s.l.) by triggering the ionization chamber with the simultaneous discharge of 5 or more GM-counters of trays AS$_1$ and AS$_2$. The frequency of EAS corresponding to pulse height more than 1.4 Po$-\alpha$ was 3.8±0.2/hr. Representing the integral density distribution at 2770 m[7] by

$$S(\geqslant\Delta)=5.0\times10^3\Delta^{-1.46}/\text{hr}\,,$$

and substituting the above mentioned value for S, we obtained for N_{10} the value 30.3.

c) Actual number of shower particles, corresponding to 1 Po$-\alpha$, should be less than N_{10} on account of the scattering of particles in Σ. The angular distribution of the cascade electrons may depend on the thickness of the absorber used, and on the energy of primary electron (or photon). However, for simplicity, we assume for it the result obtained by Franchetti et al.[8] below lead absorber in a cloud chamber, and as well assume that rms angle of the particles under lead and iron is expressed by the relation

$$\sqrt{\overline{\theta^2}}=a+\frac{b}{n}\,, \qquad (2)$$

where n is the number of particles, a and b are constants depending on the materials and their thickness. According to ref. (8), $a=30°$, $b=50°$ for 2, 3 and 4 cm thickness of lead. These values were obtained immediately below the lead plate. But it may not be correct to adopt these values in our case, where there are aluminum wall of the GM-counters and iron wall of the ionization chamber between Σ and the gaseous volume of the chamber. We, nevertheless, assume that $a=30°$, neglecting the second term of the right side of the equation (2) because of large n in our case, and that the same angular distribution holds for lead and iron. Thus, the average shower particles initiated by a vertically incident electron (or photon) N_1, corresponding to the pulse height of 1 Po$-\alpha$, is calculated numerically, namely,

$$N_1 = gN_{10} = 24.0\ , \tag{3a}$$

where $g=0.79$, and $N_{10}=30.5$. The number of shower particles corresponding to the pulse height of x Po$-\alpha$, N_x, is

$$N_x = 24.0\ x\ . \tag{3b}$$

C) When there was no material at Σ, electron (or photon) initiated showers were observed at low frequency. These background events seem to initiate from the surrounding materials and from the walls of GM-counters and of the ionization chamber, and these rates were subtracted from the data obtained with material at Σ.

D) *For the analysis of the observations, following assumptions were made*:

a) Total number of electrons obtained from the shower theory $\Pi_{th}(E_0, 0, t)$, initiated by primary electron (or photon) of energy E_0 at depth t, is represented by

$$\Pi_{th}(E_0, 0, t) = \eta \Pi(E_0, 0, t)\ , \tag{4}$$

where $\Pi(E_0, 0, t)$ is number of electrons actually observed below the absorber of thickness t, and η is a constant. We assume that η is independent on E_0.

b) The differential energy spectra of electrons and photons are expressed by

$$G(E)dE = cE^{-\gamma}dE\ , \tag{5}$$

where c and γ are constants.

c) Fluctuation of the number of shower particles obeys Poisson's distribution. Accordingly, probability P that N particles emerge in the shower initiated by primary electron (or photon) of energy E_0 is

$$P(E_0, N) = e^{-\pi}\Pi^N / N!\ , \tag{6}$$

where Π is the abbreviation of $\Pi(E_0, 0, t)$.

d) At a certain depth t, the following relation between E_0 and Π_{th} exists in some range of E_0,

$$E_0 = k\Pi_{th}^{\alpha} = k\eta^{\alpha}\Pi^{\alpha}\ , \tag{7}$$

where k and α are constants depending on t. Moreover, we neglect the variation of Π_{th} with small variation of t, and this is validated near the shower maximum.

e) Zenith angle distribution of primary electrons or photons is represented by the form of $\cos^n\theta$, where n does not depend on their energy.

f) The mean path length, in the ionization chamber, of the shower particles initiated by a primary electron (or photon) of zenith angle θ, is longer than that initiated by vertically incident one roughly by a factor of $1/\cos\theta$. This simplification is approximalely valid, even if the angular spread of the shower particles is taken into consideration.

Under the above mentioned assumptions, the counting rates of the electrons (or photons) producing cascade showers of pulse height of more than x are represented by

$$\begin{aligned} F(\geqslant N_x) &= \int_S \int_\omega \cos^n\theta dS' d\omega' \int_{N_x\cos\theta}^{\infty} G(E)dE \frac{e^{-\pi}\Pi^N}{N!} \\ &= A\int_S \int_\omega \cos^n\theta dS' d\omega' \int_{N_x\cos\theta}^{\infty} dN \frac{\Gamma(N-\alpha\gamma-\alpha)}{N!}\ , \end{aligned} \tag{8}$$

where $A=c(k\eta^{\alpha})^{-\gamma+1}$, S is the area of Σ, and ω is the solid angle which is subtended by tray A on each elements of area of Σ and in which the effective area of tray D is contained. For large N, we may obtain

$$\begin{aligned} F(\geqslant N_x) &= A\int_S \int_\omega \cos^n\theta dS' d\omega' \int_{N_x\cos\theta}^{\infty} dN \cdot N^{-(\alpha\gamma-\alpha+1)} \\ &= A' N_x^{-(\alpha\gamma-\alpha)} \int_S \int_\omega \cos^m\theta d\omega' dS'\ , \end{aligned} \tag{9}$$

where

$$A' = \frac{c(k\eta^{\alpha})^{-\gamma+1}}{\gamma-1}\ ,$$

and

$$m = n - \alpha(\gamma-1)\ . \tag{9a}$$

From the equation (7), the integral number spectra are represented by

$$F(\geqslant N_x)=BN_x^{-\nu}\ , \tag{10}$$

and

$$\nu=\alpha\gamma-\alpha\ . \tag{10a}$$

As seen in (9) the zenith angle distribution of the primary particles giving pulse height more than x is represented by $\cos^m\theta$, the relation between m and n being expressed by (9a). Thus from observed ν and m, we are able to obtain γ and n by (9a) and (10a).

§ 4. Results and Discussion

(A) *Energy spectra of primary electrons and photons.*

Integral number spectra obtained by converting mere the pulse height into the number of shower particles using (3b), are shown in Fig. 4 (a) and (b).

The former gives the spectra for the electron initiated showers, and the latter those for the photon initiated showers. The errors indicated are the statistical ones. As shown in the Figs, the integral number spectra are well represented by the power law of the form

$$F(\geqslant N)=aN^{-\nu}\ , \tag{11}$$

where ν's are listed in Table II.

In order to find γ from these ν's, we must know the values of α's. However, as α's are slowly varying functions of energy, it is necessary to find the energy interval of the primary electrons (or photons) measured in our experiment. For this purpose, we proceed as follows:

i) Barker[3] obtained an energy spectrum of of electrons of 10 MeV–400 MeV near sea level, and he also gives the absolute vertical intensities of electrons with energy higher than 10 MeV. As to $E\geqslant 300$ MeV, Chou[2] obtained energy spectra of electrons and photons near sea level up to 2 BeV. Since he did not give the absolute intensities, ordinate of the Chou's curve was normalized at 300 MeV. Our results for electrons may be diretly compared with theirs, because the above mentioned authors measured the single incident electrons. Thus it is found that the absolute intensity is represented by

$$G(E)dE$$
$$=2.2\times(\gamma-1)10^{-5}EdE/\mathrm{cm}^2\cdot\mathrm{sec}\cdot\mathrm{sterad}\cdot\mathrm{BeV}\ , \tag{12}$$

where E is energy measured in terms of BeV.

ii) As first approximation, we assume that $\alpha=1$, and $\gamma=3$, then $n=2$ by putting $m=0$ in (9a), and that the number of shower particles does not fluctuate, i.e., a certain pulse height corresponds to a certain value of energy of a primary electron. From the counting rates observed, the energy interval of the vertically incident primary electrons measured by our apparatus is estimated to be 3–20 BeV, thereby a small correction is applied to the counting rates for the particles passing through the

Table II.

Absorber Material			Pb				Fe

		I	2.83±0.16	2.80±0.10	2.75±0.09	2.85±0.09	2.87±0.15	2.75±0.13

ineffective spaces between GM-counters of trays A and B (i.e. a part of the uncertain events mentioned in § 3, A). Therefore, we use as the values of α's those between 2 BeV and 20 BeV, taking into account the obliquely incident particles.

The values of α's are obtained graphically from the calculated results by Sneider and Serber[9], and from those by Ivanenko[10),13)]. The results are listed with the values of ν's in Table II. As the values of $\Pi_{th}(E_0, 0, t)$ for photon initiated shower are not described in Ref. (10), we calculate them by the approximation formula indicated in it.

As shown in the Table, using Ivanenko's calculated results the almost constant value of γ is obtained for various thickness of lead and iron absorbers.

Thus, the values of γ's are obtained as follows:

$$\left.\begin{aligned} \gamma_e &= 2.90 \pm 0.05 \quad \text{for electrons} \\ \gamma_p &= 2.80 \pm 0.05 \quad \text{for photons}\,, \end{aligned}\right\} \qquad (13)$$

where the suffix e and p express the quantities for electrons and photons respectively.

(B) *Zenith angle distribution of primary electrons.*

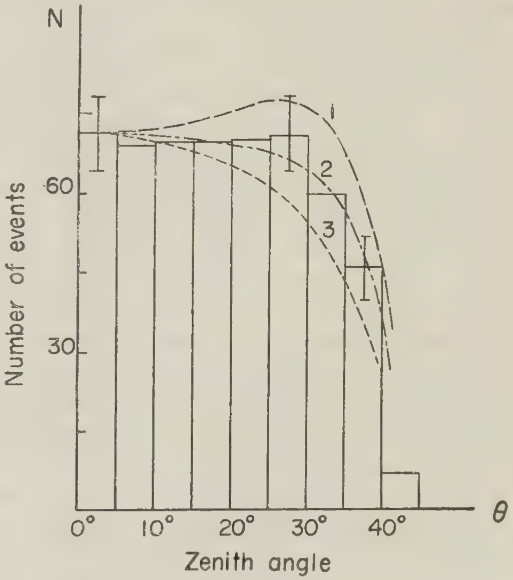

Fig. 5. Zenith angle distribution.
1: $m=-1$; 2: $m=0$; 3: $m=1$.

Concerning the electrons which produced pulse height of more than 2/3 Po$-\alpha$, we plotted the projected zenith angle distribution obtained by the discharged GM-counters in trays A and B. Fig. 5 is an example for 2 cm thickness of lead, and the curves in the Fig. are the calculated distributions for our geometry obtained by assuming $\cos^m \theta$ distribution. In the case of other thicknesses, similar results were obtained. The mean value of m thus obtained is

$$m = 0.0 \pm 0.5 \quad \text{2 cm, 3 cm and 4 cm lead and 8 cm iron}\,. \qquad (14)$$

According to (9a), these figures give $n=2\pm0.5$.

(C) *The ratio of the number of electrons and photons*

Substituting in (9) the values of γ's, m and

α's, and assuming the relation (5), the values of η's are determined for various thickness of absorbers. The results thus obtained are as follows;

$$\left.\begin{array}{ll} \eta_{\mathrm{Pb}}=2.2 & \text{for 1 cm thickness of lead,} \\ \eta_{\mathrm{Pb}}=3.0 & \text{for 2, 3 and 4 cm thickness of lead,} \\ \eta_{\mathrm{Fe}}=1.7 & \text{for 8 cm thickness of iron*.} \end{array}\right\} \quad (15)$$

It would be noted that the value of η_{Pb} is same for every thickness of lead thicker than 2 cm. (cf. (E)).

Assuming the same angular distribution for photons as that of electrons, the following value for c_e/c_p is obtained,

$$c_e/c_p=1.10\pm1.10 \ .$$

Of course, this value is the upper limit of the ratio, because we cannot separate individually the particles consisting of a narrow bundle of electrons and photons, which may likely occur in the case of high energy soft component.

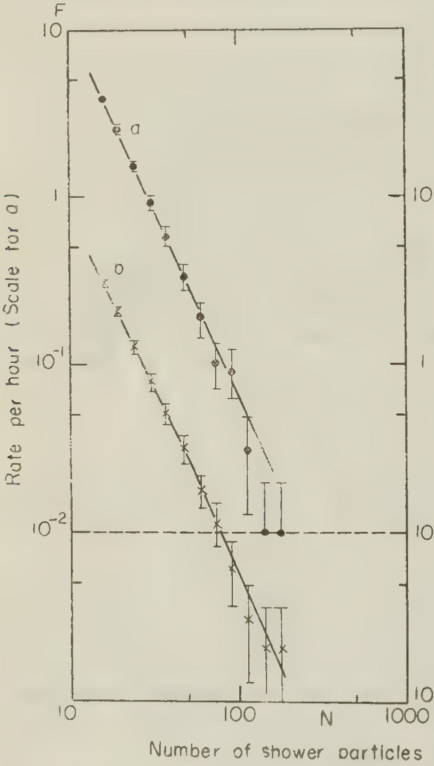

Fig. 6. Number spectra of shower particles.
a: single incident electron
b: multiple incident electrons and photons absorber thickness: 2 cm Pb.

(C) *Multiple incident electrons and photons.*

The integral number spectrum of the shower particles, initiated by multiple incident electrons and photons under 2 cm thickness of lead, is shown in Fig. 6, and that of single incident electrons under the same absorber is also shown in the same figure for comparison. Though, as seen from the Fig., the exponent of the multiple events is a little lower than that of single incident events for smaller N, we can say little about the composition of the particles and the energy of each particles in multiple events. Hewever from the ratio of multiple events to single events tabulated in Table III, we may conclude that the major part of the particles in multiple events has not so high energy that it is considerably absorbed between 2 cm and 3 cm thickness of lead.

(D) *High energy electrons and photons associated with EAS.*

The number of the events which are associated with EAS of $\Delta \geqslant 4/m^2$ and do not contain any penentrating particle is within 2% of the total single events for the pulse height of $\geqslant 2/3\,\mathrm{Po}-\alpha$ and for various thickness of absorbers. If all the events associated with EAS of $\Delta \geqslant 4/m^2$ and containing some penetrating particles are interpreted as the events produced by high energy electrons or photons incoming simultaneously with some penetrating particles, the above percentage value is raised to 11% of the total single events. This is the upper limit of the number of high energy electrons and photons associated with EAS of $\Delta \geqslant 4m^{-2}$.

In Table III, we summarized the rate of occurrence of each kind of event obtained in our measurements.

(E) *Errors involved in the data.*

a) Nuclear interactions.

Nuclear interactions in the absorber which give rise to some π^0-mesons of high energy only, or these π^0-mesons and some charged π-mesons of energy $\leqslant 380$ MeV, are classified in our criterion as the multiplicative showers initiated by primary electrons and photons. The amount of these interactions was estimated by comparison of the results

---

* According to the calculated results of Ivanenko[13]. $\eta_{\mathrm{Fe}}=1.0$ for 4 cm thickness of iron, and $\eta_{\mathrm{Fe}}=1.4$ for 8 cm iron.

Table III. No. of Events $\geq 2/3\ P_0-\alpha$ (/hr).

Absorber Material	Pb				Fe	
Absorber Thickness	1 cm	2 cm	3 cm	4 cm	4 cm	8 cm

Penetrating shower	0.85±0.10	0.92±0.10	1.05±0.09	1.10±0.11	0.35±0.06	0.83±0.13
〃 (E.A.S. associated)	0.40±0.06	0.45±0.07	0.61±0.07	0.88±0.09	0.27±0.55	0.22±0.13
Uncertain events	0.73±0.09	0.90±0.10	0.82±0.08	0.70±0.09	0.65±0.08	0.72±0.12

obtained for the electron (or photon) initiated showers under 2 cm Pb and 8 cm Fe at sea level with those at mountain altitude (2770 m a.s.l.), as will be mentioned in the succeeding paper. According to it, errors due to the nuclear interactions are at most 3% of the total electron (or photon) initiated showers at all energy even for 4 cm thickness of lead and ~10% for 8 cm thickness of iron absorber.

b) Penetrating showers.

As mentioned in §3, we classified the events, in which one or more GM-counters in tray F discharged, as the penetrating showers. There is, however, some probability that low energy cascade photons discharge them under 15 cm thickness of lead. This probability is small for $E \leqslant 10$ BeV, but increases rapidly with the increasing primary energy.[10),11)] Therefore, the deviation of the observed frequency from the power spectrum with constant exponent for large N, as seen in the Fig. 4, does not necessarily mean that the value of γ increases with increasing N, and it is rather reasonable to consider that the power law with constant γ is valid for the energy range measured.

Further, among the penetrating showers defined by §3, there will be some events in which high energy electrons (or photon) are incident on the absorber associated with the penetrating particles, and by appearance they seem to be the penetrating showers. Indeed, there are some pictures in which an electron (or photon) and a penetrating particles are incident in parallel. Though accurate probability of these events cannot be obtained, we estimate from the parallel events that it is smaller than 5% of the total number of the penetrating showers of our classification.

The accidental coincidence of electron (or photon) showers with penetrating particles, resulting from the resolving time of the hodoscopes (30 μsec) is less than 0.2% of the total number of the penetrating showers.

c) Criticism of the assumptions

We assumed Poisson's distribution for the number of shower particles emerging beneath the absorber. This assumption may be approximately valid for large N and near the shower maximum, except at small t. In our experiment where the energy range measured is 2–20 BeV, the above mentioned conditions may be fulfilled for $t=3\sim 8$. The assumption that g is a constant for various thickness and for E_0, and η a constant for E_0, may not be valid, nevertheless, we obtained a constant value of η for various thickness of lead, except at small t. This may be interpreted as the product $g\eta$ is nearly constant for various thickness and for E_0, because at higer energy g becomes larger owing to smaller spread of shower particles, and η becomes smaller owing to the shower particles of higher energy. The value of $g\eta$ is 2.36 and 1.32* for lead and iron absorber respectively.[12)] Further, it will be noted that the iron plate of the ionization chamber and the alminum wall of GM-counter in tray C absorb electrons of energy lower than 5.5 MeV, and so, in the case of lead absorber η involves this effect.[13)]

(F) *Comparison with others.*

Energy spectrum up to 100 BeV of the soft component at sea level was reported by Carmichael.[4)] According to his result, integral energy spectrum beyond 1.6 BeV is represented by a power law of slope −2.00. This result is not inconsistent with ours, taking into consideration that, though he measured electrons, photons, and multiple events in our classification as a whole, they have the nearly same exponents. Concerning to the zenith angle distribution, Barker[3)] obtains $\cos^3\theta$ distribution for electrons of lower energy. The value of the power for electrons of higher energy is less by one, and it will be discussed in relation to the origin of the high energy soft component in the succeeding paper. Chou[2)] reported that the ratio of the number of electrons is about one, and our results are in accord with his results too.

---

* Referring to (13), this value is 1.11.

§ 5. Conclusion

Concerning the electrons and photons 2–20 BeV, the following points are concluded:

(1) The differential energy spectra of electrons and photons are represented by the power law, the values of power are 2.90±0.05 and 2.80± 0.05 for electrons and photons, respectively.

(2) Vertical intensities of single incident electrons and photons of the above-mentioned energy interval are

$$G_e(E)dE=(4.1\pm0.4)\times10^{-5}E^{-2.90}dE/\mathrm{cm}^2\ \mathrm{sec.\ sterad.\ BeV}\quad \text{for electrons}$$

$$G_p(E)dE=(3.7\pm0.4)\times10^{-5}E^{-2.80}dE/cm^2\ \mathrm{sec.\ sterad.\ BeV}\quad \text{for photons,}$$

Multiple events and the soft component in EAS will increase these figures by a factor of 1.15 at most for the intensities of the total electrons and photons. In Fig. 7 the above mentioned results are summarized and illustrated.

(3) Zenith angle dependence of a single electrons is expressed by $\cos^n\theta$ where n is 2.0±0.5.

(4) The upper limit of the ratio of single electrons and photons is 1.1±0.1 at 1 BeV.

(5) The number of shower particles under the absorber is reduced by a factor of 1/3 and 1/1.4 for lead and iron respectively, comparing with the theoretically expected number.

(6) The total number of shower particles under lead absorber calculated by Ivanenko gives consistent results for our experimental data.

Ferroelectricity in Potassium Ferrocyanide Trihydrate and its Isomorphous Substances

By Shigeru WAKU, Kunio MASUNO, Toshisuke TANAKA
and Hiroshi IWASAKI

Electric Communication Laboratory, Nippon Telegraph and Telephone Public Corporation

(Received January 14, 1960)

Several $A_4[M(CN)_6]\cdot 3H_2O$ type cyano-complexes belonging to the crystal class C_{2h} were studied to examine ferroelectricity. Isomorphous substances obtained through replacing the Fe^{++} ion by Ru^{++}, Os^{++} and Mn^{++} ions show ferroelectric behavior below −14°C, −2.4°C and −40°C respectively. Ferroelectric behavior of these compounds are very similar to that of the potassium ferrocyanide trihydrate, reported before. The potassium ferrocyanide group ferroelectrics has ferroelectric axis parallel to $[10\bar{1}]$ direction. Ferroelectric transition of these substances is probably of the second order.

§1. Introduction

In the previous paper,[1] we reported the ferroelectric behavior in potassium ferrocyanide trihydrate, $K_4[Fe(CN)_6]\cdot 3H_2O$ of which crystal class is monoclinic C_{2h} and space group is $C_{2/c}$ at room temperature. The ferroelectric hysteresis loop was observed under the application of electric field parallel to [101] and $[10\bar{1}]$ direction. We could not, however, determine the direction of ferroelectric axis, and the reason why the multiple peaks appear in the dielectric constant versus temperature curve was not understood.

Some problems in the ferroelectric properties of potassium ferrocyanide trihydrate were reexamined, in parallel with the attempt to search new ferroelectric substances in its isomorphous cyano-complexes.

§2. Specimens

We growed single crystals of the cyano-complex substances, which have $A_4[M(CN)_6]\cdot 3H_2O$ type chemical composition and belong to the crystal class C_{2h}. In this paper, we will report the ferroelectric behavior in potassium ferrocyanide trihydrate and its isomorphous substances obtained through replacing the Fe^{++} ion by Ru^{++}, Os^{++} and Mn^{++}. Method of preparation of these compounds, solubility and dehydration versus temperature curves will be reported in another paper.[2] The crystals were cut perpendicular to the cleavage plane (010) and silver-painted to measure the dielectric properties.

The evaporated metal electrode was not used, as the evacuation brought about some dehydration of the crystals. Dielectric constant was measured by tuning method in 1 MC. Hysteresis loop in 50 cps was measured by ordinary Sawyer and Tower's circuit. Ferroelectric behavior of the isomorphous substances obtained through replacing some part of the potassium ions by other mono-valent ions will be reported subsequently.

Table I. Axial ratio and optical constants of $A_4[M(CN)_6]\cdot 3H_2O$ type cyano-complexes belonging to the crystal Class of C_{2h}

§ 3. Experimental Results

(1) *Optical anomaly*

Fig. 1 illustrates the external form of the crystal, crystal axes a, b, c, and optic elasticity axes X, Y, Z for complexes listed in Table I. The optical angle 2V, and the angle between $[10\bar{1}]$ and X axis, θ, in the table, are quoted from a literature.[3)]

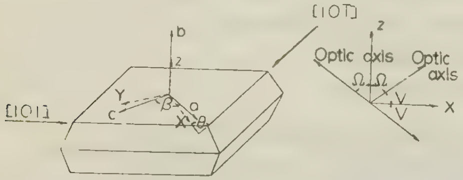

Fig. 1. Crystallographic axes *a*, *b*, *c*, optic elasticity axes *X*, *Y*, *Z* and optic axes of potassium ferrocyanide trihydrate and its isomorphous substances.

Optical anomaly is frequently observed in these crystals. From the Table I, potassium ferrocyanide single crystals are supposed to give a value of 101°50 for the optic axial angle $2\Omega=\pi-2V$. In some small crystals 2Ω is approximatly equal to this expected value, but all the large crystals give smaller angles than this, and in the extreme case, the crystals seem as if they are uniaxial. Hereafter, we will denote the former class as "normal" crystals and the latter two classes as "abnormal" crystals.

(2) *Ferroelectric Behavior in Potassium Ferrocyanide*

In the previous paper, we reported the small signal dielectric constant, spontaneous polarization and coercive field versus temperature in potassium ferrocyanide trihydrate crystal. In the curve of the dielectric constant, three conspicuous peaks at −22°C, −26°C and −33°C and two smaller peakes at −43°C and −80°C, were shown. The specimen used in the previous work was found to be an abnormal crystal with very small optic axial angle.

For a selected normal single crystal, the multiple peaks vanish except only one peak which turned out to correspond to the Curie point, as shown in Fig. 2. The figure in-

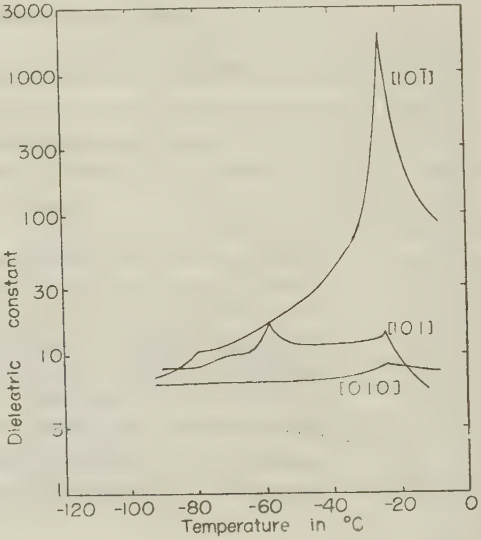

Fig. 2. Dierectric constant of $K_4[Fe(CN)_6]\cdot 3H_2O$ as a function of temperature.

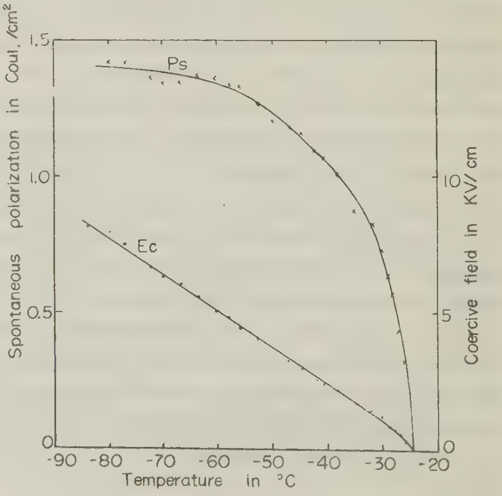

Fig. 3. Spontaneous polarization and coercive field along $[10\bar{1}]$ direction of $K_4[Fe(CN)_6]\cdot 3H_2O$ as a function of temperature.

cludes the measurements along three directions, [010], [101] and $[10\bar{1}]$. A remarkable anomaly in $[10\bar{1}]$ direction is observed at −24.5°C, but we can see no more than very weak anomaly in two other directions.

In the abnormal crystals, ferroelectric hysteresis loop appears in [101] as well as in $[10\bar{1}]$ direction, while in normal crystals it can be observed only in $[10\bar{1}]$ direction. Fig. 3 shows the curves of spontaneous polarization and coercive field strength of the normal crystal, as a function of the temperature. An abrupt increase of the spontaneous polarization, as seen at −33°C in the abnormal crystal, disappears. The spontaneous polarization of the normal crystal is two or three times as large as that of the abnormal crystal, and the coercive field of the former crystal is about a quater of that of the latter one.

(3) *Ferroelectricity in potassium ruthenoanc osmo-cyanide trihydrate complexes*

Fig. 4 and 5 show the temperature dependence of the small signal dielectric constant observed in the normal crystals of potassium

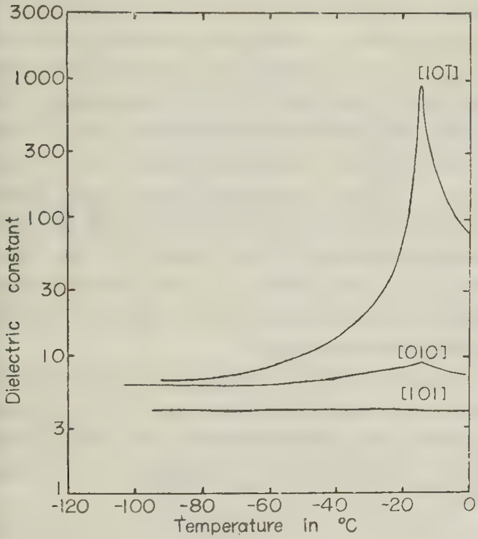

Fig. 4. Dielectric constant of $K_4[Ru(CN)_6]\cdot 3H_2O$ as a function of temperature.

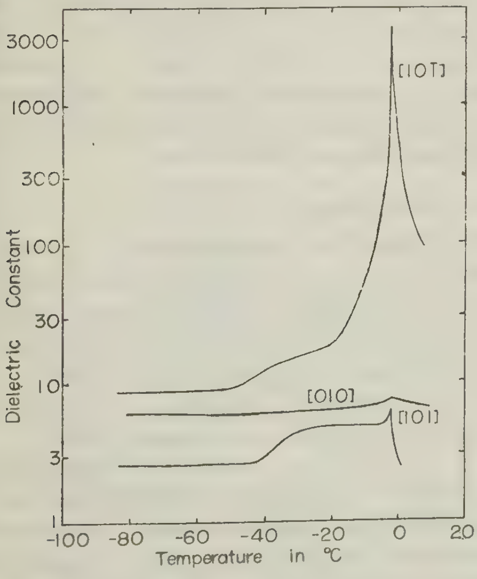

Fig. 5. Dielectric constant of $K_4[Os(CN)_6]\cdot 3H_2O$ as a function of temperature.

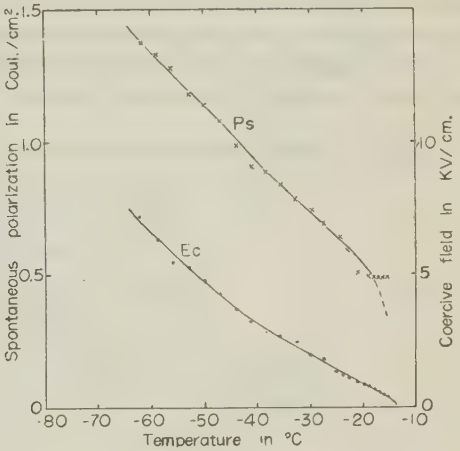

Fig. 6. Spontaneous polarization and coercive field along $[10\bar{1}]$ direction of $K_4[Ru(CN)_6]\cdot 3H_2O$ as a function of temperature.

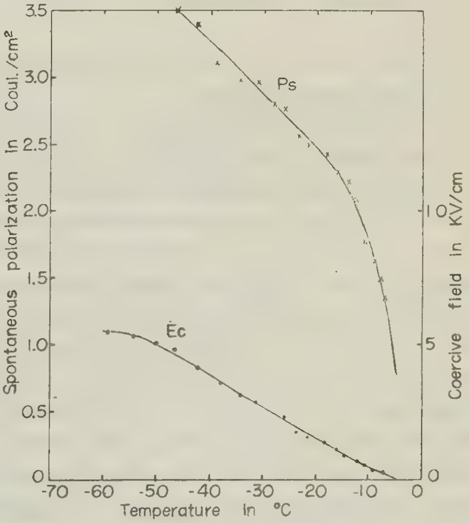

Fig. 7. Spontaneous polarization and coercive field along $[10\bar{1}]$ direction of $K_4[Os(CN)_6]\cdot 3H_2O$ as a function of temperature.

rutheno- cyanide trihydrate, $K_4[Ru(CN)_6]\cdot 3H_2O$ and potassium osmo-cyanide trihydrate, $K_4[Os(CN)_6]\cdot 3H_2O$, respectively. In the curve measured along [10$\bar{1}$] direction, remarkable peaks appear at −14°C for the ruthenocyanide and −2.4°C for the osmocyanide. These peaks correspond to the one observed at −24.5°C for potassium ferrocyanide.

Spontaneous polarization and coercive field along [10$\bar{1}$] direction are shown in Fig. 6 for the ruthenocyanide and in Fig. 7 for the osmocyanide. In the [101] and [010] directions, the hysteresis loop does not appear in the whole temperature range of measurement for two substances. By and large, the properties of these crystals are very similar to those of the normal crystal of potassium ferrocyanide.

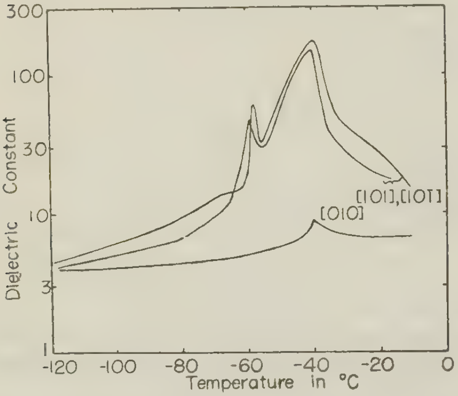

Fig. 8. Dielectric constant of $K_4[Mn(CN)_6]\cdot 3H_2O$ as a function of temperature.

(4) *Ferroelectricity in potassium manganocyanide trihydrate complex*

Fig. 8 shows the temperature dependence of the small signal dielectric constant of potassium manganocyanide trihydrate, $K_4[Mn\cdot(CN)_6]\cdot 3H_2O$. There are two peaks at about −40°C and −58°C in the curves measured along [101] and [10$\bar{1}$] directions. Ferroelectric hysteresis loop appears in both directions below −40°C. The existence of conspicuous peak of dielectric constant at other temperatures than Curie point and the existence of the ferroelectric hysteresis phenomenon in both [101] and [10$\bar{1}$] directions are quite similar to the dielectric behavior of abnormal potassium ferrocyanide crystal having small optic axial angle 2Ω. This crystal is supposed to be also an abnormal one having small optic axial angle. Since the color of this crystal is dark violet, conoscopic observation of the interference figure was unsuccessful.

Spontaneous polarization of this crystal is very small and coercive field is very large.

§4. Discussions

In the preceding sections, we see that the normal single crystals of three isomorphous cyano-complexes exhibit remarkable dielectric anomaly and hysteresis loop only in the [10$\bar{1}$] direction. The fact shows that the ferroelectric axis lies along [10$\bar{1}$] direction. On the other hand, when the crystals have optical anomaly, dielectric anomaly and hysteresis loops are observable in two independent directions, and furthermore peculiar peaks appear in the dielectric constant versus temperature curve. These discrepancies, which makes the situations complicated, will be explained in connection with the cause of the optical anomaly. Discussions on the optical anomaly related to the X-ray study will be reported in a subsequent paper.

Change of the spontaneous polarization near the Curie point as seen in Fig. 3, 6 and 7 suggests that the transition in these isomorphous substances is probably of a second order.

Covalent radii of Fe^{++}, Ru^{++}, Os^{++} and Mn^{++} having octahedral coordination are 1.23, 1.33, 1.33 and 1.12Å respectively, while the Curie points of these four ferroelectric complexes are −24.5°, −14°, −2.4°, and −40°C respectively. Hence, it may be concluded that the ferroelectric transition temperature increases with increasing the ionic radius of the complex ion $M(CN)_6^{----}$.

§5. Conclusions

1. Potassium rutenocyanide, potassium osmocyanide and potassium manganocyanide show ferroelectric behavior below −14.5°C, −2.4°C and −40°C respectively similar to that obtained for potassium ferrocyanide.

2. Ferroelectric transition of these substances is probably of a second order.

3. As the ionic radious of complex ion $M(CN)_6^{----}$ of potassium ferrocyanide group ferroelectrics becomes larger, ferroelectric transition temperature shifts toward the higher side.

4. There are remarkable differences in

ferroelectric behavior between normal crystals having the normal optic axial angle and abnormal crystals having smaller optic axial angles. Only in [10$\bar{1}$] direction, normal crystals show dielectric anomaly and hysteresis loop.

5. Ferroelectric axis of these substances is parallel to [10$\bar{1}$] direction.

The authors are very grateful to Dr. H. Hirabayashi, Dr. R. Kiriyama, Mr. H. Toyoda and Dr. N. Niizeki for their helpful discussions.

Interaction of Conduction Electrons with Acoustic Waves in Many-Valley Semiconductors

By Nobuo MIKOSHIBA
Electrotechnical Laboratory, Nagatacho, Tokyo

(Received February 6, 1960)

A semi-classical theory is given for explaining the characteristics of the interaction of conduction electrons with acoustic waves in many-valley semiconductors such as n-Ge. In general, the ultrasonic absorption coefficient can be written as

$$\Lambda=\Lambda_P+\Lambda_K\ ,$$

where Λ_P is due to the change of the deformation potential energy of electrons caused by net intervalley transitions, Λ_K due to the change of the kinetic energy caused by intravalley transitions. The acousto-electromotive force can be also written as

$$F=F_P+F_K\ .$$

In the low frequency range the dominant terms are Λ_P and F_P, but Λ_K and F_K predominate in sufficiently high frequency range. For longitudinal waves propagating in the ⟨110⟩ direction and transverse waves propagating in the ⟨100⟩ direction and polarized in the ⟨010⟩ direction, F is identical with the formula of Weinreich-Sanders-White in the low frequency range. But in contrast to their formula, F does not decrease in the high frequency range owing to the increase of F_K and has the same order of magnitude as that for longitudinal waves in simple semiconductors. In special cases such as for longitudinal waves propagating in the ⟨100⟩ direction and transverse waves propagating in the ⟨110⟩ direction and polarized in the ⟨1$\bar{1}$0⟩ direction, $\Lambda_P=F_P=0$ and then the interaction becomes essentially identical with that in simple semiconductors.

§1. Introduction

Recently, Weinreich-Sanders-White[1] have derived a correct formula for the acousto-electric effect by transverse waves in n-Ge using so-called phenomenological approach, which is in good agreement with their experiments. There remain some questions, however, about the applicability of their phenomenological approach, because (a) it ignores the effect of the motion of the impurity charge and (b) it may be applicable only to the low frequency range i.e. $ql \ll 1$, where q is the wave number of acoustic waves and l the mean free path of conduction electrons. In fact, as has been shown in the previous paper[2], Weinreich-Holstein's phenomenological approach[3] for longitudinal waves in simple semiconductors was applicable only under two conditions; (a) $C \gg m\omega_P^2/q^2$ and (b) $ql \ll 1$, where C is the deformation potential constant, m the effective mass, ω_P the plasma frequency of conduction electrons.

The object of this paper is to apply a self-consistent semiclassical method to many-valley semiconductors such as n-Ge and to clarify the characteristic features of the interaction of conduction electrons with acoustic waves. The Brillouin zone of Ge is a truncated octahedron and the minima of conduction band lie on the edges in the ⟨111⟩ direction. Then n-Ge has eight half-valleys, i.e., four valleys, the deformation potential of which is given by[4]

$$U^{(\alpha)}=[\Xi_d\delta_{ij}+\Xi_u K_i^{(\alpha)}K_j^{(\alpha)}]u_{ij}\ , \tag{1.1}$$

where Ξ_d and Ξ_u are the deformation potential constants for the dilatation and the uniaxial shear respectively, $K_i^{(\alpha)}$ the i-component of the unit vector pointing from the center of the Brillouin zone to the (α)-valley, u_{ij} the (i, j)-component of the strain tensor. It will be sufficient for the object of this paper to consider following four cases.

(A) Longitudinal Waves:

(A1) Asymmetrical two class case. For longitudinal waves propagating in the ⟨110⟩ direction, for example, four valleys are classified into (+) and (−)-classes, the deformation potentials of which are

$$\left.\begin{aligned} U^{(+)}&=(\Xi_d+\tfrac{1}{3}\Xi_u+\tfrac{1}{3}\Xi_u)u_{ll}=(\Xi_d+\tfrac{2}{3}\Xi_u)u_{ll}\ , \\ U^{(-)}&=(\Xi_d+\tfrac{1}{3}\Xi_u-\tfrac{1}{3}\Xi_u)u_{ll}=\Xi_d u_{ll}\ , \end{aligned}\right\} \tag{1.2}$$

respectively. Then net interclass transitions may take place between two classes, similarly to (B1)-case.

(A2) Simple case. For longitudinal waves propagating in the ⟨100⟩ direction, for example, the deformation potentials are the same for four valleys and are given by

$$U=(\Xi_d+\tfrac{1}{3}\Xi_u)u_{ll}\ . \tag{1.3}$$

Therefore, if we take the *directionally averaged* effective mass and intravalley relaxation time, the interaction in this case is essentially identical with that in simple semiconductors discussed in the previous paper[2].

(B) Transverse Waves:

(B1) Symmetrical two class case. For transverse waves propagating in the ⟨100⟩ direction and polarized in the ⟨010⟩ direction, four valleys are classified into (+) and (−)-classes, the deformation potentials of which are

$$U^{(\pm)}=\pm\tfrac{1}{3}\Xi_u u_{ij}\ , \tag{1.4}$$

respectively. This case was studied by Weinreich et al.[1] from a phenomenological point of view.

(B2) Simple case. For transverse waves propagating in the ⟨110⟩ direction and polarized in the ⟨$1\bar{1}0$⟩ direction, the deformation potentials of valleys are all equal to zero. Therefore, if we take the *suitably averaged* effective mass and intravalley relaxation time, the interaction is essentially identical with that in simple semiconductors. We shall study the characteristic features of many-valley semiconductors i.e. (A1) and (B1)-cases in this paper.

In § 2, the basic equations of the semiclassical approach are solved for these cases. The numerical estimations and the approximate expressions for physical quantities involved in the basic equations are tabulated in § 3. In § 4, we shall calculate the ultrasonic absorption and the acoustoelectric effect for various frequency ranges. Some physical discussions of the results obtained will be given in the last section.

§ 2. Basic Equations

We make the following assumptions throughout this paper.

(a) We consider only the case of one carrier. Then the recombination of electrons and holes is neglected.

(b) Following effects induced by acoustic waves are ignored; (b1) ionization of electrons from impurities and (b2) recombination of electrons with charged impurities.

(c) The anisotropy of the effective mass and the relaxation time in each valley is taken into account, by using the directionally averaged quantities of them.

(d) The relaxation time of the distribution of electrons in each valley, τ_0, is written as[4]

$$1/\tau_0=1/\tau_1+1/\tau'\ , \tag{2.1}$$

where τ_1 is the intravalley transition time and τ' the intervalley transition time. The velocity dependence of τ_1 and τ' are neglected.

(e) We classified the loss mechanism of the acoustic energy into two parts. One is due to the change of the deformation potential energy of electrons caused by the interclass transition. When the local fluctuation of the number density of electrons in (+) or (−)-class, $n^{(+)}$ or $n^{(-)}$, deviates from the local equilibrium fluctuation, $n_{eq}^{(+)}$ or $n_{eq}^{(-)}$, $n^{(\pm)}$ relaxes to $n_{eq}^{(\pm)}$ in the interclass relaxation time τ, being accompanied with the energy transfer from acoustic to lattice systems. The other is due to the change of the kinetic energy caused by the intravalley transition. When the distribution function f of electrons in each valley deviates from the local equilibrium distribution f_0, f relaxes to f_0 in the intravalley relaxation time τ_0, being accompanied with the kinetic energy transfer. Two loss mechanisms are assumed to be *independent* and then total losses are given by the sum of two terms.

(f) The local equilibrium fluctuations, $n_{eq}^{(+)}$ and $n_{eq}^{(-)}$, associated with net interclass relaxation are determined by two assumptions.

(f1) The ratio of $n_{eq}^{(+)}$ and $n_{eq}^{(-)}$ is determined by the Boltzmann factor of the difference of the deformation potentials between two classes. This assumption does not hold for a degenerate electron gas.

(f2) It is assumed that intervalley transition has no influence on the distribution of electrons in $\boldsymbol{r}$-space in the first approximation. Then the sum of $n_{eq}^{(+)}$ and $n_{eq}^{(-)}$ can be put nearly equal to $(n^{(+)}+n^{(-)})$. The assumptions (e) and (f2) may be verified from the fact that $\tau \gg \tau_0$.

Making use of these assumptions, we shall solve Maxwell's equation, the equation of continuity and the Boltzmann equation, for the self-consistent determinations of $n^{(\pm)}$ (local fluctuation of the number density of electrons), $\boldsymbol{E}$ (internal electric field) and $\boldsymbol{J}^{(\pm)}$ (internal current density). Maxwell's equation is written as

$$\frac{\partial}{\partial t}\left(\boldsymbol{J}-N_0e\boldsymbol{u}+\frac{\varepsilon}{4\pi}\cdot\frac{\partial \boldsymbol{E}}{\partial t}\right)=-\frac{c^2}{4\pi}\cdot \mathrm{curl\,curl}\,\boldsymbol{E}\,, \tag{2.2}$$

where N_0 is the number density of ionized impurities and equal to the density of electrons in equilibrium, ε the dielectric constant, c the light velocity, e the charge of an electron. Since the local velocity of ionized impurities varies as $\boldsymbol{u}\propto \exp[i(\omega t-\boldsymbol{qr})]$, we get from (2.2)

$$E_{\parallel}=\frac{i\omega_P{}^2m_{\parallel}}{\omega e}\left(\frac{J_{\parallel}{}^{(+)}+J_{\parallel}{}^{(-)}}{N_0e}-u_{\parallel}\right), \tag{2.3a}$$

$$E_{\perp}=-\frac{m_{\perp}k_0{}^2}{q^2e\tau_0}\left(\frac{J_{\perp}{}^{(+)}+J_{\perp}{}^{(-)}}{N_0e}-u_{\perp}\right), \tag{2.3b}$$

where the subscripts $\parallel$ and $\perp$ refer to components parallel and perpendicular to $\boldsymbol{q}$ taken in z-direction, respectively, and we put

$$\left.\begin{aligned}\omega_P{}^2&=4\pi N_0\, e^2/m_{\parallel}\varepsilon\,,\\ k_0{}^2&\equiv i4\pi N_0\, e^2\omega\tau_0/m_{\perp}c^2\,.\end{aligned}\right\} \tag{2.4}$$

In (2.3b) we neglect the displacement current.

The equation of continuity in each class is given by

$$\frac{\partial}{\partial t}[n^{(\pm)}e]+\frac{\partial J_{\parallel}{}^{(\pm)}}{\partial z}=R(\mp\to\pm)\,, \tag{2.5}$$

where $R(\mp\to\pm)$ means the rate of net interclass relaxation.[1] From the assumption (f), the local equilibrium fluctuation associated with the interclass transition is determined by

$$\left.\begin{aligned}&(N_0/2+n_{eq}^{(+)})/(N_0/2+n_{eq}^{(-)})=\exp[-(U^{(+)}-U^{(-)})/kT]\,,\\ &n_{eq}^{(+)}+n_{eq}^{(-)}=n^{(+)}+n^{(-)}\,,\end{aligned}\right\} \tag{2.6}$$

i.e.,

$$n_{eq}^{(\pm)}=\frac{n^{(+)}+n^{(-)}}{2}\pm\frac{N_0\Delta qu}{4kT\omega}, \tag{2.7}$$

where k is the Boltzmann constant, T the absolute temperature and we make use of the relations,

$$U^{(\pm)}\equiv C^{(\pm)}u_{ij}=-C^{(\pm)}qu/\omega, \qquad \Delta\equiv C^{(+)}-C^{(-)}.$$

In (2.7) and hereafter, u means $u_{\parallel}$ or $u_{\perp}$ according as it is concerned with longitudinal or transverse waves. Then

$$R(\mp\to\pm)=-\left(\frac{2e}{\tau_c}\right)\left[n^{(\pm)}-\frac{n^{(+)}+n^{(-)}}{2}\mp\frac{N_0\Delta qu}{4kT\omega}\right], \tag{2.8}$$

where it is taken into account that only *two* or *three* intervalley transitions belong to the interclass transition, i.e. the interclass transition time $\tau_c=3\tau'/2$. The factor 2 in a numerator in the right hand side of (2.8) is due to the fact that one interclass transition gives rise to a decrease of $(n^{(+)}-n^{(-)})$ by 2. Defining the interclass relaxation time as $\tau\equiv\tau_c/2$, we obtain from (2.5) and (2.8),

$$n^{(\pm)}=\frac{q}{2\omega e}(J_{\parallel}^{(+)}+J_{\parallel}^{(-)})\pm\frac{1}{(1+i\omega\tau)}\left[\frac{iq\tau}{2e}(J_{\parallel}^{(+)}-J_{\parallel}^{(-)})+\frac{N_0\Delta qu}{4kT\omega}\right]. \tag{2.9}$$

For the electrons in each valley, whose equilibrium concentration is $N\equiv N_0/4$, the Boltzmann equation is written as

$$\frac{\partial f}{\partial t}+(\boldsymbol{v}\cdot\nabla_r)f+\frac{e}{m}(\boldsymbol{E}'\cdot\nabla_v)f=-\frac{f-f_0(|\boldsymbol{v}-\boldsymbol{u}|)}{\tau_0}, \tag{2.10}$$

where

$$E_{\parallel}'\equiv E_{\parallel}-iCq^2u/\omega e, \qquad E_{\perp}'\equiv E_{\perp}. \tag{2.11}$$

The distribution function is solved as

$$\left.\begin{aligned}
&f=f_0(|\boldsymbol{v}-\boldsymbol{u}|)-\boldsymbol{\Psi}(\boldsymbol{v})\cdot\partial f_0/\partial v,\\
&f_0(\boldsymbol{v})=\exp\left[\tfrac{1}{2}m(v_1^2-v^2)/kT\right],\\
&v_1^2=\left(\frac{2kT}{m}\right)\ln\left\{2^{1/2}\pi^{3/2}\left(\frac{h^2}{mkT}\right)^{3/2}(N+n)\right\},
\end{aligned}\right\} \tag{2.12}$$

where

$$\left.\begin{aligned}
&\boldsymbol{\Psi}(\boldsymbol{v})=\frac{[(e\boldsymbol{E}'\tau_0/m)+\boldsymbol{u}](\boldsymbol{v}/v)+(nv_0^2/3Nv)}{1+i\omega\tau_0-iq\tau_0v_z}-\left(\frac{\boldsymbol{u}\boldsymbol{v}}{v}+\frac{nv_0^2}{3Nv}\right),\\
&v_0^2=3kT/m_{\parallel},
\end{aligned}\right\} \tag{2.13}$$

and h is the Planck constant. For longitudinal waves in (A1)-case, we get

$$\Psi(v)=\frac{aA}{ql}\cdot\frac{x}{1-iax}+\frac{aB}{ql}\cdot\frac{v_0}{v}\cdot\frac{1}{1-iax}-u_{\parallel}x-B\frac{v_0}{v}, \tag{2.14}$$

where we put for brevity

$$A\equiv\frac{eE_{\parallel}\tau_0}{m_{\parallel}}-i\frac{C\tau_0q^2u_{\parallel}}{m_{\parallel}\omega}+u_{\parallel}, \qquad B\equiv\frac{nv_0}{3N} \tag{2.15}$$

and

$$a\equiv ql/(1+i\omega\tau_0), \qquad l\equiv\tau_0v, \qquad x\equiv\cos\theta.$$

For transverse waves in (B1)-case,

$$\Psi(\boldsymbol{v})=\frac{aA_1}{ql}\cdot\frac{\sqrt{1-x^2}}{1-iax}\cos\phi-u_\perp\sqrt{1-x^2}\cos\phi$$
$$+\frac{aA_2}{ql}\cdot\frac{x}{1-iax}+\frac{aB}{ql}\cdot\frac{v_0}{v}\cdot\frac{1}{1-iax}-B\,\frac{v_0}{v}\,, \tag{2.16}$$

where

$$A_1\equiv\frac{eE_\perp\tau_0}{m_\perp}+u_\perp\,,\qquad A_2\equiv\frac{eE_\parallel\tau_0}{m_\parallel}-i\,\frac{C\tau_0q^2u_\perp}{m_\parallel\omega}\,. \tag{2.17}$$

The local current density is calculated from (2.14), (2.16) and the current expression,

$$\boldsymbol{J}=Ne\boldsymbol{u}-\frac{2em^3}{h^3}\int\boldsymbol{v}\Psi(\boldsymbol{v})\frac{\partial f_0}{\partial v}\,d^3v\,, \tag{2.18}$$

as follows;

$$J_\parallel=\frac{3Nep_0}{ql_0}\left(\frac{A}{a_0}+iB\right),\qquad J_\perp=0 \tag{2.19}$$

for longitudinal waves and

$$J_\parallel=\frac{3Nep_0}{ql_0}\left(\frac{A_2}{a_0}+iB\right),\qquad J_\perp=\frac{Nea_0g_0A_1}{ql_0} \tag{2.20}$$

for transverse waves. In (2.19) and (2.20), modified Pippard's functions[5] p_0 and g_0 are used, and their approximate expressions for various frequency ranges are given by

$$\left.\begin{aligned}p_0&\cong\frac{1}{3}(ql_0)^2-\frac{1}{3}(ql_0)^4 &&(ql_0\ll1)\,,\\ &\cong1-\left(\frac{3\pi}{2}\right)^{1/2}(ql_0)^{-1} &&(ql_0\gg1)\,,\\ &\cong1-3(\omega\tau_0/ql_0)^2 &&(\omega\tau_0\gg1)\end{aligned}\right\} \tag{2.21}$$

and

$$\left.\begin{aligned}g_0&\cong1-\frac{1}{3}(ql_0)^2 &&(ql_0\ll1)\,,\\ &\cong\left(\frac{3\pi}{2}\right)^{1/2}(ql_0)^{-1} &&(ql_0\gg1)\,,\\ &\cong3(\omega\tau_0/ql_0)^2 &&(\omega\tau_0\gg1)\,,\end{aligned}\right\} \tag{2.22}$$

where

$$l_0\equiv\tau_0v_0\,,\qquad a_0\equiv ql_0/(1+i\omega\tau_0)\,.$$

The self-consistent solutions for $n^{(\pm)}$, $\boldsymbol{E}$, $\boldsymbol{J}^{(\pm)}$ can be obtained from (2.3a), (2.3b), (2.9), (2.19) and (2.20). They are arranged as follows:

(A) Longitudinal Waves;

$$J_\parallel{}^{(\pm)}=\frac{N_0eu_\parallel}{2}(Q_1\mp Q_2)\,, \tag{2.23}$$

$$n^{(\pm)}=\frac{qN_0u_\parallel}{2\omega}\left(Q_1\pm\frac{\Delta}{2kT}G\right), \tag{2.24}$$

$$E_\parallel=\frac{i\omega_P{}^2m_\parallel u_\parallel}{\omega e}(Q_1-1)\,, \tag{2.25}$$

where we put for brevity as

$$\left.\begin{aligned} Q_1 &\equiv \frac{1+i\dfrac{\omega\tau_0}{(\omega_P\tau_0)^2}+\dfrac{1}{2}\cdot\dfrac{C^{(+)}+C^{(-)}}{m_{\|}v_0^2}\cdot\dfrac{(ql_0)^2}{(\omega_P\tau_0)^2}}{1+i\dfrac{ql_0a_0(\omega\tau_0)}{3(\omega_P\tau_0)^2p_0}\left(1-i\dfrac{p_0}{\omega\tau_0}\right)}\ , \\ Q_2 &\equiv i\frac{\Delta p_0}{2kT\omega}\{(1+i\omega\tau_0)-(1+i\omega\tau)^{-1}\}/\{\tau_0+p_0\tau(1+i\omega\tau)^{-1}\}\ , \\ G &\equiv \left\{\frac{1}{\tau}+\frac{p_0}{\tau_0}(1+i\omega\tau_0)\right\}\Big/\left\{\frac{1}{\tau}(1+i\omega\tau)+\frac{p_0}{\tau_0}\right\}\ . \end{aligned}\right\} \tag{2.26}$$

(B) Transverse Waves;

$$J_{\|}^{(\pm)}=\mp\frac{N_0eu_\perp}{2}Q_2\ , \tag{2.27}$$

$$n^{(\pm)}=\pm\frac{qN_0u_\perp}{2\omega}\cdot\frac{\Delta}{2kT}G\ , \tag{2.28}$$

$$E_{\|}=0 \tag{2.29}$$

and

$$J_\perp=2J_\perp^{(+)}=2J_\perp^{(-)}=N_0eu_\perp P\ , \tag{2.30}$$

$$E_\perp=\frac{m_\perp k_0^2u_\perp}{eq^2\tau_0}(1-P)\ , \tag{2.31}$$

where

$$P\equiv g_0'(q^2+k_0^2)/(q^2+g_0'k_0^2)\ , \qquad g_0'\equiv a_0g_0/ql_0\ . \tag{2.32}$$

In the limit of $\Delta\to0$, these basic equations are reduced to those in simple semiconductors.[2]

§ 3. Numerical Estimations

In this section, we take tentatively a sample of n-Ge for the numerical estimations of physical quantities involved in the basic equations. The values of physical parameters are taken as $\rho=5.4\ \mathrm{g\ cm^{-3}}$, $\mathcal{E}=16$, $m=0.1m_0$ (m_0: electronic mass), $V=5\times10^5\ \mathrm{cm\ sec^{-1}}$, $\Xi_d=-3.7$ ev, $\Xi_u=16$ ev, $\tau_0=5\times10^{-13}$ sec, $\tau=10^{-10}$ sec, $T=10^2$ °K, $N_0=10^{16}\ \mathrm{cm^{-3}}$. For later uses the approximate expressions of A and B will be given for various frequency ranges, the critical frequencies of which are given as follows:

$\omega_1=5\times10^{10}$ (the frequency at which $ql_0=1$) ,

$\omega_2=2\times10^{12}$ (the frequency at which $\omega\tau_0=1$) ,

$\omega_3=10^{10}$ (the frequency at which $\omega\tau=1$) ,

$\omega_4=2.6\times10^4$ (the frequency at which $q^2=|k_0^2|$) ,

$\omega_5=1.1\times10^{10}$ (the frequency at which $|C^{(+)}+C^{(-)}|/2=m_{\|}^*\omega_P^2/q^2$ for longitudinal waves) ,

$\omega_6=1.6\times10^{11}$ (the frequency at which $v_0^2=3\omega_P^2/q^2$) .

First we shall give the approximate expression of the function G in (2.26). If $ql_0\ll1$ and $\omega\tau\ll1$, we can put

$$G\cong(1+i\omega\tau_R)^{-1}\cong1-i\omega\tau_R\ , \tag{3.1}$$

where

$$1/\tau_R=1/\tau+p_0/\tau_0\cong 1/\tau+q^2D \tag{3.2}$$

and D is the diffusion constant[1]. If $ql_0\gg 1$, $\omega\tau\gg 1$ and $\omega\tau_0<1$, G becomes

$$G\cong\frac{ql_0}{a_0}\left(1-i\frac{\omega\tau_0}{p_0}\right). \tag{3.3}$$

Under the condition $\omega\tau_0\gg 1$, G approaches p_0.

For longitudinal waves, we consider three frequency ranges in which the approximate expressions for A and B are given as follows:

(1) $ql_0\ll 1$, $\omega\tau\ll 1$, $|C^{(+)}+C^{(-)}|/2\ll m_{\|}\omega_P^2/q^2$, $v_0^2\ll 3\omega_P^2/q^2$;

$$A^{(\pm)}\cong\frac{ql_0a_0}{3p_0}\left(1-i\frac{p_0}{\omega\tau_0}\right)u_{\|}\mp\frac{i}{3}\cdot\frac{(ql_0)^2}{\omega\tau_0}\cdot\frac{\Delta}{2kT}u_{\|}\,, \tag{3.4a}$$

$$B^{(\pm)}\cong\frac{1}{3}\cdot\frac{ql_0}{\omega\tau_0}u_{\|}\pm\frac{1}{3}\cdot\frac{ql_0}{\omega\tau_0}\cdot\frac{\Delta}{2kT}(1-i\omega\tau_R)u_{\|}\,. \tag{3.4b}$$

(2) $ql_0\gg 1$, $\omega\tau\gg 1$, $|C^{(+)}+C^{(-)}|/2\gg m_{\|}\omega_P^2/q^2$, $v_0^2\ll 3\omega_P^2/q^2$;

$$A^{(\pm)}\cong\mp\frac{i}{3}\,\frac{(ql_0)^2}{\omega\tau_0}\cdot\frac{\Delta}{2kT}u_{\|}+\frac{1}{3}\cdot\frac{C^{(+)}+C^{(-)}}{2kT}\cdot\frac{(ql_0)^3a_0}{3(\omega_P\tau_0)^2p_0}\left(1-i\frac{p_0}{\omega\tau_0}\right)u_{\|}\,, \tag{3.5a}$$

$$B^{(\pm)}\cong\pm\frac{1}{3}\cdot\frac{(ql_0)^2}{\omega\tau_0a_0}\cdot\frac{\Delta}{2kT}\left(1-i\frac{\omega\tau_0}{p_0}\right)u_{\|}+\frac{1}{3}\cdot\frac{C^{(+)}+C^{(-)}}{2kT}\cdot\frac{(ql_0)^3}{3(\omega_P\tau_0)^2(\omega\tau_0)}u_{\|}\,. \tag{3.5b}$$

(3) $ql_0\gg 1$, $\omega\tau\gg 1$, $|C^{(+)}+C^{(-)}|/2\gg m_{\|}\omega_P^2/q^2$, $v_0^2\gg 3\omega_P^2/q^2$;

$$A^{(\pm)}\cong-\frac{i}{3}\cdot\frac{C^{(\pm)}}{kT}\cdot\frac{(ql_0)^2}{\omega\tau_0}u_{\|}\,, \tag{3.6a}$$

$$B^{(\pm)}\cong\frac{1}{3}\cdot\frac{(ql_0)^2}{\omega\tau_0a_0}\cdot\frac{C^{(\pm)}}{kT}\left(1-i\frac{\omega\tau_0}{p_0}\right)u_{\|}\,. \tag{3.6b}$$

The expressions of A_2 and B in transverse waves are given in two frequency ranges:

(1) $ql_0\ll 1$, $\omega\tau\ll 1$;

$$A_2^{(\pm)}\cong-\frac{i}{3}\cdot\frac{\Delta}{2kT}\cdot\frac{(ql_0)^2}{\omega\tau_0}u_{\perp}\,, \tag{3.7a}$$

$$B^{(\pm)}\cong\pm\frac{1}{3}\cdot\frac{ql_0}{\omega\tau_0}\cdot\frac{\Delta}{2kT}(1-i\omega\tau_R)u_{\perp}\,. \tag{3.7b}$$

(2) $ql_0\gg 1$, $\omega\tau\gg 1$;

$$A_2^{(\pm)}\cong-\frac{i}{3}\cdot\frac{C^{(\pm)}}{kT}\cdot\frac{(ql_0)^2}{\omega\tau_0}u_{\perp}\,, \tag{3.8a}$$

$$B^{(\pm)}\cong\frac{1}{3}\cdot\frac{(ql_0)^2}{\omega\tau_0a_0}\cdot\frac{C^{(\pm)}}{kT}\left(1-i\frac{\omega\tau_0}{p_0}\right)u_{\perp}\,. \tag{3.8b}$$

Finally we can put

$$A_1^{(\pm)}\cong u_{\perp}/g_0' \tag{3.9}$$

for $q^2\ll|k_0^2|$ and

$$A_1^{(\pm)}\cong u_{\perp} \tag{3.10}$$

for $q^2 \gg |k_0^2|$.

In the next section, we shall calculate the ultrasonic absorption and the acoustoelectric effect using these approximate expressions for A and B.

§ 4. Ultrasonic Absorption and Acoustoelectric Effect

As has been mentioned previously in § 2, the absorption coefficient by conduction electrons is given by the sum of two terms, one due to the change of the kinetic energy and the other due to the change of the deformation potential energy of electrons. The coefficient Λ_P due to the deformation potential can be calculated as follows. When the local fluctuation $n^{(\pm)}$ deviates from $n_{eq}^{(\pm)}$, the potential energy $(U^{(\pm)}-U^{(\mp)})$ is transferred to lattice system in the interclass transition time τ_c owing to one transition. Therefore, the energy absorbed per unit volume and unit time $W_{P^{(\pm)}}$ becomes

$$W_{P^{(\pm)}}=\frac{1}{2}\,\mathrm{Re}\left[\left(\frac{U^{(\pm)}-U^{(\mp)}}{2\tau}\right)^*(n^{(\pm)}-n_{eq}^{(\pm)})\right]. \tag{4.1}$$

Then,

$$\begin{aligned}\Lambda_P&=2(W_{P^{(+)}}+W_{P^{(-)}})/\rho|u|^2V\\&=\frac{N_0\Delta^2}{4\rho V^3kT\tau}\cdot\mathrm{Re}\,(H+I)\,,\end{aligned} \tag{4.2}$$

where we put

$$H=\left(\frac{p_0}{\tau_0}\right)\cdot\frac{(1+i\omega\tau)^{-1}-(1+i\omega\tau_0)}{(1+i\omega\tau)/\tau+p_0/\tau_0}\,, \tag{4-3}$$

$$I=i\omega\tau/(1+i\omega\tau)\,. \tag{4.4}$$

The formula (4.2) can be applied to both longitudinal and transverse waves.

The coefficient Λ_K due to the kinetic energy can be calculated by a similar formula for monovalent metals[6] and simple semiconductors[2];

$$\Lambda_K=\Lambda_{K^{(+)}}+\Lambda_{K^{(-)}}\,, \tag{4.5a}$$

$$\Lambda_{K^{(\pm)}}=-\frac{2m^4}{\rho|u|^2V\tau_0h^3}\int_0^\infty\frac{\partial f_0}{\partial v}\,v^3\,dv\int_{-1}^1dx\int_0^{2\pi}d\phi|\Psi^{(\pm)}(\boldsymbol{v})|^2\,. \tag{4.5b}$$

Total losses are given by $\Lambda=\Lambda_P+\Lambda_K$.

The acoustoelectric effect can be defined as the average dc force exerted by acoustic waves on an electron[1]. Effective forces responsible for the effect have two components, one associated with the intravalley transition in each valley and the other associated with the interclass transition. Owing to the interclass transition, the acoustic energy density suffers an energy loss $(U^{(\pm)}-U^{(\mp)})$ from each of $(n^{(\pm)}-n_{eq}^{(\pm)})$ electrons in a distance $V\tau_c$. This means that each electron exerts an effective force $-(U^{(\pm)}-U^{(\mp)})/V\tau_c$ on acoustic vibrations. From the principle of reaction, each electron is exerted the effective force

$$X^{(\pm)}=\{U^{(\pm)}-U^{(\mp)}\}/2V\tau \tag{4.6}$$

by acoustic waves. As has been shown in the previous papers,[2],[6] the acoustic energy density suffers also an energy loss $mv\Psi^{(\pm)}(v)$ from an electron with the velocity $\boldsymbol{v}$ in a distance $V\tau_0$. Then in a similar way to (4.6), the effective force associated with the intravalley transition is given by

$$Y^{(\pm)}(\boldsymbol{v})=mv\Psi^{(\pm)}(\boldsymbol{v})/V\tau_0\,. \tag{4.7}$$

Thus, the acousto-electromotive force can be written as

$$F=\frac{1}{2N_0e}\,\mathrm{Re}\Big[X^{(+)*}(n^{(+)}-n_{eq}^{(+)})+X^{(-)*}(n^{(-)}-n_{eq}^{(-)})$$
$$+\sum_{\boldsymbol{v}} Y^{(+)*}(\boldsymbol{v})\Big\{-\Psi^{(+)}(\boldsymbol{v})\frac{\partial f_0}{\partial v}\Big\}+\sum_{\boldsymbol{v}} Y^{(-)*}(\boldsymbol{v})\Big\{-\Psi^{(-)}(\boldsymbol{v})\frac{\partial f_0}{\partial v}\Big\}\Big], \tag{4.8}$$

which satisfies a well-known relation

$$F=\Lambda\gamma/N_0eV \tag{4.9}$$

($\gamma\equiv\rho|u|^2V/2$: acoustic energy flow density). In the same manner as Λ, we can write $F=F_P+F_K$.

First we calculate Λ_P and F_P from (4.2), (4.3), (4.4) and (4.8). The formulae for various frequency ranges are tabulated as follows:

(a) $ql_0\ll1,\ \omega\tau\ll1,\ \omega\tau_0\ll1$;

$$\Lambda_P\cong\frac{N_0\Delta^2}{4\rho V^3kT}\cdot\omega^2\tau\Big(1-\frac{2}{3}q^2v_0^2\tau\tau_0\Big), \tag{4.10a}$$

$$F_P\cong\frac{\Delta^2\gamma}{4\rho eV^4kT}\cdot\omega^2\tau\Big(1-\frac{2}{3}q^2v_0^2\tau\tau_0\Big). \tag{4.10b}$$

(b) $ql_0\gg1,\ \omega\tau\gg1,\ \omega\tau_0<1$;

$$\Lambda_P\cong\frac{N_0\Delta^2}{4\rho V^3kT}\Big(\frac{3\pi}{2}\Big)^{1/2}\Big(\frac{V\tau_0}{v_0\tau}\Big)\omega, \tag{4.11a}$$

$$F_P\cong\frac{\Delta^2\gamma}{4\rho eV^4kT}\Big(\frac{3\pi}{2}\Big)^{1/2}\Big(\frac{V\tau_0}{v_0\tau}\Big)\omega. \tag{4.11b}$$

(c) $ql_0\gg1,\ \omega\tau\gg1,\ \omega\tau_0\gg1$;

$$\Lambda_P\to\frac{3N_0\Delta^2}{4\rho V^3kT\tau}\Big(\frac{V}{v_0}\Big)^2, \tag{4.12a}$$

$$F_P\to\frac{3\Delta^2\gamma}{4\rho eV^4kT\tau}\Big(\frac{V}{v_0}\Big)^2, \tag{4.12b}$$

which hold for both longitudinal and transverse waves. We can see that the interclass transition rapidly decreases as the frequency of waves exceeds $1/\tau$.

The formulae for Λ_K and F_K in longitudinal waves are calculated from (4.5), (4.8), (2.14), (3.4)–(3.6) as follows:

(1) $ql_0\ll1,\ \omega\tau\ll1,\ |C^{(+)}+C^{(-)}|/2\ll m_{\parallel}\omega_P^2/q^2,\ v_0^2\ll3\omega_P^2/q^2$;

$$\Lambda_K=\frac{N_0\Delta^2\omega^2\tau_0}{4\rho V^3kT}\Big(1+\frac{1}{3}q^2v_0^2\tau_R^2\Big), \tag{4.13a}$$

$$F_K=\frac{\Delta^2\gamma\omega^2\tau_0}{4\rho eV^4kT}\Big(1+\frac{1}{3}q^2v_0^2\tau_R^2\Big). \tag{4.13b}$$

(2) $ql_0\gg1,\ \omega\tau\gg1,\ \Delta/2kT\gg|C^{(+)}+C^{(-)}|q^2/2m_{\parallel}\omega_P^2\gg1,\ v_0^2\ll3\omega_P^2/q^2$;

$$\Lambda_K=\frac{N_0\Delta^2\omega}{4\rho V^3kT}\Big(\frac{3\pi}{2}\Big)^{1/2}\Big(\frac{V}{v_0}\Big), \tag{4.14a}$$

$$F_K=\frac{\Delta^2\gamma\omega}{4\rho eV^4kT}\Big(\frac{3\pi}{2}\Big)^{1/2}\Big(\frac{V}{v_0}\Big). \tag{4.14b}$$

(3) $ql_0 \gg 1,\ \omega\tau \gg 1,\ |C^{(+)}+C^{(-)}|q^2/2m_{\parallel}\omega_P{}^2 \gg \Delta/2kT,\ v_0{}^2 \ll 3\omega_P{}^2/q^2$;

$$\Lambda_K = \frac{1}{3}\left(\frac{3\pi}{2}\right)^{1/2}\left(\frac{C^{(+)}+C^{(-)}}{2}\cdot\frac{q^2}{m_{\parallel}\omega_P{}^2}\right)^2\cdot\frac{N_0 m_{\parallel} v_0\omega}{\rho V^2}, \tag{4.15a}$$

$$F_K = \frac{1}{3}\left(\frac{3\pi}{2}\right)^{1/2}\left(\frac{C^{(+)}+C^{(-)}}{2}\cdot\frac{q^2}{m_{\parallel}\omega_P{}^2}\right)^2\cdot\frac{m_{\parallel} v_0\omega\gamma}{\rho e V^3}. \tag{4.15b}$$

(4) $ql_0 \gg 1,\ \omega\tau \gg 1,\ v_0{}^2 \gg 3\omega_P{}^2/q^2$;

$$\Lambda_K = \left(\frac{3\pi}{2}\right)^{1/2}\left\{\frac{|C^{(+)}|^2+|C^{(-)}|^2}{2}\right\}\frac{N_0\omega}{\rho V^2 kTv_0}, \tag{4.16a}$$

$$F_K = \left(\frac{3\pi}{2}\right)^{1/2}\left\{\frac{|C^{(+)}|^2+|C^{(-)}|^2}{2}\right\}\frac{\omega\gamma}{\rho e V^3 kTv_0}. \tag{4.16b}$$

It should be remarked that in the low frequency range a term due to the electronic viscosity,

$$\Lambda_{K,vis} \cong \frac{2N_0kT\omega^2\tau_0}{\rho V^3} \tag{4.17a}$$

or

$$F_{K,vis} \cong \frac{2kT\omega^2\tau_0\gamma}{\rho e V^4} \tag{4.17b}$$

must be added to (4.13). But this term can be neglected in comparison with the main term in (4.13).

The formulae for Λ_K and F_K in transverse waves are calculated from (4.5), (4.8), (2.16), (3.7) and (3.8). As is easily seen, Λ_K or F_K can be divided into two independent terms, one associated with $J_{\parallel}$ and the other associated with $J_{\perp}$; i.e.

$$\left.\begin{aligned}\Lambda_K &= \Lambda_{K\parallel}+\Lambda_{K\perp},\\ F_K &= F_{K\parallel}+F_{K\perp}.\end{aligned}\right\} \tag{4.18}$$

The formula for each term in (4.18) are calculated as follows:

(A) $\Lambda_{K\parallel}$ and $F_{K\parallel}$.

(1) $ql_0 \ll 1,\ \omega\tau \ll 1$;

$$\Lambda_{K\parallel} \cong \frac{N_0\Delta^2\omega^2\tau_0}{4\rho V^3 kT}\left(1+\frac{1}{3}q^2v_0{}^2\tau_R{}^2\right), \tag{4.19a}$$

$$F_{K\parallel} \cong \frac{\Delta^2\gamma\omega^2\tau_0}{4\rho e V^4 kT}\left(1+\frac{1}{3}q^2v_0{}^2\tau_R{}^2\right). \tag{4.19b}$$

(2) $ql_0 \gg 1,\ \omega\tau \gg 1$;

$$\Lambda_{K\parallel} \cong \left(\frac{3\pi}{2}\right)^{1/2}\frac{C^2N_0\omega}{\rho V^2 kTv_0}, \tag{4.20a}$$

$$F_{K\parallel} \cong \left(\frac{3\pi}{2}\right)^{1/2}\frac{C^2\omega\gamma}{\rho e V^3 kTv_0}, \tag{4.20b}$$

where $|C| \equiv |C^{(+)}| = |C^{(-)}|$.

(B) $\Lambda_{K\perp}$ and $F_{K\perp}$.

(1) $ql_0 \ll 1,\ q^2 \lesssim |k_0{}^2|$;

$$\Lambda_{K\perp} \cong \frac{N_0kT\omega^2\tau_0}{\rho V^3}, \tag{4.21a}$$

$$F_{K\perp} \cong \frac{kT\omega^2\tau_0\gamma}{\rho e V^4}. \tag{4.21b}$$

(2) $ql_0 \gg 1,\ q^2 \gg |k_0{}^2|$;

$$\Lambda_{K\perp} \to N_0 m_{\perp}/\rho V\tau_0, \tag{4.22a}$$

$$F_{K\perp} \to m_{\perp}\gamma/\rho e V^2\tau_0. \tag{4.22b}$$

The results obtained in this section will be discussed in the next section.

§ 5. Discussions

(A) Low frequency range ($ql_0 \ll 1,\ \omega\tau \ll 1$).

The terms due to the electronic viscosity, (4.17) for longitudinal and (4.21) for transverse waves, can be neglected in general. Because of the fact,

$$\Lambda_P/\Lambda_K = F_P/F_K \cong \tau/\tau_0 \tag{5.1}$$

from (4.10), (4.13) and (4.19), the terms due to the change of the deformation potential energy predominate in the low frequency range. The complete formulae can be rewritten as

$$\Lambda \cong \frac{N_0\Delta^2}{4\rho V^3 kT}\cdot\omega^2(\tau_R+\tau_0), \tag{5.2a}$$

$$F \cong \frac{\Delta^2\gamma}{4\rho e V^4 kT}\cdot\omega^2(\tau_R+\tau_0), \tag{5.2b}$$

using the definition of τ_R in (3.2). This formula, (5.2b), is nearly identical with Weinreich-Sanders-White's[1)],

$$F = \frac{\Delta^2\gamma}{4\rho e V^4 kT}\cdot\frac{\omega^2\tau_R}{1+(\omega\tau_R)^2}, \tag{5.3}$$

which is in good agreement with the experiment by transverse waves in the low frequency range.

(B) High frequency range ($ql_0 \gg 1$, $\omega\tau \gg 1$).

From (4.11), (4.14) or (4.16) and (4.20), we get

$$A_P/A_K = F_P/F_K \simeq \tau_0/\tau \tag{5.4}$$

i.e., the terms due to the change of the kinetic energy predominate in the high frequency range. As the frequency increases, A and F do not decrease, in contrast to Weinreich-Sanders-White's formula, owing to the increase of A_K and F_K. In the sufficiently high frequency range, we can see that each valley has *independent contributions* to A and F by the amount of the same order as that of longitudinal waves in simple semiconductors[2] (see (4.16) and (4.20)). The experimental check of our theory may be expected in future.

The author should express his thanks to M. Shibuya and W. Sasaki for the valuable discussions.

Filamentary Crystals grown from the Solid Metal

By George SINES

University of California, Los Angeles 24, California, U.S.A.

(Received February 13, 1960)

A theoretical analysis and experimental evidence show that a source of energy for spontaneous whisker growth is the elastic strain energy arising from the anisotropy of thermal expansion. Observation of whisker growth on a Bragg bubble raft suggests that the growth mechanism could be by cooperative repetitive movement of dislocations. The conditions for whisker growth from the solid are presented and by fulfilling them growths were produced on gold, silver, bismuth, lead, indium, and lead-indium alloys. The crystallographic orientations of a number of tin whiskers are reported, one of which had a transition between two orientations although it was straight. The tensile strengths of several tin whiskers were measured and observed to be lower than calculated from bending tests. The high elastic strain of 5% in bending was observed for an indium one.

§ 1. Introduction

Although filamentary crystals have been recognized as an interesting phenomenon for over a hundred years,[1] it is only recently that appreciable attention has been focused on them by chance observations of new forms.[2],[3] Also, only recently has the knowledge of crystal imperfections become sufficient to propose possible mechanisms for their growth.

Filamentary crystals, commonly called whiskers, are characterized by (1) their high ratio of length to thickness, (2) the presence of some with straight sections, (3) constancy in cross-section over considerable portions of their length, (4) many them being single crystals, (5) straight sections which have major crystallographic directions as their axes, (6) their thickness which is usually within the range of 0.01 to 10 microns, (7) and that some are hundreds of times stronger than the metal from which they grew.[4–7,20]

Some of the processes by which filamentary crystals have been grown are the controlled supersaturation of vapor over a suitable surface,[8–10] the reduction of metal halides on a suitable substrate,[5,11,12] the chemical reaction on a solid,[13,14] the precipitation from a solution,[15–17,20] the heating of metals,[18,19] and a spontaneous action on solid metal.[21] This paper is concerned with the properties and conditions for growth of filamentary crystals of the last process. Filamentary crystals grown by several different processes are unusually strong,[4–7,20] but it was crystals of this type that were first shown by Herring and Galt[4] to have unusual strength: they bent tin ones to cause an elastic strain of 2 or 3% at the outer fiber.

Two recent papers review the various types of filamentary growths.[22,23]

§ 2. Sources of Energy for Growth

Several sources of energy for the creation of the free surface of the filament which grows spontaneously from the solid should be considered:

(1) The surface may oxidize to a depth sufficient to make the net surface free energy negative has been proposed by Frank[24]. Thus an initial microscopic protrusion would tend to grow in order to expose more surface for oxidation.

(2) If the filament is free, or almost free, of dislocations and if the bulk material is filled with dislocations, the energy of distortion of the crystal lattice by the dislocations becomes available as the whisker grows. However, a mechanism for unsnarling the many interlocked dislocations to release their energy is difficult to imagine.

(3) The author suggests that a probable source of energy is the release of elastic strain energy on a scale more gross than that of the crystal imperfections, such as dislocations. The energy could be from micro-residual stresses or from externally applied forces. All of the metals which have been shown to grow whiskers spontaneously from the solid, i.e. tin, cadmium, zinc,[21] and antimony[25] have a common characteristic: They all have a high degree of anisotropy in their coefficients of thermal expansion as is shown in Table I. Such great anisotropy of thermal expansion causes residual stresses in a polycrystalline medium if the temperature is changed from that at which it solidified or was deposited.

Table I. (Ref. 26)

Metal	Temperature	Coefficients of thermal expansion ($\times 10^{-6}$/°C	
		parallel to principal axis	perpendicular to
zinc	20–100°C	63.9	14.1
cadmium	20	52.6	21.4
beta tin	20	30.5	15.5
antimony	20	15.6	8.0

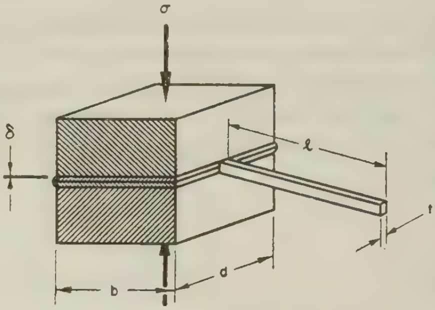

Fig. 1. Compression-induced growth of filaments from between plated blocks.

The following analysis shows that a moderate stress can provide sufficient energy for a whisker to grow. Figure 1 shows a whisker growing out from the edge of the plating between two plated blocks which are being compressed by a stress σ. The length of the whisker is l and it has a square cross-section t thick. As the plating metal moves out from between the blocks to form the whisker, the separation between the backing surfaces will decrease by an amount δ. Assuming the plating decreases uniformly in thickness over the region under consideration which is b wide by d long, the volume of the metal extruded is $bd\,\delta$. The volume of the metal extruded must equal the volume of the whisker

$$bd\,\delta = lt^2 \qquad \text{so} \qquad \delta = lt^2/bd\,. \tag{1}$$

For the free surface which is created, $4tlS$ units of energy must be provided, where S is the surface energy per unit area. The work done by the stress in moving through the distance σ is $\sigma\, bd\,\delta$. This provides the energy for the surface. An additional source f energy is the elastic energy which the vhisker material had while it was under tress between the plates.

$$\sigma\, bd\,\delta+\frac{\sigma^2}{2E}lt^2=4tlS\,. \qquad (2)$$

The term $(\sigma^2/2E)lt^2$ is much smaller than $bd\,\delta$ and can be neglected. Inserting δ from Eq. (1)

$$\sigma=4S/t\,. \qquad (3)$$

Assuming a common value for the surface energy of a metal of 10^3 ergs/cm² and a whisker of a thickness of 10^{-4} cm, $\sigma=4\times10^7$ dynes/cm² or about 600 psi. This shows that he relief of a very moderate stress can provide the surface energy needed.

The applied stress σ could be caused by external forces or it could be a residual stress caused by interaction with adjacent grains. Consider a metal oriented so that its direction of maximum coefficient of thermal expansion s parallel to the minimum of the adjacent grains. For a change of temperature ΔT, his would cause a stress of approximately

$$\sigma=\Delta T(\alpha_{\max}-\alpha_{\min})E$$

where E is the modulus of elasticity. A change in temperature of only 10°C would cause a stress in tin of $10(1.5\times10^{-4})7\times10^6=1000$ psi. For this order of magnitude calculation, an average value of E was used.

The above calculation demonstrates that he energy can be easily supplied by residual tresses arising from the anisotropy of the he coefficient of thermal expansion in a polycrystalline sample. Further evidence that oxidation may not be essential to the growth f filamentary crystals from the solid has been found at Bell Laboratories,[25] where they grew tin whiskers in a highly gettered vacuum of better than 10^{-8} mm of oxygen. A ough calculation shows that there was not nough oxygen to form a monomolecular layer on a one micron-size whisker a millimeter long, thus, it is likely that the source f energy was from the release of residual tresses.

A demonstration that a source of energy or whisker growth exists other than that of oxidation would be to grow them on a metal hat does not oxidize. In Experiment E9-1, See Sec. F) gold whiskers grew under an externally applied compressive stress from old plated on stainless steel. These whiskers were thin and straight as can be seen in Fig. 2. Gold does not oxidize although it may have an adsorbed monomolecular layer of oxygen. Even with an adsorbed layer, the net surface free energy is not negative. In Exp. E9-2, whiskers also grew from silver in pressure clamps at 400°C, which is above the temperature for dissociation of silver oxide.

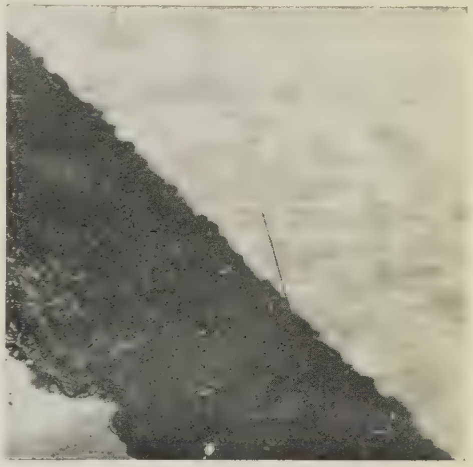

Fig. 2. Compression-induced gold filamentary crystals. Magnification: ×450 with ×1/2 in reproduction. See Summary of Experiments, Exp. E9-1.

Some metals which readily oxidize, lead, indium,[21),25)] and lead-indium alloys have not been observed to grow whiskers spontaneously,* but grew them when placed in pressure clamps. (Exp. E10-1, E10-2, and E10-3)

A compressive stress applied to the plated surfaces as shown in Fig. 1 greatly accelerates the rate of growth of whiskers on metals on which they also grow spontaneously. This was shown by Fisher, Darken, and Carroll[27)] for tin. Appreciable crops of whiskers grew within a day instead of the weeks or months required for spontaneous growth. Exp. E11-1 and E11-2 show that the growth of whiskers can also be accelerated on zinc and cadmium plate.

This acceleration of growth by the compressive stress has been explained as the effect of the stress gradient in accelerating the diffusion of the metal in the bulk to the base of the whisker.[27),28)] An additional effect which could hasten the growth is the reduction of the activation energy of the atom when it moves from the bulk into the whisker. Although it has been shown here that a moderate stress can provide sufficient energy for the formation of the free surface, it says nothing about the rate at which growth proceeds. Both oxidation and stress could reduce the height of the activation barrier which the atom must cross to become part of the whisker.

---

* Whiskers grew on bismuth under pressure, Exp. E10-4, but no reports of long-term observations for spontaneous growth are published. It is likely that spontaneous growth would occur at room temperature because its diffusivity and anisotropy of thermal expansion is comparable to those of the metals which do.

An additional cooperative action could occur with stress and oxidation. A whisker could start by the release of elastic strain energy, thereby creating the surface geometry required by Frank's[24)] analysis and then proceed to grow from energy of oxidation. This could partially explain the transition from a high initial growth rate to the much slower final growth rate observed by Fisher et al.[27)]

Fig. 3. The extrusion of a "filamentary crystal" with a Bragg bubble model. Fig. 3a shows the bubbles being forced between two square-cornered barriers in the upper left and upper right corners by a pusher out of view at the bottom. Often the movement shown in Fig. 3b occurs: A dislocation is created at the left corner and moves to the apex position (2) where it aids in the formation of another dislocation which moves off to the right (3), and then the remaining dislocation moves up to the right (4), thereby depositing another row of atoms to the base of the filament. Then the procedure repeats from left to right as in a mirror image to add the next row. Readjustments occur in the parent crystal by additional movements of dislocations to its boundaries. Fig. 3c illustrates an alternate action which is often observed. A dislocation moves from the crystal boundary (3) to join the one already at the apex (2), combines with it and then the resultant moves up and to the right (4) as before. Several other repetitive processes also have been observed. In the photograph of the bubble model, Fig. 3a, a dislocation is at position 2 and another at position 4 as identified in both Figs. 3b and 3c

dislocations have been advanced by Frank[24] and by Eshelby[29], respectively, as mechanisms by which atoms could move from the bulk into the regular crystalline structure of the filament. This is compatible with the observation of Arnold[30] that growth occurs from the base. It may be possible that a cooperative movement of dislocations exists which would result in their growth but with less dislocation climb. In Fig. 3 a two dimensional cooperative movement of dislocations is shown to result in the deposition of an additional layer of bubbles to the “filamentary crystal”. It should be possible to conceive repetitive, three-dimensional cooperative movements of dislocations which could add layer after layer to a filament.

Filaments have been known to grow on metals having only one or only a few planes of easy slip: tin is tetragonal, and cadmium and zinc are hexagonal; therefore, it incorrectly might be supposed that growth can occur only on metals having a few slip systems. However, Exp. E9–1 and E10–1 show that gold and lead, which are face-centered cubic metals having many slip systems, grow whiskers.

For those metals which grow whiskers spontaneously at room temperature, Zn, Cd, Sn, and Sb, the room temperature was be-

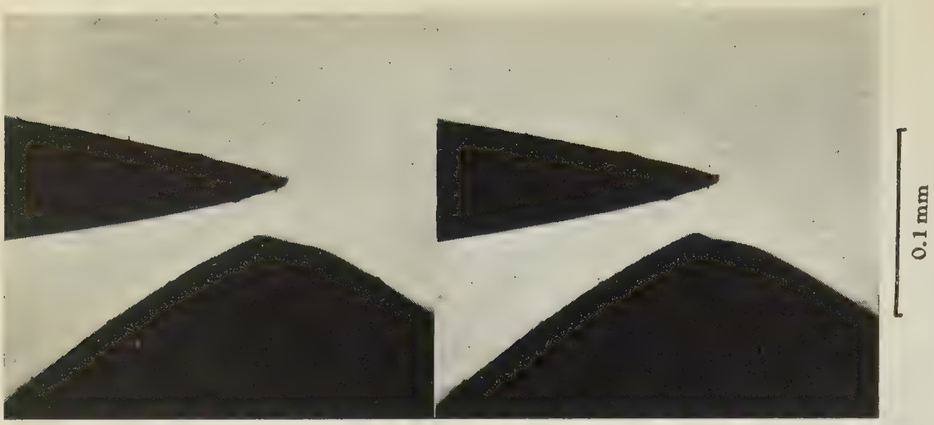

Fig. 7 (a). An indium whisker of 0.8μ diameter elastically bent to a radius of curvature of 8μ. See the Summary of Experiments, Exp. S-3b. (b) The indium whisker after failing by sudden plastic deformation at two localized places.

tween 0.4 and 0.6 of their melting temperatures expressed in degrees absolute. Metals on which compression-induced growth occurred, indium, lead, lead-indium alloys, and bismuth, are in this same range except for indium which is even nearer to its melting point at room temperature. A rough direct correlation can be made between the melting points and the activation energies for both the rates of diffusion and of creep for metals, the interrelated phenomena which cause mass transport in solids. Thus, to get sufficient mass transport in metals having higher melting temperatures, silver and gold, it was necessary to use elevated temperatures to obtain compression-induced growth. (Exp. E9-1, E9-2)

In compression-induced growth, some consideration has been given to the effect of the pressure gradient in aiding the transport of metal to the base.27),28) The applied compression, probably greatly intensified by the stress concentration of the contacting surface disparities of the plate, is reduced to zero on the free filament. The theory of plasticity shows that the change in stress occurs in a distance roughly equal to the thickness of the plate. The effect of this severe pressure gradient in compression-induced growth is necessary in order to explain the unusual rapidity of mass transport. A crude analysis of soft plating being squeezed between steel plates shows that the gradient is inversely proportional to the thickness of the plating. If the growth rate is limited by the rate of mass transport under a pressure gradient, the thicker layers of plating would grow whiskers more slowly. (also gross extrusion of the plating occurs when it is thick.) In the experiments by the author, it was generally observed that thin plating does grow filaments faster but that there is a limit to the thinness of the plating on which abundant growth occurs. Reasons for this limit may be (1) the thickness of the plating tends to limit the thickness of the filament and the dislocation mechanism may have to be a certain critical size to operate, (2) the supply of metal available for the growth is more limited and also (3) the ratio of surface energy needed, to the elastic energy released, is less for thin whiskers. (however, if oxidation is the source of energy, one would expect thinner filaments to grow more rapidly because they expose more surface to oxidation) Many observations by the author indicated that when the plating is thinner than 0.00005″ few whiskers grew.

In Exp. E10-3, compression-induced whiskers grew on 64%Pb-36%In and 84%In-16%Pb alloys. (weight) Growths on alloys have also been obtained by Baker13) on 95%Sn-5%Sb, 95%Sn-5%Pb, 95%Sn-5%Zn, and 90%-Sn-10%Zn. All of his alloys have very little solid solubility at room temperature, except antimony which has about 3%. Whiskers failed to grow on terne plate, 25%Sn-75%Pb, by compression-induction in Exp. E11-4. These results indicate that when the extent of two phases are of the same magnitude that filaments may not grow, that when the primary constituent is continuous they do, and that alloy whiskers can grow from solid solutions.

An essential feature of the growth of a filamentary crystal from the solid is the mechanism of mass transport to its root. Growths on alloys may reveal something of the mechanism because, if simple diffusion is the means of transport, enrichment of one of the species of the alloy would be expected in the filament because there is usually a large difference in the rate of diffusion of the species. In Exp. E10–3 on 84%In–16%Pb alloy, the whisker examined had the same composition as the parent metal. This indicates that the transport mechanism may not be simple diffusion but by some mechanism more akin to creep in that the transport of metal may be by the movement of dislocations throughout the bulk of the metal which would cause little or no enrichment.

Several metals were cast as single crystals, bi-crystals, and large-grained poly-crystals and then were set aside to see if they would spontaneously grow whiskers. According to the analysis on the effect of micro-residual stress, none would be expected to grow on the single crystals but should on the others. Exp. P–1 showed that only a few grew and that one of the few groups, three whiskers, occurred on a small sliver crystal in a specimen which consisted of a very large crystal of tin and that the whiskers grew near to their interface. Also there was evidence that the sample had been plastically deformed in handling. While these tests are not conclusive for the original purpose, they do reveal an unusual sparseness of growth. This may indicate that the dislocations which form during solidification may not be adequate to provide a proper array of dislocations for the growth mechanism and thus plastic deformation may be a pre-requisite to abundant growth. Growth on a sample consisting of a few grains might be expected to occur near a grain boundary because the larger thermal stresses and the greater diffusivity there would supply energy for the growth and aid the transport of metal to the root.

§ 4. The Structure of Filamentary Crystals

X-ray studies on whiskers grown from the solid metal have shown that a major crystallographic direction is along the fiber axis: Zinc and cadmium ones have their hexagonal *c*-axes in the fiber direction.[25)] Tin has been observed to have the [001] and [111] directions along the axis; the author in Exp. 0–1 found these two orientations and also the [101] and [100] directions, and for a Pb–In alloy [111] (Exp. E10–3c).

It has been postulated by Levy[31)] and by Baker[18)] and reasonably substantiated that the "kink" angles between straight segments of whiskers can be correlated with their probable crystallographic axes. However, Fig. 4, presents a tin whisker which showed no discontinuity of surface texture, cross-section, or direction, although it showed both the [101] and [001] orientations on the X-ray film. More careful study showed that the base had the [101] and the tip the [001] orientation. Only when viewed under polarized light could the transition be detected by the colors. This may be a rather common occurrence because the tin whiskers shown in Fig. 5 show many discontinuities in color when viewed under polarized light at places where no physical discontinuity can be observed. This does not contradict the observations of Levy and of Baker for if a change in direction occurs the angle may be related to the orientations of the adjacent segments.

Three whiskers out of six when subjected to a lateral compression split longitudinally as a reed might when stepped upon. This was interpreted to indicate that the whiskers were either hollow or had some type of a longitudinal imperfection. Later direct examination of cross-sections showed that some were indeed hollow.[32),33)]

The structure of the curled and twisted crystals must be very interesting but no one has studied it. Although not common, a uniform helical whisker as shown in Fig. 6 is sometimes observed.

§ 5. Strength of Filamentary Crystals grown from the Solid

It was noticed that among the whiskers grown from the many metals, that many of each metal had strengths comparable to those measured previously for tin[4)] (except silver for which the growth was too sparse for a determination). More quantitative bend tests on lead, an indium-lead alloy, indium, and tin are presented in Exp. S–1, S–2, S–3, and S–4.

One indium whiskers was very strong: Fig. 7 shows it bent to a strain of 5% in the outer fibers. This is within the range predicted for the theoretical strength for metals by Orowan[34] who states that it seems reasonable for the theoretical shear strength to be between 1/10 and 1/50 of the shear modulus, which corresponds to elastic tensile strains between 7.5 and 1.5%.

The great increase of the strength of filamentary crystals over the strength of larger specimens can not be attributed to just their smallness, because the author and others[13] have handled many which had no appreciable strength. Moreover, Baker[35] has drawn wires down to the thinness of whiskers by the "Taylor Process". These wires did not have unusual strength; therefore, it is presumed that the filamentary crystals exhibit such high strengths because they are perfect[4] or nearly perfect.[36]

Note the catastrophic nature of the failure of the indium whisker shown in Fig. 7b. Severe local plastic deformation occurred suddenly at the two places when the stress was only slightly increased (as can be seen by the slight change in spacing of the probes when compared to Fig. 7a). The sharp bends are probably not fractured because the bottom segment is smoothly curved which indicates that stress is still being transmitted to the next segment.

In Exp. S–5a a successful tensile test was made on a tin whisker 1.5 microns thick. It withstood a tensile stress of 10,600 psi (7.3×10^8 dyne/cm^2) which corresponds to an estimated elastic strain of 0.16% before fracturing. No necking at the fracture could be observed at the magnification of ×500. Another tin whisker broke near to the point of attachment in Exp. S–5b, but it did withstand a stress of 3,500 psi (2.4×10^8 dyne/cm^2).

Some reasons why tensile tests may show lower strength than bending tests are (1) the danger of damage is greater because more handling is needed in tensile tests, (2) the comparatively few tensile tests which have been performed may not have been sufficient to discover unusually strong one, and (3) the possible existence of a "size effect", i.e. the volume of material subjected to high stress is much greater in the tensile test so there is a greater probability of having an imperfection highly stressed. Although the tensile strength of whiskers may be lower than the bending strength, nevertheless it is usually much higher than a large single crystal of the same material.

§ 6. Summary of Experiments

For compression induced growth, ring clamps similar to Fisher's[27] were used. The outer diameter was 1-1/2 in., the inner diameter 7/8 in. and 3/8 in. in thickness. The compression was applied by a 1/4 in. Nat. Fine screw. For high temperature use, all parts were made of stainless steel.

The plated steel was cut into 3/8 in. squares, stacked between 1/4 in. thick backing plates, placed in the clamp and the screw lightly tightened. The thickness of the steel plate was in the range of 0.006 and 0.020 in.. Usually the stack consisted of about eight pieces of varying thickness of plating, from the thinnest flash plating of less than 0.0001 to about 0.002 in.. One side of the laminated stack was filed flat, given a metallographic polish, and then the screw was tightened. Quantitative measurement of the clamping force was not meaningful because the disparities of the plate and plating must cause the stress to be very non-uniform, thus making it impossible to know the local stress at the point where the individual growths occurred. It was common to have some gross extrusion of the plating at the lamina thicker than 0.0005 in., and sometimes local plastic deformation could be seen at some places on the steel plate.

Exp. E9–1

Sample: gold electroplated on stainless steel sheet. Environment: dry hydrogen. Test: 11 days at 250°C—no whiskers, +11 days at 300°C—possibly two very fine short whiskers, +14 days at 325°C—whiskers appeared, +16 days at 325°C—more whiskers appeared. Whisker growths occurred at the interfaces between 0.0001–0.0001, 0.0001–0.0003, and 0.0003–0.0003 in. plating. See Fig. 2.

Exp. E9–2a

Sample: silver electroplated on mild steel. Environment: nitrogen at 5 psi above atmospheric, not very pure because blue oxide formed on the clamp. Test: 48 hrs. at 400°C two whiskers appeared, one straight, 1μ thick $\times 80\mu$ long; the other a segmented 4 piece iral polygon of total length of 100μ, thick-ess 1μ. The spiral polygon was very similar the tin ones grown by Levy.[31] The plating the interface was 0.005 in..

xp. E9–2b

ample: silver electroplated on stainless steel. nvironment: nitrogen. Test: 11 days at 50°C—very short whiskers appeared on the innest lamina which was less than 0.0001 ., +11 days at 550°C—no appreciable ngthening. (suspect sublimation rate is equal their growth rate.)

xp. E9–2c

ample: silver electroplated on mild steel. nvironment: nitrogen. Test: 18 hours at 00°C. Very fine, 0.2μ, short, 5μ, dense rowth appeared on the thickest lamina 0.003 ..

xp. E10–1

ample: lead electroplated <0.0001, 0.0003, .0005, and 0.0008 in. thick on mild steel. nvironment: room temperature and atmo-phere. Test: whiskers appeared in less than ne minute after tightening the clamp. rowths appeared only on the interfaces be-ween the bare steel—0.0001 and 0.0001—.0003 in. plating. Most growths curled and inked, but some were straight.

xp. E10–2a

ample: indium electroplated ≪0.0001, <.0001, and 0.0001 in. thick on mild steel. nvironment: room temperature and air. est: whiskers appeared in about 10 seconds n the interface between the thinnest and ext thinnest plating.

xp. E10–2b

ample: indium hot-dipped on steel, scraped about 0.0001 in. and then remelted. En-ironment: room temperature and air. Test: hiskers appeared in about an hour.

xp. E10–3a

ample: indium-lead alloy, 84% indium by eight, hot-dipped on steel, scraped to about .0001 in. thickness, and remelted. Environ-nent: room temperature and air. Test: hiskers appeared in about one minute.

xp. E10–3b

ample: lead-indium alloy, 64% lead by weight, ot-dipped on steel, scraped to about 0.0001 . thickness, and remelted. Environment: oom temperature and air. Test: whiskers ppeared in several minutes.

Exp. E10–3c

Purpose: Compare the composition of an alloy whisker with that of the metal from which it grew.

Sample: (1) a whiskers grown by pressure induction from indium-lead alloy. See Exp. E10-3a. Approximate size 1μ×1μ×0.3 mm. (2) fine filings from the parent plating, extruded with gum tragacanth into a filament shaped specimen 0.5 mm. dia..

Apparatus: X-ray diffraction Cu K_α 50 kV, 15 ma. beam collimated to 0.5 mm. diameter. Single crystal rotation camera of 60 mm. dia. called " Unicam ".

Test: The diffraction pattern from the whisker rotating about its fiber axis was superimposed upon the same film with that of the filing sample rotating about its axis. Exposure time for the whisker was 90 hrs; the filings 8 hrs. Comparison of the powder line and the layer line spots at about $\theta=45°$ for the (123) line showed the spots and the line superimposed within the accuracy of observation using a strong magnifying glass. The estimated accuracy of the film reading was ±0.03 mm. The values for the change of lattice parameter with composition for indium-lead alloys as measured by Tyzack and Raynor[37] show this accuracy of measurement corresponds to ±0.8 atom % lead. The alloy's composition as measured by chemical analysis was 9.57 atom % lead. From the layer line spacing and the identification of all the single crystal diffraction spots, the axis of the whisker was determined to be the [111] direction using the body-centered tetragonal lattice.

Exp. E10–4

Sample: Bismuth electroplated on steel. Plating was 0.002 in. thick. Environment: Room temperature and air. Test: The sample was inspected at approximately two month intervals. No growth was noticed until 11 months. Profuse growth with many whiskers 100μ long.

Exp. E11–1

Sample: Zinc electroplated on steel. Plating was <0.0001, 0.0003, 0.0005, 0.0014 in. in thickness. Environment: Room temperature and air. Test: The sample was inspected every two days and whiskers were observed after eight days. Most of the growth was on the 0.0001—0.0003 interface and the 0.0003—0.0003 interfaces. No growth on the thicker interfaces at that time. The longest whisker was about 25μ at the eighth day.

Exp. E11-2

Sample: Cadmium electroplated on steel. The plating had a rough appearance with protruding crystals against a finer crystalline background 0.007 in. thick as measured with a micrometer. Environment: Room temperature and air. Test: No growth in the first 6 hrs. At 24 hrs. there were 7 whiskers 4 to 30μ long. At 4 days no additional lengthening of existent whiskers could be seen. There was one additional whisker noted but it could have been missed in previous examinations.

Exp. E11-3

Sample: Terne plate of nominal composition 85% lead and 15% tin (by weight), hot-dipped. 4 lb/single base box and also 1 lb/single base box of nominal thickness 0.00017 and 0.00004 in. respectively. Environment: Room temperature and air. Test: In first day small knobby protrusions appeared which were about 5μ long. After 3 years no whiskers or other growth appeared.

Exp. 0-1 Crystallographic orientation of whiskers (See also Exp. E10-c.)

Samples: Compression-induced tin whiskers, 10 samples from 1 to 2μ thick and longer than 0.5 mm.

Apparatus: X-ray diffraction using a Cu K_α 50 kV, 15 ma. beam collimated to 0.5 mm. diameter. Single crystal rotation camera of 60 mm. dia. called "Unicam." Exposures were from 10 to 24 hrs.

Test: Crystallographic direction of the whisker axes were (1) [100], (2) [100], (3) [101], (4) [100], (5) [001], (6) [100], (7) [101], (8) straight but consists of two crystals, tip segment [001] and base segment [101], (9) [001], and (10) consists of two crystals at a small angle to each other, tip segment [100] and the base segment [101]. Summary: 5 segments [100], 4 segments [101] and 3 segments [001].

Exp. P-1 Spontaneous growth

Zinc, tin, and cadmium samples were cast in bars 1/8 in. dia. and 3 in. long. The casting process was varied so that some samples had fine grain while others had larger grain up to where some consisted of a single crystal. They were stored in plastic boxes and examined after a 4 year period. Because of the danger of destroying growths by handling, only the upper half surface was examined. 25 samples were examined. On a zinc sample of three grains, a cadmium sample of 10 grains, and a tin sample of 2 grains, groups of straight fibers, 4 to 10 per sample, grew close together and they were definitely not stray particles. The most interesting aspect is the small number of growths which appeared on such a large total surface that clearly recognizable as whiskers.

Bending strengths of whiskers

The whiskers were loaded as buckled columns by micromanipulators. The curvature of the bends were measured from microphotographs. The thicknesses were estimated at × 500 magnification by using a scale in the ocular of the microscope. All whiskers were compression-induced growths from plated steel.

Experiment	Material	Thickness (μ) t	Radius (μ) r	Strain (%) $e=t/2r$
S-1a	Pb	1.7	28	3.0
S-1b	Pb	1.7	52	1.6
S-2	Pb-In, 84% In	3.0	50	3.0
S-3a	In	1.8	20	4.5*
S-3b	In	1.8		3.4**
S-3c	In	0.8	8	5.0
S-4	Sn	1.5	190	0.4

* possibly some plastic bending

** bent from an initial curvature of $r_1=45$ to $r_2=25$

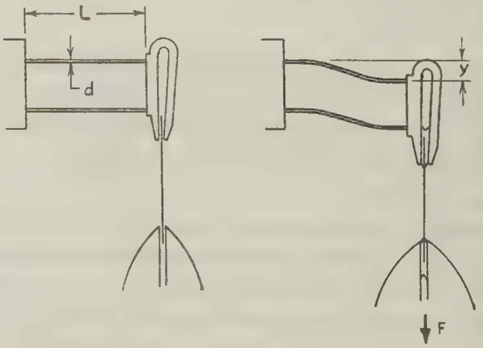

Fig. 8. Force measuring device for tensile tests of fine filaments.

Tensile tests on tin whiskers

A schematic drawing of the tensile testing apparatus is shown in Fig. 8. The force measuring device consists of two parallel ixed-end flexure beams which avoid rotation f the crosshead. The force F to cause the leflection y of this system is calculated to be $=(FL^3/24EI)$ where $I=(\pi d^4/64)$. The length f the weighing beams was 0.50 in.. The eam set No. 1 was made of tungsten wire .003 in. dia. and a more sensitive set, No. 2, vas made of molybdenum wire 0.002 in. dia.

The whisker was detached from its growth ite and inserted in the 10μ-slot in the crosshead. Cellulose cement, greatly thinned with cetone, was applied, it flowed into the slot y capillary attraction and quickly hardened, hereby fastening the whisker. The other nd of the whisker was similarly fastened nto a slot on a bar held by a micro-manipuator. The micro-manipulator pulled the whisker and the deflection of the weighing beams was measured by a scale in the ocular of the microscope.

Attachment by cellulose cement minimizes the stress concentration at the point of attachment because its modulus of elasticity is much lower than that of the metal.

The calculated force-deflection characteristics for the weighing beams were used instead of an experimentally calibrated values because this error was small compared to that in estimating the size and shape of the specimens' cross-section.

Exp. S–5a was performed on a tin whisker from compression induced growth. The measured thickness was 1.5μ and the cross-section was assumed to be square.

	Test	Metal	Thickness (microns)	Length (microns)	Weigh Beam	Deflection of weigh Beam (microns)	Stress (psi)	(10^8 dyne/cm^2)	Fracture location
Exp. S–5a,	*1	Sn	1.5	240	#1	25	10,600±1200	7.3	Center
	2			120	#1	18	8,000±1000	5.5	At attachment
	3			25	#1	25	10,600±1200	7.3	Near 〃
Exp. S–5b,		Sn	1.3	—	#2	34	3,500± 500	2.4	

* All three tests were performed on the same whisker which was progressively shorter after repeated fractures.

§ 7. Conclusions

The success of growing whiskers from a number of solid metals by providing the necessary conditions for their growth leads the author to believe that they can be grown on many other metals and alloys. An opportunity to study the material transport mechanism operative at the root of the whisker is presented by the discovery of alloy whiskers; enrichment (or the absence of enrichment) of one species of metal in the whisker should distinguish between pure diffusion and dislocation movement. The author intends to xploit this opportunity provided by alloy whiskers in future studies.

The author wishes to thank the many sponsors of the Institute for the Study of Metals, niversity of Chicago, for their support of his research and to thank his colleagues here for their helpful interest. Mrs. Betty ealson and Mr. K. Ikeuye greatly helped in he preparation and examination of the specimens. Dr. W. Hu made the X-ray determinations of the whisker orientations.

The author wishes to thank the Fulbright Commission which made it possible for him to prepare this manuscript at the Tokyo Institute of Technology and to thank Profs. Y. Takagi and H. Maniwa, of that Institute, for their aid and advice.

Heitler-London Approach to Electrical Conductivity, II. A Proof of the Hopping Motion

By Tatsumi KUROSAWA

Institute for Solid State Physics, University of Tokyo, Tokyo, Japan

(Received March 1, 1960)

A foundation of the Heitler-London approach to electrical conductivity is given, which has been left unproved in the previous paper (J. Phys. Soc. Japan **15** (1960) 802), applying Van Hove's method. The hopping motion of electron is realized under the conditions: large effective mass, strong interaction with lattice and the presence of a potential fluctuation through lattice.

§ 1. Introduction

As discussed in detail in the previous paper[1], the Heitler-London approach is more adequate than the usual Bloch approach to treat the conduction problem in the case that the effective mass of electrons (or holes) is very large and the electron-lattice interaction is also very strong. In that paper, we also discussed some characteristic features expected on the basis of the Heitler-London approach and applied the theory to several examples for which this approach seems to be adequate. However, we considered the motion of the electron in the crystal to be represented by the hopping motion, that is, a sort of random flight motion from an ion to an adjacent ion with certain transition probabilities, without any proof. In other words, we regarded the motion of the electron as characterized by the transport equation

$$\frac{dP_n(t)}{dt}=\sum_{n'}\{W_{nn'}P_{n'}(t)-W_{n'n}P_n(t)\}\,, \qquad (1)$$

where $P_n(t)$ is the probability that the electron is localized around an ion n at a time t, and $W_{n'n}$ is the transition probability of the electron from the ion n to n'.

In this paper, we shall prove this equation under two conditions. The two conditions are as follows. (I) The interaction energy between two states, one of which corresponds to the state where the electron is localized around an ion and another corresponding to that around the other ion, is very small. In other words, the effective mass of the electron is very large. (II) There exists some amount of potential fluctuation from ion to ion due to impurities and other wandering electrons; more exactly speaking, the electron finds no place of the equal potential energy among the nearest neighbouring and the second nearest neighbouring ions. These conditions are rather formal and abstract, and physically more useful but mathematically less exact expression of these conditions may be

$$\hbar\times(\text{transition probability}) < (\text{mean potential fluctuation})\,. \qquad (2)$$

In his two papers of 1955[2] and 1957[3], which we shall refer as A and B in the following, Van Hove has proved that the statistical behaviour of a sufficiently large system started from an appropriate initial state obeys such equations as Eq. (1), if the perturbing Hamiltonian is sufficiently small and has characteristic singularity properties. In our case, however, the perturbing Hamiltonian, which causes the jumping motion of the electron from an ion to another, has extra singularities in addition to those required by Van Hove. These extra singularities work to maintain the wave-like motion of the electron as a usual polaron. If the conditions mentioned before are not satisfied, the motion of the electron becomes more or less wave-like in virtue of the extra singularities. Thus, Eq. (1) is not exact in this case. If the conditions are satisfied, however, we can prove that the extra singularities do not cause any wave-like motion, though this is to be said rather self-evident, because the jumping motion of the electron must be accompanied with emission or absorption of phonons to conserve the energy.

§ 2. A Proof of the Hopping Motion

Let us imagine an electron (or a hole) with large effective mass and interacting strongly with lattice. As discussed in the previous paper, the electron is bound around a certain ion by its deep potential and induced lattice deformation, for a considerably long time. We express such a state as $|n, \{N(n)\}\rangle$. By the notation n we denote the position of the ion which captures the electron, and by $\{N(n)\}$* a set of quantum numbers of the lattice vibration. Further, by use of the notation (n), we understand that the lattice makes a vibration deforming around the ion n. We denote the total Hamiltonian of the system as $H+\lambda V$. The states $|n, N(n)\rangle$'s are the eigenstates of H. So that,

$$H|n, N(n)\rangle=\{E(N)+\Delta V(n)\}|n, N(n)\rangle\ , \qquad (3)$$

where $E(N)$ means the energy of the phonon system:

$$E(N)=\sum_i N_i\hbar\omega_i\ , \qquad (4)$$

and $\Delta V(n)$ is the potential energy of the electron which comes from the fluctuation of the lattice potential.** The second term of the Hamiltonian λV is the perturbation which connects the states with different n's, and λ is a dimensionless parameter characterizing the size of the perturbation. We assume that the perturbation has a finite matrix element only when the ions n and n' are nearest neighbouring.*** Moreover, we assume that

$$\langle n, N(n)\,|\,n', N'(n')\rangle=\delta_{nn'}\cdot\delta_{NN'}\ . \qquad (5)$$

As is well-known, Van Hove2),3)**** has proved that the statisticalbehaviours of a system follow the transport equation of the Markoff type in the limit of $\lambda\rightarrow 0$, if the size of the system is sufficiently large and the perturbation satisfies certain conditions. Therefore, we see that, if these conditions are satisfied in the present case, we have Eq. (1). The perturbation λV which we consider, however, does not satisfy Van Hove's condition (see Section 2 of A) in the following two points.***** (1) When $N\neq N'$, the matrix element $\langle n, N(n)|V|n', N'(n')\rangle$ is a quantity of the order of magnitude $\Omega^{-s/2}$ ($s=1, 2, 3, \cdots$; Ω is the total volume of the system). However, it may be a finite quantity even when $n\neq n'$, if N happens to be equal to N'; the presence of the singularity of the type $\delta_{NN'}$. (2) The matrix element

$$\langle n, N(n)|\,VA_1VA_2V\cdots A_mV\,|n', N'(n')\rangle$$

has a singularity of the type $\delta_{NN'}$ besides the type $\delta_{nn'}\cdot\delta_{NN'}$ in Van Hove's papers. The operators A_k's represent some diagonal operators with respect to $|n, N(n)\rangle$. The physical meaning of these singularities is very important. They work to maintain the wave-like motion of the electron as a polaron. If the effective mass of the electron is small and the electron-lattice interaction is weak, the matrix element $\langle n, N(n)|V|n', N(n')\rangle$ is large and the effect of these singularities is so predominant, that the Heitler-London picture of the current breaks down. If, however, the effective mass is large and the interaction is strong, the effect of the singularities to the motion of the electron will be small as compared with that of the other transition matrix elements. Hence we may be allowed to use Eq. (1) as an approximate equation. We shall, however, assume that the potential energy of the electron is slightly different from ion to ion because of a random distribution of impurity ions and other wandering electrons. Then, we shall see that Eq. (1) is valid so long as the conditions (I) and (II) are satisfied. By following closely to Van Hove's procedure we shall derive Eq. (1) for the hopping motion of the electron in a lattice with a fluctuating potential.

We assign the initial state of the system as:

$$\psi(0)=\sum_n\sum_N c(n, N)\,|\,n, N(n)\rangle\ . \qquad (6)$$

The nature of the coefficients $c(n, N)$ has been discussed in A and B. The time variation of ψ is determined by:

$$\begin{aligned}\psi(t)&=\exp\left[-\frac{i}{\hbar}(H+\lambda V)t\right]\psi(0)\\ &=U(t)\psi(0)=\sum_\mu U_\mu(t)\psi(0)\ ,\end{aligned} \qquad (7)$$

where $U_\mu(t)$ is

---

* Hereafter, we abbreviate $\{N(n)\}$ to $N(n)$.

** Here we take the electron energy in the average lattice potential as the energy standard.

*** This assumption is not essential but introduced for the sake of convenience.

**** Hereafter we shall refer to these papers as A and B.

***** The following discussions are similar to Van Hove's in many points. In such cases, we shall only refer to the relevant places in Van Hove's papers, for the sake of simplicity.

$$U_\mu(t)=\left(-\frac{i\lambda}{\hbar}\right)^\mu\int_{t\geq t_\mu\geq t_{\mu-1}\geq\cdots\geq t_1\geq0}dt_1\,dt_2\cdots dt_\mu\sum_{n_\mu}\cdots\sum_{n_0}$$
$$\times\sum_{N_\mu}\cdots\sum_{N_0}|n_\mu,N_\mu(n_\mu)\rangle\cdot\exp\Big[-\frac{i}{\hbar}\{\mathcal{E}_\mu(t-t_\mu)+\mathcal{E}_{\mu-1}(t_\mu-t_{\mu-1})$$
$$+\cdots+\mathcal{E}_1(t_2-t_1)+\mathcal{E}_0t_1\}\Big]\cdot\langle n_\mu,N_\mu(n_\mu)|V|n_{\mu-1},N_{\mu-1}(n_{\mu-1})\rangle$$
$$\times\cdots\langle n_1,N_1(n_1)|V|n_0,N_0(n_0)\rangle\cdot\langle n_0,N_0(n_0)|\,, \tag{8}$$

nd

$$\mathcal{E}_i=E(N_i)+\Delta V(n_i)\,. \tag{9}$$

First, we can prove that the effect of the extra singularities mentioned before on $U_\mu(t)$ is nly an energy shift of the states $|n,N(n)\rangle$. For this purpose, it is convenient to decompose $U_\mu(t)$ into components each of which corresponds to a definite spatial path $n_0\to n_1\to\cdots\to n_\mu$:

$$U_\mu(t)=\sum_{n_0}\cdots\sum_{n_\mu}U_\mu(t;[n_0,n_1,\cdots,n_\mu])=\sum_j U_\mu(t;[j])\,. \tag{10}$$

$U_\mu(t;[j])$ contains only summations over the states of the lattice vibration N, therefore it esembles Van Hove's $U_\mu(t)$ in its singularity properties* except that $\langle N|V|N'\rangle$ has the ingularity $\delta_{NN'}$ in the present case. Thus, as Van Hove has shown, we can disregard the o-called interlocked pairs.

At first, we consider the case $N_0=N_\mu$. It corresponds to the diagonal transition schemes of A. From the same reason as in A, we can neglect the transition schemes containing higher order processes like $N_0\to N'\to N''\to N'\to N_0$ or $N_0\to N'\to N''\to N_0$, in the limit of $\lambda\to0$. Thus, we know that $U_\mu(t;[j])$ consists of only three kinds of successive transitions: $N_0\to N_0$, $N_0\to N'\to N_0$ and $N_0\to N'\to N'\to N_0$.

The corresponding part of these processes in Eq. (8) is, for $N_0\to N_0$,

$$\langle n_i,N_0(n_i)|V|n_{i-1},N_0(n_{i-1})\rangle\exp\left[-\frac{i}{\hbar}\{\mathcal{E}_i(t_{i+1}-t_i)+\mathcal{E}_{i-1}(t_i-t_{i-1})\}\right], \tag{11}$$

for $N_0\to N'\to N_0$,

$$\sum\nolimits_{N'}\langle n_{i+1},N_0(n_{i+1})|V|n_i,N'(n_i)\rangle\langle n_i,N'(n_i)|V|n_{i-1},N_0(n_{i-1})\rangle$$
$$\times\exp\left[-\frac{i}{\hbar}\{\mathcal{E}_{i+1}(t_{i+2}-t_{i+1})+\mathcal{E}_i(t_{i+1}-t_i)+\mathcal{E}_{i-1}(t_i-t_{i-1})\}\right], \tag{12}$$

and for $N_0\to N'\to N'\to N_0$, a similar but somewhat lengthy formula. If we integrate (11) with respect to the intermediate time t_i, it becomes

$$\frac{\hbar}{i}\frac{1}{(\mathcal{E}_i-\mathcal{E}_{i-1})}\langle n_i,N_0(n_i)|V|n_{i-1},N_0(n_{i-1})\rangle\Big[\exp\left\{-\frac{i}{\hbar}\mathcal{E}_{i-1}(t_{i+1}-t_{i-1})\right\}$$
$$-\exp\left\{-\frac{i}{\hbar}\mathcal{E}_i(t_{i+1}-t_{i-1})\right\}\Big], \tag{11$'$}$$

when $\mathcal{E}_i\neq\mathcal{E}_{i-1}$, and

$$\langle n_i,N_0(n_i)|V|n_{i-1},N_0(n_{i-1})\rangle(t_{i+1}-t_{i-1})\exp\left\{-\frac{i}{\hbar}\mathcal{E}_i(t_{i+1}-t_{i-1})\right\}, \tag{11$''$}$$

when $\mathcal{E}_i=\mathcal{E}_{i-1}$, although this case can not happen because of the condition (II) in §1. Similarly, we can integrate the other two processes with respect to the intermediate times. The results are summarized illustratively in Figs. 1, 2, 3, where only the order of magnitude** and the frequency of time variation are shown, for only these two factors are important to the present discussion. The meaning of these figures may be self-explanatory, for instance, Fig. 1 means that the integration of (11) gives

---

* This fact may be easily seen, if we disregard the fixed quantum numbers $n_0, n_1, \cdots, n_\mu$ and identify our N with Van Hove's α.

** Note that $O(t_{i+1}-t_{i-1})$'s are $O(\lambda^{-2})$.

$$O(1)\times\exp\left\{-\frac{i}{\hbar}\mathcal{E}_{l-1}(t_{l+1}-t_{l-1})\right\}+O(1)\times\exp\left\{-\frac{i}{\hbar}\mathcal{E}_{l}(t_{l+1}-t_{l-1})\right\}\qquad(\mathcal{E}_l\neq\mathcal{E}_{l-1}),$$

and

$$O(t_{l+1}-t_{l-1})\times\exp\left\{-\frac{i}{\hbar}\mathcal{E}_{l}(t_{l+1}-t_{l-1})\right\}\qquad(\mathcal{E}_l=\mathcal{E}_{l-1})$$

respectively.

The further integration with respect to the end times of each process can be performed by applying the results of Fig. 1 and by substituting $O(t)$ for the factors like $O(t_{l+1}-t_{l-1})$. This substitution is permissible so long as we are interested in only the order of magnitude, because $O(t_{l+1}-t_{l-1})$'s are slowly varying functions of t_{l+1} and t_{l-1} compared with $\exp\{-i\mathcal{E}_l(t_{l+1}-t_{l-1})/\hbar\}$'s.

Thus, we can examine the contribution to $U_\mu(t;[j])$ with $N_0=N_\mu$ from an arbitrary transition scheme $|n_0, N_0(n_0)\rangle\to|n_1, N_1(n_1)\rangle\to\cdots\to|n_\mu, N_0(n_\mu)\rangle$. The results can be summarized as follows. If there are n_α states with energy $\mathcal{E}_\alpha$, n_β states with energy $\mathcal{E}_\beta$ and so on, among the states with the phonon state N_0 in a transition scheme, this transition scheme contributes to $U_\mu(t;[j])$ the following order of magnitude,

$$\lambda^\mu\left\{O(t^{n_\alpha-1})\exp\left(-\frac{i}{\hbar}\mathcal{E}_\alpha t\right)+O(t^{n_\beta-1})\exp\left(-\frac{i}{\hbar}\mathcal{E}_\beta t\right)+\cdots\right\}. \tag{13}$$

Thus, remembering the condition (II) in §1, we may conclude that the $U_\mu(t)$ with $N_0=N_\mu$ consists of the repetitions of only two types of the processes $|n_0, N_0(n_0)\rangle\to|n', N'(n')\rangle\to|n_0, N_0(n_0)\rangle$ and $|n_0, N_0(n_0)\rangle\to|n', N_0(n')\rangle\to|n_0, N_0(n_0)\rangle$, in the limit of $\lambda\to0$. These processes only contribute to the energy shift of the unperturbed state $|n_0, N_0(n_0)\rangle$.

After the same manipulations as in A (Section 5), we know that $U^W(t)$, the sum over all $U_\mu(t)$'s with $N_0=N_\mu$, is given by a simple formula

$$\langle n, N(n)|U^W(t)|n', N'(n')\rangle=\delta_{nn'}\cdot\delta_{NN'}u^W(t;n,N), \tag{14}$$

and

$$u^W(t;n,N)=\exp\left[-\frac{i}{\hbar}\{E(N)+\Delta V(n)+\lambda^2\Delta(n,N)\}t-\frac{\lambda^2}{\hbar}\Gamma(n,N)t\right]. \tag{15}$$

Here $\lambda^2\Delta(n,N)$ and $\lambda^2\Gamma(n,N)$ are the energy shift and the width of the state $|n, N(n)\rangle$.

Moreover, we have

$$u(t)=U^W(t)+\sum_{\mu=1}^{\infty}\tilde{U}_\mu(t)\ , \tag{16}$$

here

$$\tilde{U}_\mu(t)=\left(-\frac{i\lambda}{\hbar}\right)^\mu\int dt_1\cdots dt_\mu\{U^W(t-t_\mu)VU^W(t_\mu-t_{\mu-1})\cdots VU^W(t_1)\}_{nd}\ . \tag{17}$$

he notation $\{\ \ \}_{nd}$ means that the states connected by V in $\{\ \ \}_{nd}$ are to have mutually fferent N, hence we have Eqs. (16) and (17) without special concern for the extra singular-ies. Thus, the extra singularities make a finite contribution to $U(t)$ only through the above vo types of processes and cause only the energy shift.

Next, let us consider the probability that the electron is found at a time t on an ion n:

$$\begin{aligned}P_n(t)&=\sum_N\langle U(t)\psi(0)|n,N(n)\rangle\langle n,N(n)|U(t)\psi(0)\rangle\\&=\langle U(t)\psi(0)|\,p_{[n]}|U(t)\psi(0)\rangle\ .\end{aligned} \tag{18}$$

the process of reduction, we insert (16) into (18), and the following matrix element appears,

$$\langle\psi(0)|\{U^{W*}(t_1')V^*\cdots V^*U^{W*}(t-t_{\mu'}')\}_{nd}\,p_{[n]}\{U^W(t-t_\mu)V\cdots VU^W(t_1)\}_{nd}|\psi(0)\rangle\ .$$

Vhen we write it explicitly by the $|n,N(n)\rangle$ representation, we see that it contains the ingularity of the type (2):

$$\sum_N\langle n',N'(n')|\{\ \ \}_{nd}|n,N(n)\rangle\langle n,N(n)|\{\ \ \}_{nd}|n'',N'(n'')\rangle\ ,\qquad(n'\neq n'')\ .$$

he physical meaning of this singularity is the interference between the partial wave which omes from $|n',N'(n')\rangle$ to $|n,N(n)\rangle$ and that from $|n'',N'(n'')\rangle$ to $|n,N(n)\rangle$ $(n'\neq n'')$. In rder to investigate this interference we imagine two definite paths $[j]$ and $[j']$, and consider he matrix element

$$\begin{aligned}&\langle\tilde{U}_\mu(t;[j'])\psi(0)|\,p_{[n]}|\tilde{U}_\mu(t;[j])\psi(0)\rangle\\&=\left(\frac{\lambda}{\hbar}\right)^{2\mu}\int_{t\geq t_\mu'\geq\cdots\geq t_1'\geq0,\ t\geq t_\mu\geq\cdots\geq t_1\geq0}dt_1'\cdots dt_\mu'dt_1\cdots dt_\mu\cdot\sum_{N_\mu'}\cdots\sum_{N_0'}\sum_{N_\mu}\cdots\sum_{N_0}\\&\qquad c^*(n_0',N_0')c(n_0,N_0)\{\langle n_0',N_0'(n_0')|V|n_1',N_1'(n_1')\rangle\\&\qquad\times\cdots\langle n_{\mu-1}',N_{\mu-1}'(n_{\mu-1}')|V|n_\mu',N_\mu'(n_\mu')\rangle\}_{nd}\\&\qquad\times\langle n_\mu',N_\mu'(n_\mu')|\,p_{[n]}|n_\mu,N_\mu(n_\mu)\rangle\{\langle n_\mu,N_\mu(n_\mu)|V|n_{\mu-1},N_{\mu-1}(n_{\mu-1})\rangle\\&\qquad\times\cdots\langle n_1,N_1(n_1)|V|n_0,N_0(n_0)\rangle\}_{nd}\\&\qquad\times u^{W*}(t-t_\mu';n_\mu',N_\mu')u^W(t-t_\mu;n_\mu,N_\mu)\\&\qquad\times\cdots u^{W*}(t_1';n_0',N_0')u^W(t_1;n_0,N_0)\ ,\end{aligned} \tag{19}$$

here the summation is taken over all phonon states. This matrix element has a similar tructure as (6–9) in A: $\langle U(t)\varphi|A|U(t)\varphi'\rangle$. In Van Hove's case, the finite contribution comes nly from the following procedure. Take the sum concerning $N_\mu(N_\mu=N_\mu')$ under the con-ition $N_{\mu-1}=N_{\mu-1}'$, and then take the sum concerning $N_{\mu-1}$ $(=N_{\mu-1}')$ under the condition $_{\mu-2}=N_{\mu-2}'$, and so on. We easily see that the situation is the same in the present case. y performing such summation we have the expression:

$$\begin{aligned}&\left(\frac{\lambda}{\hbar}\right)^{2\mu}\int dt_1'\cdots dt_\mu'dt_1\cdots dt_\mu\sum_{N_0}\cdots\sum_{N_\mu}c^*(n_0',N_0)c(n_0,N_0)\\&\quad\times\langle n_\mu',N_\mu(n_\mu')|\,p_{[n]}|n_\mu,N_\mu(n_\mu)\rangle\{\langle n_\mu,N_\mu(n_\mu)|V|n_{\mu-1},N_{\mu-1}(n_{\mu-1})\rangle\\&\quad\times\langle n_{\mu-1}',N_{\mu-1}(n_{\mu-1}')|V|n_\mu',N_\mu(n_\mu')\rangle\cdots\langle n_1,N_1(n_1)|V|n_0,N_0(n_0)\rangle\\&\quad\times\langle n_0',N_0(n_0')|V|n_1',N_1(n_1')\rangle\}_{nd}u^{W*}(t-t_\mu';n_\mu',N_\mu)u^W(t-t_\mu;n_\mu,N_\mu)\\&\quad\times\cdots u^{W*}(t_1';n_0',N_0)u^W(t_1;n_0,N_0)\ .\end{aligned} \tag{20}$$

In order to perform the time integrals, we introduce new variables

$$\tau_j=\frac{1}{2}(t_j+t_j')\,,\qquad \tau_j'=t_j-t_j' \tag{21}$$

and insert (15) into (20). After a simple calculation we reduce the time dependent part of (20) to a product of the following factors:

$$\begin{aligned}&\exp\Big[-\frac{i}{\hbar}\{(V_j'+\lambda^2\varDelta_j')-(V_j+\lambda^2\varDelta_j)-(V_{j-1}'+\lambda^2\varDelta_{j-1}')+(V_{j-1}+\lambda^2\varDelta_{j-1})\}\tau_j\\&\qquad+\frac{\lambda^2}{\hbar}\{(\varGamma_j+\varGamma_j')-(\varGamma_{j-1}+\varGamma_{j-1}')\}\tau_j\Big]\\&\times\exp\Big[-\frac{i}{\hbar}\{E(N_{j-1})+(V_{j-1}'+\lambda^2\varDelta_{j-1}'+V_{j-1}+\lambda^2\varDelta_{j-1})/2\}\tau_j'\\&\qquad+\frac{i}{\hbar}\{E(N_j)+(V_j'+\lambda^2\varDelta_j'+V_j+\lambda^2\varDelta_j)/2\}\tau_j'\\&\qquad+\frac{\lambda^2}{\hbar}\{(\varGamma_j-\varGamma_j')/2-(\varGamma_{j-1}-\varGamma_{j-1}')/2\}\tau_j'\Big]\,,\qquad (j=1,2,\cdots,\mu)\end{aligned} \tag{22}$$

where $V_j=\varDelta V(n_j)$ and $\varDelta_j=\varDelta(n_j, N_j)$. According to Van Hove, we perform the integrations concerning τ_j'. When the path $[j]$ is identical to the path $[j']$, each n_j is equal to n_j' and we have in the limit $\lambda\to 0$:

$$2\pi\exp\left\{\frac{2\lambda^2}{\hbar}(\varGamma_j-\varGamma_{j-1})\tau_j\right\}\cdot\delta(E(N_{j-1})+\varDelta V(n_{j-1})-E(N_j)-\varDelta V(n_j))\,.$$

If we perform the integration with respect to τ_j's, we obtain the result of the order of magnitude $\lambda^{2\mu}\times O(t^\mu)=O(1)$. On the other hand, when the path $[j]$ is different from the path $[j']$, there appears at least one factor of the following type:

$$\exp\left\{-\frac{i}{\hbar}(\varDelta V(n_j)-\varDelta V(n_j'))(\tau_{j+1}-\tau_j)\right\}\,,\qquad \varDelta V(n_j)\neq\varDelta V(n_j')\,.$$

Thus, we see that the matrix element,

$$\langle\tilde{U}_\mu(t;\,[j'])\psi(0)|p_{[n]}|\tilde{U}_\mu(t;\,[j])\psi(0)\rangle\qquad([j]\neq[j'])\,,$$

has the order of magnitude of $\leq\lambda^{2\mu}\times O(t^{\mu-1})=O(\lambda^2)$. By a similar argument, we see that the matrix element,

$$\langle\tilde{U}_{\mu'}(t;\,[j'])\psi(0)|p_{[n]}|\tilde{U}_\mu(t;\,[j])\psi(0)\rangle\qquad(\mu'\neq\mu)\,,$$

has the order of magnitude of $\leq O(\lambda^{|\mu'-\mu|})$. Therefore, we find that the interference between the different paths does not contribute in the limit of $\lambda\to 0$. Thus, the extra singularities have no effect, and we can conclude that the time evolution of $P_n(t)$ follows the transport equation (1).

Thus the Eq. (1) is derived under the condition $\lambda\to 0$. Although the neglected higher order terms with respect to λ are very complicated and have not a simple physical meaning, by examining them we may imagine that a rough condition for the hopping motion will be given by (2).

Exchange Interaction and Cubic Crystal Field Splitting Parameter of Fe^{3+} in Spinel Structure

By Yoshikazu SUGIURA

Electrotechnical Laboratory, Nagata-cho, Tokyo, Japan

(Received March 5, 1960)

The line widths of paramagnetic resonance absorption of Fe^{3+} ions in $MgAl_2O_4$ and $ZnAl_2O_4$ polycrystals and of Mn^{2+} ions in $ZnAl_2O_4$, having the same spinel crystal structure as ferrite, are measured as a function of concentration.

The cubic crystal field splitting parameters a of Fe^{3+} ion at A- and B-sites are determined from the line widths extrapolated to zero concentration: $a_A=1.0\times10^{-2}\,\mathrm{cm}^{-1}$ and $a_B=3.1\times10^{-2}\,\mathrm{cm}^{-1}$. $a_B/a_A=3.1$.

On the other hand, the magnitudes of exchange integral between Fe^{3+} ions in A- and B-sites or in B- and B-sites are estimated from the decrease of line width due to exchange narrowing as the concentration increases, namely, $J_{AB}/g\beta=1.32\times10^5$ Oe and $J_{BB}/g\beta=1.90\times10^3$ Oe. The Curie temperatures obtained from the exchange integral are in agreement with the Curie temperatures of Mg-ferrite and Zn-ferrite measured experimentally.

§1. Introduction

Since the mechanism of magnetization in ferrites was cleared by Néel[1] and was called "Ferrimagnetism", the development on basic understanding of ferrite has been very great.

Ferrites are oxides constructed with divalent ions (Mn^{2+}, Fe^{2+}, Ni^{2+} and Co^{2+} etc.) and trivalent iron ions. The crystal structure is similar to that of $MgAl_2O_4$ and hence is called "Spinel" structure. A unit cell is constructed of 8 A-sites (metal ions surrounded by 4 oxygen ions forming a regular tetrahedron) and 16 B-sites (metal ions surrounded by 6 oxygen ions forming a regular octahedron). The total number of oxygen ions in the unit cell is 32.

It is well known that, in ferrimagnetic crystals, the magnetic ions in A- and B-sites have a strong tendency to have their spin oriented antiparallel to each other, and the interactions between magnetic ions in A- and A-sites or in B- and A-sites are weak, so the total magnetization is given by the difference of magnetization between ions in A-sites and B-sites. The magnitudes of such exchange interaction are estimated from the Curie temperatures and the curves of magnetization *vs* temperature.

On the other hand, it is very interesting to see what the origin of magnetic anisotropy in ferrites are. It is suggested by Yoshida and Tachiki[2], using one-ion model, that the magnetic anisotropy of Ni- and Mn-ferrites arises from the anisotropy of the crystalline field acting on Fe^{3+} ion. They estimate the cubic crystal field splitting parameter a in the cubic term of the ground-state spin Hamiltonian, $a/6x(S_x^4+S_y^4+S_z^4)$, at A- and B-sites, respectively, by analyzing the experimental anisotropy constant *vs* temperature in Mn-ferrite

In order to examine the validity of the theory, it is needed to measure directly the values and signs of cubic crystal splitting parameter of Fe^{3+} ion in A- and B-sites of ferrite.

The values and signs of a were estimated by Rado *et al*[3] and Kriessman *et al*[4] by analyzing the magnetic anisotropy of Mg-ferrite, where the population of Fe^{3+} ions in A- and B-sites depended on the initial temperature whence the samples were cooled rapidly to room temperature, and the magnetic anisotropy varied with the population.

Watanabe[5] calculated a of Mn^{2+} ion and Fe^{3+} ion in nearly cubic crystalline field by the higher-order perturbation method. From his result the sign of a is concluded to be always positive in both sites, but this conclusion is in conflict with the negative sign of a obtained in Mg-ferrite by Rado *et al.*

In relation to this problem, Geschwind[6] determined the values and signs of a in Fe^{3+} ion surrounded by oxygen ions forming octahedron and tetrahedron in yttrium gallium garnet, $3Y_2O_3\cdot5Ga_2O_3$, having a crystal struc ture different from ferrite, and showed that the signs of a in both sites are positive and $a_{oct.}/a_{tet.}=3.0$.

Our purposes are to show how the line widths of paramagnetic resonance absorption of Fe^{3+} and Mn^{2+} ions in $MgAl_2O_4$ and $ZnAl_2O_4$ polycrystals depend on the concentration and how this behaviour is explained by the dipole-dipole interactions and the exchange narrowing.

The magnitudes of cubic crystal field splitting parameter a of Fe^{3+} ion in A- and B-sites and the values of exchange integral between Fe^{3+} ions in A- and B-sites or in B- and B-sites are also estimated by analyzing the experimental results.

§ 2. Experiment

$MgAl_2O_4$ and $ZnAl_2O_4$ were selected for the material from the following reasons.

They have the crystal structure of spinel type, isomorphous with ferrite. Moreover, in regard to the positions of Fe^{3+} and Mn^{2+} ions it is allowable to take the next assumptions.

$ZnFe_2O_4$ and $ZnAl_2O_4$ are both known to be of normal spinel structure, namely, all the Fe^{3+} and Al^{3+} ions occupy B-sites in these crystals. So it is quite natural to assume that Fe^{3+} ions occupy B-sites in place of Al^{3+} ions in $ZnAl_2O_4$.

On the other hand, Fe^{3+} ions in $MgFe_2O_4$ take either A- or B-site according to the initial temperature where rapid cooling treatment begins, hence it is supposed that they can occupy both of the two sites also in $MgAl_2O_4$.

Thus by observing the behaviour of Fe^{3+} ions in $ZnAl_2O_4$ and $MgAl_2O_4$ we can get information about the interaction between Fe^{3+} ions in B- and B-sites and A- and B-sites. Moreover, it has been revealed during the experiment that for very low concentration, Fe^{3+} ions occupy A-site in $MgAl_2O_4$.

Mn^{2+} ions in $ZnAl_2O_4$ are used for the purpose of investigating the interaction of ions in A- and A-sites.

It should be desirable to use single crystals for such an experiment, but single crystals of $MgAl_2O_4$ prepared by flame fusion technique proved to be unsatisfactory for the present experiment because of the broadness of the resonance line, and single crystals of $ZnAl_2O_4$ could not be obtained at all. So polycrystalline samples were used throughout the experiment.

Al_2O_3, Fe_2O_3, MgO, ZnO and $MnCO_3$, all of chemical pure grade, are used for preparing the sample. Proper amounts of components are mixed in a mill, and after having been pressed into a small circular disc, they are sintered in air at 1200°C. Higher sintering temperature would lead to a production of Fe^{2+} ions.

The X-ray patterns show that $Zn(Al, Fe)_2O_4$ have perfectly spinel structure for the whole range of concentration, but, for $Mg(Al, Fe)_2O_4$, pure spinel structure is only observed when the concentration of Fe^{3+} ions is high (>1%), while for lower concentration an evidence for the existence of a second phase of unknown structure is also found in the patterns.

The measurements of paramagnetic resonance absorption are performed with the ordinary microwave transmission method, using a rectangular resonant cavity of TE_{103} mode, at a frequency of about 24.5 KMc. The magnetic field is modulated with a frequency of about 1 Kc.

As the modulation of magnetic field is used, the result obtained is the differential of the absorption curves. So the width between maximum slope of absorption curve is measured in various samples and it is simply described as line width in the following.

Fig. 1 indicates the variation of line width with the concentration* of $MgFe_2O_4$ in

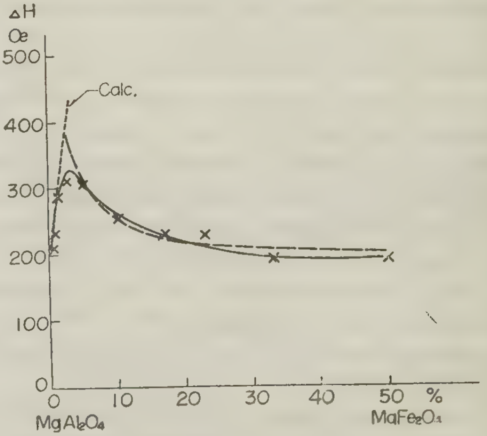

Fig. 1.

---

* The percentage indicated means the atomic percentage of Fe^{3+} measured from the composition ratio before sintering.

gAl$_2$O$_4$. In the range of small concentration f MgFe$_2$O$_4$ the line width increases rapidly, nd beyond about 4% of MgFe$_2$O$_4$ it decreases lown to a value nearly equal to the one exrapolated to pure MgAl$_2$O$_4$. The results will e discussed in the next section, considering he cubic crystal field splitting parameter and he exchange interaction.

In Fig. 2 the variation of line width with he concentration of ZnFe$_2$O$_4$ in ZnAl$_2$O$_4$ is hown. The tendency of the curve is similar o the one shown in Fig. 1, but the value exrapolated to zero concentration is about three imes as large as in Fig. 1 and the composition orresponding to the maximum of line width s about 30% of ZnFe$_2$O$_4$. The difference will e explained with the different crystal field cting on the magnetic ions situated at *A*-ite and *B*-site, as discussed in the next ection.

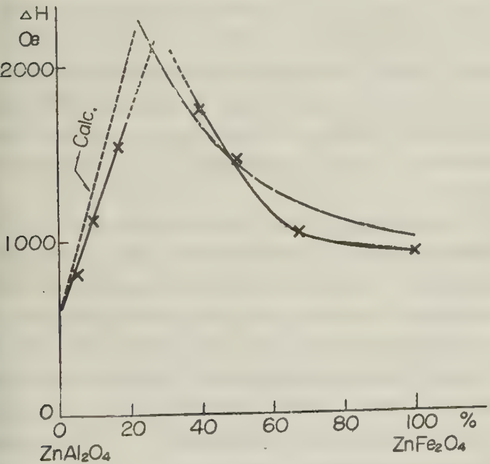

Fig. 2.

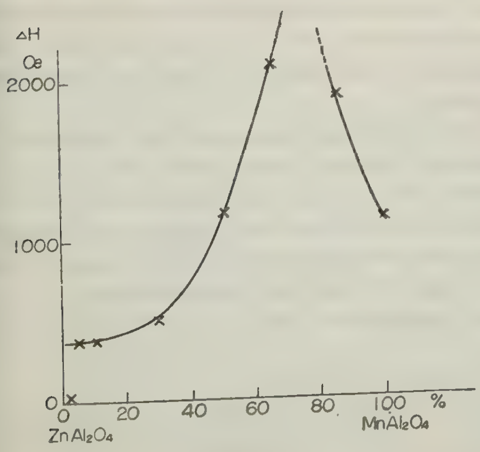

Fig. 3.

Fig. 3 indicates the same behaviour of line width in the case of MnAl$_2$O$_4$ mixed in ZnAl$_2$O$_4$. As Mn^{2+} ions have nuclear moments, hyperfine structure consisting of six lines is observed in the range below 1% of MnAl$_2$O$_4$. The distances between absorption lines are nearly equal, giving a numerical value of 86±2 oersteds, in agreement with the hyperfine splitting of other oxides[7]. The line width of each single line is 23 oersteds at 1% of MnAl$_2$O$_4$. For Mn^{2+} concentration >5%, the lines overlap with one another to give a single broad line, and the overall width of this broad line is the only observable quantity, which is shown in Fig. 3. The result that the apparent width of the line is nearly constant for concentrations less than 30% will be due to the line splitting.

§ 3. Results and Discussions

(A) *Cubic crystal field splitting parameter*

When the concentration of Fe^{3+} ion approaches zero, the line width tends to a finite value in each case of MgAl$_2$O$_4$ and ZnAl$_2$O$_4$, namely 190 oersteds and 580 oersteds, respectively.

It is likely that the line width is due to the crystalline field of Fe^{3+} ions directed at random in polycrystal, because the dipole-dipole interaction does not contribute to line width in very low concentration. Therefore, the difference of the extrapolated width in the two cases seems to show the different crystalline field of Fe^{3+} ion in MgAl$_2$O$_4$ and ZnAl$_2$O$_4$. Considering that Fe^{3+} ions in MgAl$_2$O$_4$ can take the position of *A*-site and Fe^{3+} ion in ZnAl$_2$O$_4$ prefer to occupy *B*-site, it may be concluded that the difference corresponds to the different crystalline field in *A*- and *B*-sites.

It is well known that Mn^{2+} and Fe^{3+} ions have a ground state of $^6S_{5/2}$ and a cubic field splits the sixfold degeneracy of the free ion into a twofold and fourfold degenerate level. Using the cubic crystal field splitting parameter a, the magnetic fields necessary for the transition of five fine structure lines in the very strong field range are given to the first order by[8]

$$M=\frac{1}{2}\longrightarrow-\frac{1}{2}\qquad H=H_0\,,$$

$$M=\pm\frac{3}{2}\longrightarrow\pm\frac{1}{2}\qquad H=H_0\pm\left(\frac{5}{2}\right)pa\,,$$

$$M=\pm\frac{5}{2}\longrightarrow\pm\frac{3}{2}\qquad H=H_0\mp 2pa\ ,$$

where $3a$ is the splitting between the twofold and fourfold levels, $p=1-5\phi$, $\phi=l^2m^2+m^2n^2+n^2l^2$ and l, m, n are the direction cosines of the magnetic field with respect to the cubic axes of the crystals.

In the case of polycrystal the five lines are brought together to be observed as a single line. The second moment of such an absorption line is given by

$$\langle \Delta H^2\rangle=\frac{16}{21}\frac{a^2}{(g\beta)^2}\ ,$$

where the line width of an individual absorption line is neglected in comparison with the splitting. g is the g-factor of the magnetic ion and β is the Bohr magneton.

From this relation the splitting parameter a will be obtained from the second moment of experimental resonance absorption line. As it is very difficult to determine the second moment from the experimental curves directly, it is calculated using its relation with the width of the absorption line, assuming the latter to be gaussian, although the assumption is not a very good approximation.

The magnitude of a in each site are obtained from the line width extrapolated to zero concentration as follows.

$$|a_A|=1.0\times10^{-2}\,\mathrm{cm}^{-1}\ ,$$

$$|a_B|=3.1\times10^{-2}\,\mathrm{cm}^{-1}\ .$$

The ratio a_B/a_A is 3.1, but the sign cannot be estimated.

These values are to be compared with the a-value of Fe^{3+} in MgO[9], surrounded by oxygen ions forming octahedron, namely, $+2.05\times10^{-2}\,\mathrm{cm}^{-1}$, and with the values obtained in yttrium gallium garnet, namely, $+0.616\times10^{-2}\,\mathrm{cm}^{-1}$ and $+1.850\times10^{-2}\,\mathrm{cm}^{-1}$ for Fe^{3+} ions in tetrahedral and octahedral sites, respectively. Although the estimations given here is very rough, the agreement seems to be rather satisfactory, indicating that the assumptions made on the positions of Fe^{3+} ions in the present experiment are appropriate ones.

The ratio of the values of a for A- and B-sites given above is more reliable than the individual a-values, because the difficulty arising from the line shape is cancelled out.

This ratio will be used in the next place to calculate the position of oxygen ions in the crystal according to the method used by Geschwind[6].

Watanabe[5] has shown that a splitting arising from perturbations by excited state involve the cubic crystalline potential, $V=C(x^4+y^4+z^4-3/5\,r^3)$, to even powers only and will first appear as V^2. Consequently, the sign of a should be independent of the sign of V. The constant C appearing in the cubic potential V is $-35q/9d^5$ and $+35q/4d^5$ for tetrahedral and octahedral sites, respectively, where d is the distance from the center of the site to the charges q located at the corners. If $a\propto V^2$, then $a_B/a_A=(9/4)^2\times(d_A/d_B)^{10}$.

In spinels d is given as[10]

$$d_A=a(1/8+\delta)\sqrt{3}\ ,$$

$$d_B=a\sqrt{1/16-1/2\,\delta+3\delta^2}\ ,$$

where $\delta=u-3/8$. Parameter u indicates the positions of the oxygen ions in the spinel structure and is in the neighbourhood of 3/8. If u is exactly 3/8, the oxygen ions from a cubic close-packed array. A value of u greater than this implies a contraction of the oxygen lattice about the octahedrally coordinated metal ions and a corresponding expansion about the tetrahedrally coordinated ones.

Taking $u=0.383$, we can obtain $a_B/a_A=3.06$ almost equal to the experimentally obtained value, 3.1. This value of u is considered to be fairly well defined, as the value of a is very sensitive to a slight change in the u-value, (2.74 for $u=0.382$ and 3.38 for $u=0.384$). Hasting and Corliss[11] determined u by the neutron diffraction as 0.385 in $ZnFe_2O_4$ and 0.381 in $NiFe_2O_4$.

From the agreement between their values and the present value it is concluded that the assumption of $a\propto V^2$ is valid, provided it is allowed to calculate V with the point charge model.

Geschwind[6] obtained $a_{oct.}/a_{tet.}=3.00\pm0.1$ in yttrium gallium garnet, which is of different crystal structure from spinel structure, and the signs of a are always positive. He showed also by reexamination that the negative sign of a reported before was a mistake.

In Mg-ferrite Rado[3] and Kriessman[4] reported the values of a_A and a_B together with their signs. According to their results, the sign is positive at B-site and negative at A-site. This is in conflict with both Watanabe's theory and our conclusion.

We also measured the magnetic anisotropy of Mg-ferrite at 4.2°K, 90°K and room temperature. Diverse results were obtained according to the thermal history of the sample. No definite conclusions about the sign of a_A nor a_B can be given at present.

In the case of 1% Mn^{2+} ions in $ZnAl_2O_4$, the line width of 23 Oe is observed. From this value, a of Mn^{2+} ion at A-site is estimated to be $1.2\times10^{-3}\,cm^{-1}$, in agreement with the values already reported for Mn^{2+} ions in various crystals.

B) *Interaction between magnetic ions*

It is found in Figs. 1 and 2 that, as the concentration of Fe^{3+} ions increases, the line width increases rapidly and when it reaches a certain value, the line width begins to decrease down to a finite value.

This behaviour can be explained by the dipole-dipole interaction and the exchange nteraction as shown in the following.

Dipole interactions are long range forces, so their contribution to the line width is large n the low concentration of magnetic ions. They are described in the simple cubic lattice structure on an isotropic average[12] as

$$\Delta H_d^{M.sl.}=2\sqrt{5.1}\quad g\beta n\sqrt{S(S+1)}\ ,$$

where n is the density of spins per cubic centimeter and S is spin quantum number. The line shape is assumed to be gaussian. The values calculated with the lattice constant of 8.09Å for $MgAl_2O_4$ and $ZnAl_2O_4$ are plotted n Figs. 1 and 2 with the dotted lines. In spite of rough estimation, the curves coincide satisfactorily with experimental results. So he increase of line width in the low-concentration region may be attributed to the dipole-dipole interactions between magnetic ons.

When the exchange interactions are strong between the same kind of magnetic ions, the ine width by dipole interactions are narrowed s explained by Van Vleck[13] and Anderson *t al*[12]. The decrease of line width observed n the present experiment seems to be due to his exchange narrowing. In the following ve shall try to explain this decrease on this point of view and estimate the magnitude of xchange integral.

Now, we assume that the effective exchange nteractions exist between magnetic ions. 'ollowing the method by Anderson and Weiss[12], the line width in simple cubic crystal on an isotropic average is given as

$$\Delta H^{M.sl.}=2\frac{H_d^2}{H_e^{eff}}\ ,$$

$$H_d^2=5.1\ (g\beta n)^2\ S(S+1)\ ,$$

$$H_e^{eff}=\sqrt{2.83}\quad\frac{J^{eff}}{g\beta}\quad\sqrt{S(S+1)}\ ,$$

where the line shape is again assumed to be gaussian. H_d means the field of the dipole interaction, H_e^{eff} means the field of the effective exchange interaction and J^{eff} is an effective exchange integral to be discussed below.

The density of spins n is translated to mole percent of $MgFe_2O_4$ or $ZnFe_2O_4$, x, by

$$n=\frac{16x}{a^3}\ ,$$

where a is the lattice constant.

It is found in this experiment that H_d increases in proportion to x and after the exchange narrowing begins at $H_d\approx H_e^{ff}$, H_d^2/H_e^{ff} decreases as x increases. So H_e^{eff} must be a function of the third or higher power of x.

Now, we assume

$$J^{eff}=\alpha Jx^3\ ,$$

where α is a proportional constant and J is an exchange integral between valence electrons of adjacent magnetic ions. In accordance with the kind of sites occupied by magnetic ions, J means J_{AA}, J_{AB} and J_{BB}, and corresponds to the exchange integral used in pure ferrites.

The values of $\Delta H^{M.sl}$ calculated according to this assumption are also given in Figs. 1 and 2 in broken lines, taking 9.45×10^5 oersteds and 1.36×10^4 oersteds as $\alpha\frac{J}{g\beta}$ for Mg(Al, Fe)$_2$O$_4$ and Zn(Al, Fe)$_2$O$_4$, respectively. In spite of rough assumptions used of the simple cubic crystal, the calculated curves show considerable agreements with the experimental curves.

The meaning of J^{eff} will be considered next and the value of α will be estimated. Then, the Curie temperatures estimated from the J values obtained in such a way shall be compared with the experimental Curie temperatures of Mg- and Zn-ferrites.

The number of pairs between magnetic ions is $n(n/N)^2z$, where n is the number of magnetic ions, N is the total number of sites which can be occupied by the magnetic ions, and z is the number of the nearest neighbours. It is assumed that a magnetic ion occupies a lattice point independently and the probability is n/N. As the energy of exchange interaction per pair is $2JS(S+1)$, the total energy of a magnetic system is given by

$$2JS(S+1)n(n/N)^2z$$

Then, a single lattice point has the energy of $2JS(S+1)(n/N)^3z$ on an average.

In order to compare the case of dilluted magnetic ions with the case of undiluted ions treated by Anderson *et al*, the following concept is introduced. All lattice points are occupied by magnetic ions with quantum number S, and are placed in the effective field of exchange interaction H_e^{eff}, so the energy per one lattice point is $g\beta H_e^{eff}\sqrt{S(S+1)}$. If this energy is assumed to be the same as the energy obtained in the case of diluted magnetic ions, the effective exchange integral is given by J as follows, using H_e^{eff} by Anderson.

$$J^{eff}=\frac{2}{\sqrt{2.83}}zJ\left(\frac{n}{N}\right)^3=\frac{2}{\sqrt{2.83}}zJx^3 .$$

If we set z equal to six for consistency with our previous assumption of simple cubic lattices, α is calculated as 7.15. Using this value of α, $J/g\beta$ are calculated to be 1.32×10^5 and 1.90×10^3 oersteds in $MgAl_2O_4$ and $ZnAl_2O_4$, respectively. These values of J seem to correspond to the exchange integrals between A- and B-sites and between B- and B-sites, respectively.

Using the relation between the Curie temperature and the exchange integral in simple cubic lattices, $k\theta=\frac{2}{3}JzS(S+1)$, the Curie temperature of Mg- and Zn-ferrites can be estimated at 620°K and 9°K from the value of J obtained above.

The Curie temperature of Mg-ferrite was reported as 713°K by Gorter[10] and the Néel point of Zn-ferrite as 9°K by Corliss[14]. In spite of the rough assumption of exchange narrowing, our values show surprising agreements with these obtained by Gorter and Corliss. So the values of exchange integral estimated above are thought to be satisfactory.

Using the same methods, the value of exchange integral of Mn^{2+} ions in A- and A-sites is estimated to be 1.90×10^2 oersteds and the Curie temperature is expected to be 0.9°K in $MnAl_2O_4$.

§4. Summary

The variation of line widths of paramagnetic resonance absorption with the concentration of Fe^{3+} ions in $MgAl_2O_4$ and $ZnAl_2O_4$ are observed and explained by the dipole-dipole and exchange interactions.

The cubic crystal field splitting parameter a of Fe^{3+} ion are estimated to be 1.0×10^{-2} cm^{-1} and 3.1×10^{-2} cm^{-1} at the A- and B-sites, respectively. The ratio a_B/a_A is 3.1 and is explained by the potential due to point charge according to Geschwind, considering u-parameter of oxygen position. The value of $u=0.383$ gives the best fit for the ratio obtained in experiment.

The exchange integral between A- and B-sites and B- and B-sites are obtained. The values are $J_{AB}/g\beta=1.32\times10^5$ Oe and $J_{BB}/g\beta=1.90\times10^3$ Oe, and the Curie temperature of Mg-ferrite and the Nèel point of Zn-ferrite estimated from the values of J are in good agreement with the experimental ones.

On Mn^{2+} ions in $ZnAl_2O_4$ the values of a and $J_{AA}/g\beta$ are obtained to be 1.2×10^{-3} cm^{-1} and 1.90×10^2 Oe. The Curie point of $MnAl_2O_4$ is estimated to be 0.9°K.

The author would like to express his gratitude to Dr. G. M. Hatoyama for his kind encouragement. I am also indebted to Dr. K. Yoshida and T. Mitsuma for the many helpful discussions and Mr. A. Nakamura for the measurement.

Characteristics of Germanium *p-n* Junction with Irregular Structure

By Masami TOMONO

Central Research Laboratory, Hitachi, Ltd.
Kokubunji, Tokyo, Japan

(Received March 9, 1960)

A transistor was made with an imperfect emitter junction having an irregular structure made by applying a very thin indium layer on an *n* type germanium pellet and a comparatively perfect collector junction having regular structure. The current flowing into the imperfect emitter was divided into various components, and the voltage-current characteristics of each component was studied. Among these, a particular attention was paid on the electron current component which flows through the minute area of the *m–n* junction existing at the irregular part of the *p–n* junction. From these studies the phenomena of the voltage-current characteristics of the emitter differing greatly from the Shockly Equation, the abnormally strong current dependency of the current amplification factor of the transistor, and the floating-potential of the emitter are explained.

1. Introduction

Considerable research has been carried out eretofore concerning the electrical properties f the comparatively perfect *p-n* junction made y alloying indium on *n* type germanium. And it is well known that its electrical properties follow the Shockley Equation quite losely(1)(2). However, it is also known that, n the case of an actual *p-n* junction, there re many defects around the edge and a large everse current flows through these area(3). is known from experience that, even when e edges are removed by careful electrolytic ching process(4)(5), a large reverse current ill persists in some cases and thus the elerical properties do not conform with the ockley Equation. This is probably due to regular structure at parts other than the dge of the *p-n* junction. There have been any reports dealing with such irregular structure, but the direct relation between such ructure and the rectifying characteristics has ot been explained very clearly. In order to arify the electrical properties of a *p-n* juncon having such an irregular structure, the thor made a transistor with a very imperct *p-n* junction by alloying a very thin indin layer on the surface of an *n* type geruma- um pellet to serve as the emitter and a perct *p-n* junction by alloying a sufficiently ick layer of indium on the other surface of the pellet to serve as the collector. The forward and reverse characteristics of the transistor were then measured. The current flowing through the imperfect emitter junction was divided into many components in an attempt to examine the phenomenon of the great deviation of the voltage current-characteristics from the Shockley Equation.

§ 2. Method of Experiment

p-n junctions were made by alloying indium layers of $15\,\mu\sim200\,\mu$ in thickness and diameter of approximately 0.8 mm on *n* type germanium having a $2.55\,\Omega$cm resistivity. Thin indium layers of $20\,\mu$ or less were applied on the germanium by vacuum evaporation. A spacer and weight were used in order to prevent spherical coagulation due to surface tension and to insure the uniform alloying of the indium over the prescribed area when the indium layer is thin. The maximum temperature of alloying is 515°C. In the first experiment, after alloying indium on only one surface of the germanium pellet, the indium was amalgamated by the ordinary method using mercury and this amalgam was removed by using nitric acid. The recrystallized layer of *p* type germanium thus exposed was observed with a microscope. On the other hand, the cross section of the germanium pellet was made and polished to study the structure of the *p-n* junction. The relationships between the thickness of the indium layer and the electrical properties of the rectifiers of the *p-n* junctions made in this manner were investigated. Next, in order to investigate the cause and characteristic of the excess current of an imperfect *p-n* junction having a thin indium layer, thansistors of the type shown in Fig. 1 were made with various alloyed indium thickness for the emitter and sufficient indium thickness for the collector.

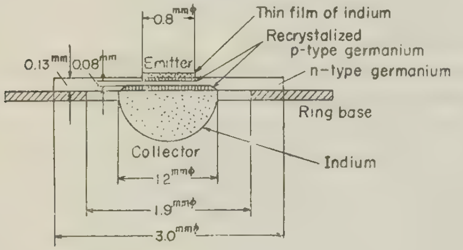

Fig. 1. Dimensions of the transistors used in the experiment.

The measurements were made after removing the imperfect *p-n* junction around the edge of the collector dot by ordinary electolytic etching(4)(5). The forward and reverse currents flowing through the emitter, collector and base electrodes as well as the emitter's floating potential when reverse bias is applied on the collector and the current amplification factor of the transistor were measured.

§ 3. Experimental Results

3.1 *Microscopic observation*

The results of observation of the surface of the recrystalized *p* type germanium layer exposed after the removal of the indium through amalgamation with mercury, are shown in Fig. 2.

It can be seen that the *p* type germanium and *n* type germanium exist in mossaic form when the indium layer is thin. In order to ascertain this finding, a heated tungsten needle was applied along the diameter of the recystallized germanium layer part of a specimen with indium thickness of 20 μ, and the polarity (+) (−) of the thermo-electromotive force was determined. The polarity of the electormotive force would be different depending whether the part with which the needle is in contact is *p* type or *n* type. The results are shown in Fig. 3. From this results, it can be seen that *n* type germanium remained unchanged at the parts of the plaits of figure 2 (A) sample.

Next, Fig. 4. shows the results of observation of the cross section of the *p-n* junction obtained by polishing the pellet at an angle of about 10° to the surface. As shown in Fig. 4 (A) when the thickness of indium is 30 μ, the *p* layer is very irregular and there are some parts where the *p* layer has not been formed. When the indium layer is 60 μ, Fig. 4 (B), the *p* layer becomes more regular, but the *p-n* boundary shape is still irregular. In constrast, when the indium layer is 200 μ, Fig. 4 (C), the *p-n* boundary is formed completely but there are some irregular parts along its edge.

Next, a specimen was made by alloying a thick indium layer on *n* type germanium. When the irregular part around the edge of this specimen's *p* layer was examined, it was found that fine line shaped and dot shaped indium was left in the *p* type germanium layer and that these indium streaks and dots were in direct contact with the *n* type germanium base. One such example is shown in Fig. 5. The size of the remaining indium streaks

ndicated by the arrow marks in the Figure re about 10 μ, but the tip of the streaks hich are in dierect contact with the n type ermanium base are about 1 μ in diameter. he Figure also shows indium left in dot orm which directly contacts the germaniun ase.

2 *Relation between indium layer thickness and p-n junction characteristics*

Voltage-current characteristics were measu- ed for p-n junctions made by varying the ickness of the indium layer over the range of 15 μ~200 μ. Fig. 6 shows the relation between the current density and the thickness of the indium layer obtained for many specimens by applying a reverse voltage of

-6 V. It can be seen that, when the indium layer thickness becomes less than 30 μ, the reverse current flowing through the junction increases quite rapidly.

3.3 *Forward characteristics of transistor's emitter, collector and base*

The transistors used for these measurements were constructed with collector having the alloyed indium layer of sufficient thickness, and the emitter having the indium layer of various thickness. The voltage-current relations of the transistor's collector and base were measured while the bias of -6 V was applied on the collector and the emitter was variously biased in forward direction.

Table I. Indium layer thickness of emitter of specimens

Specimen	Thickness of indium larger
No. 1	200 μ
No. 2	60
No. 3	20
No. 4	30
No. 5	15

The thicknesses of the indium layers of the specimens used in this experiment are given in Table I. Fig. 7 shows the realtion between the emitter voltage and emitter current.

The relation between voltage V and current I can generally be expressed by the following equation.

$$I=I_0\{\exp(\beta V)-1\} \quad (1)$$

When the value of β in the above equation is obtained directly from the incline of the curve in the 100~150 mV range, it is near 40 Volt^{-1} for the specimens No. 1 and No. 2. This value is near $8/kT$ at normal temperature. Here q is the electron charge, k is Boltzmann's constant and T is the absolute temperature. But, in the cases of No. 4 and No. 5, the value is somewhat smaller. All these values are listed in Table II.

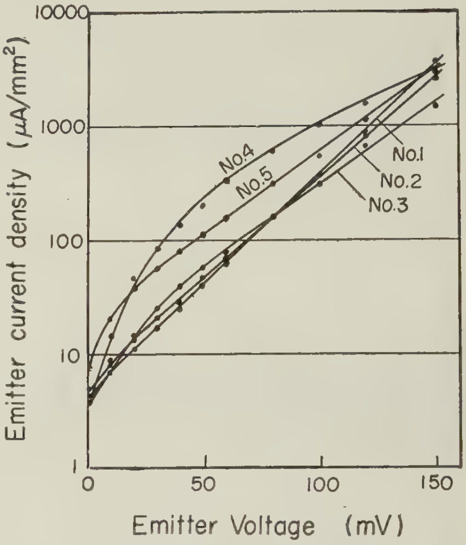

Fig. 7. Relation between emitter voltage and emitter current when emitter bias is positive and collector bias is negative (collector bias, -6V)

It is noted that for the specimens No. 4 and No. 5 the absolute values of the current in the relatively low voltage range (below 0.1 volt) is much larger than those obtained for No. 1, No. 2 and No. 3 The collector currents under the same bias

Table II. Constants for the emitter, collector and base when emitter bias is positive and collector bias is negative (collector bias, -6V)

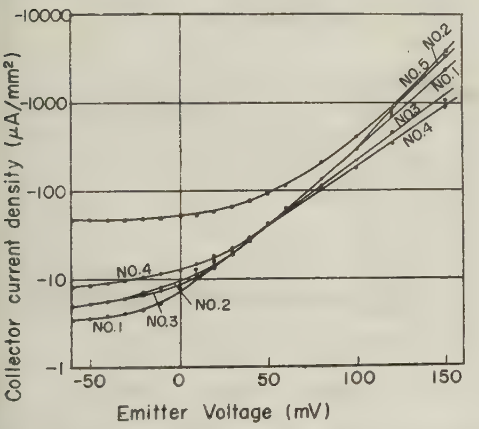
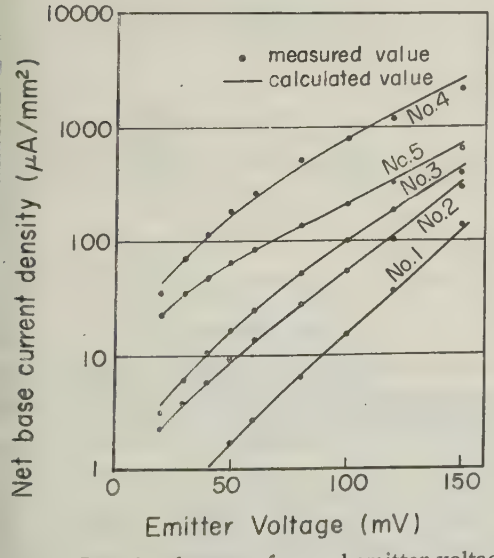
* β was not determined because V~log I curve had no linear part.

nditions are given in Fig. 8. Comparison Fig. 8 with Fig. 7 shows that, in case of). 1, No. 2 and No. 3, the general trend of e collector current is quite similar to that the emitter current. In the cases of No. and No. 5, the values of β obtained in the nge of 100~150 mV are somewhat smaller an these of the former three. These values e given in Table II. For the case of No. 5 e amount of the current in the low voltage nge is about twice as large as those of No. No. 2, No. 3 and No. 4.



ig. 8. Relation between forward emitter voltage and rollector current when emitter bias is positive and collector bias is negative (collector bias, -6V)



ig. 9. Relation between forward emitter voltage and net base current when emitter bias is positive and collector bias is negative (1) (collector bias, -6V)

Fig. 9 shows the relation between the forward emitter voltage and the net base current I_B+I_{CSO}, where I_B is the base current under the same condition and I_{CSO} is the collector cut-off current. In this case, contrary to the results shown in Fig. 7 and Fig. 8, the absolute value of the current changes greatly from one transistor to another. The base current of No. 1 is very small but those of No. 4 and No. 5 are about 10 times as large. As for the value of β, it is difficult to obtain for No. 4 because there is no linear part in the curve, and in case of No. 5, the value is very small. These results are given in Table II.

Furthermore, in order to examine the base current, the $V_B\sim(I_B+I_{CSO})$ relation is given by linear scale in Fig. 10. (V_E is the emitter voltage.) A distinctive feature is that the low voltage parts of the curves are straight lines.

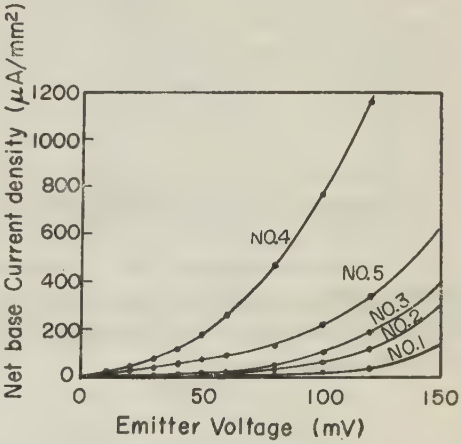


Fig. 10. Relation between forward emitter voltage and net base current when emitter bias is positive and collector bias is negative (2) (collector bias, -6V)

3.4 *Reverse characteristics of emitter and collector*

Fig. 11 shows the voltage-current characteristics obtained when the collector was biased at -6 V and reverse various voltage was applied on the emitter. In the cases of specimens No. 1 and No. 2, the absolute value of the current is small and the current saturates when the voltage becomes high, while, in the case of No. 3, the current shows no saturation characteristics. In cases of No. 4 and No. 5, the absolute value of the current is extremely large and it increases gradually with the increase of the applied voltage.

Fig. 12 shows the relation between the collector voltage and collector current when a negative bias of -6 V was applied on the emitter and the collector was variously biased in the reverse direction. The reverse currents of No. 1, No. 2 and No. 3 are small as in the case of Fig. 11, but the reverse current of No. 4 is 2~3 times larger and that of No. 5 is much greater. In contrast to the aforementioned case of the emitter, all specimens showed current saturation characteristics.

Fig. 13 shows the characteristics when the emitter voltage is low in Fig. 11. In this case, the currents of specimens No. 1, No. 2, No. 3 and No. 4 show saturation characteristics, but the rise of the curve of No. 5 is very slow and shows no saturation characteristics.

Fig. 14 shows the characteristics when the collector voltage of Fig. 12 is low. In comparison to Fig. 13, the absolute value of the current is small but the general tendency is the same.

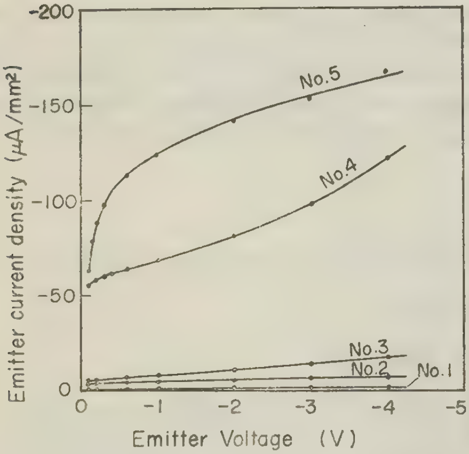

Fig. 11. Reverse characteristics of emitter when collector bias is negative and sufficiently large (1) (collector bias, -6V)

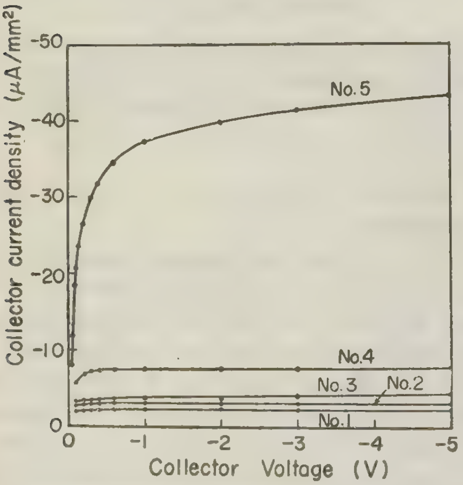

Fig. 12. Reverse characteristics of collector when emitter bias in negative and sufficiently large (1) (collector bias, -6V)

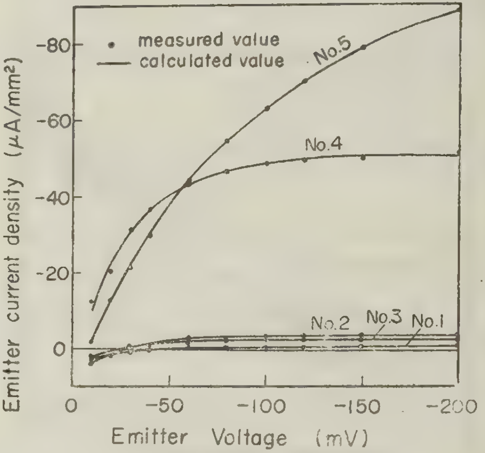

Fig. 13. Reverse characteristics of emitter when collector bias is negative and sufficiently large (2) (collector bias, -6V)

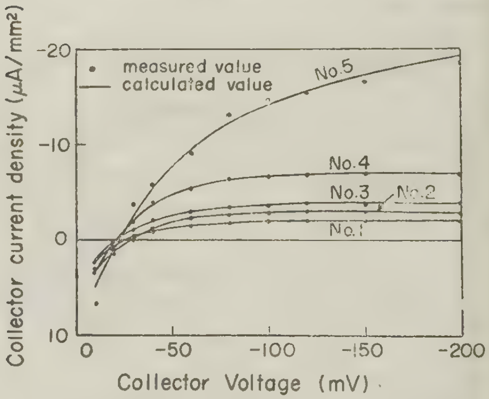

Fig. 14. Reverse characteristics of collector when emitter bias is negative and sufficiently large (2) (collector bias, -6V)

3.5 *Current amplification factor*

Fig. 15 shows the relation between the emitter current and current amplification factor α_{oe} when the collectors of these transistors are biased at -6 V. In case of No. 1 which has a complete emitter, the current mplification factor α_{ce} is practically constant, respective of the emitter current. But, in e cases of No. 4 and No. 5 whose emitters re incomplete, the absolute value of α_{ce} is mall and depends quite heavily upon the mitter current. It has been known that the $_{ce}$ of silicon transistors is highly dependent n the emitter current(7)(8), and the compara-vely smaller dependency of α_{ce} of germa-ium transistors in the range of low emitter urrents has also been known(9). However, uch a strong current dependency of α_{ce} of ermanium transistors was little known eretofore.

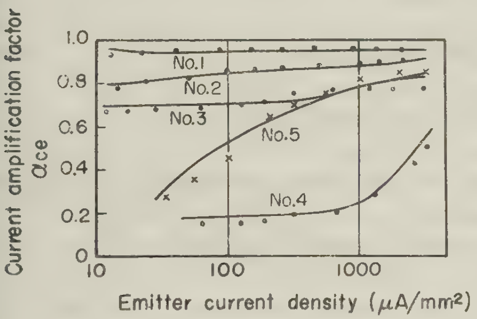

Fig. 15. Relation between emitter current and amplification factor
(●, × measured value, ——computed value)

Table III. Measured value and computed value of floating potential

Speci-men	Measured value of α_{ce}	Calculated V_f value from Eq. (25)	Calculated V_f value from Eq. (20)	Measured V_f value
No. 1	0.928	−66.9mV	−68.3mV	−67.0mV
No. 2	0.719	−32.3	−23.4	−28.1
No. 3	0.646	−26.4	−17.8	−21.2
No. 4	0.139	− 3.81	− 2.41	− 2.86
No. 5	0.171	− 4.77	− 5.19	− 7.43

.6 *Floating potential of emitter*

Table III shows the results obtained by mea uring the floating potentials which were in uced between the emitter and base when he collector was biased at −6 V. The magni udes of the floating potentials are in the ame order as the α_{ce} values in Fig. 15. A oteworthy point is that the floating potantials f No. 4 and No. 5 are very small.

§ 4. Discussion

The results of the foregoing experiments clarified that *p-n* junctions made by alloying a thin indium layer on *n* type germanium have irregular structure whereby the rectifying characteristics and transistor characteristics are abnormal. The relation between the structure and abnomal electrical properties of such *p-n* junctions shall be discussed in the following.

4.1 *Irregular structure of p-n junctions*

As seen in Fig. 2, Fig. 3 and Fig. 4, *p-n* junctions made by alloying a thin layer of indium on germanium have locally well grown and undergrown *p* type germanium parts mosaically on the lower side of the indium layer. This condition is believed to be caused by the different conditions, in which the indium wets the germanium during the initial period of alloying, probably due to the difference in the states of germanium oxide layer existing from the begining on the surface. Such phenomenon will not occur if sufficiently thick indium is alloyed. But, even in this case, a minute portion of indium may be left in the *p* type germanium and this may directly contact the *n* type germanium of the base as shown in Fig. 5. The model of the structure of a *p-n* junction having such an irregular structure is shown in Fig. 16. It may be supposed that such irregular structures will appear in the various forms listed below.

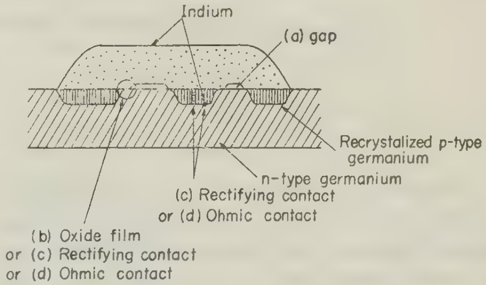

Fig. 16. Model diagram of the cross section of imperfect *p–n* junction

a. There is a gap between the indium and *n* type germanium base.

b. The indium and *n* type germanium are contacting via an insulating oxide film.

c. The indium and *n* type germanium base have a rectifying contact (called *m–n* junction hereafter).

d. The indium and n type germanium base have an ohmic contact.

e. An area having a large surface recombination velocity exists around the edge of any of the above irregular structures.

4.2 *Equations of the voltage-current characteristics of an irregular p-n junction*

By combining all the aforementioned results, the following equations can be given for the electrical characteristics of irregular p-n junctions. In these equations, both the voltage and current of the emitter and collector are expressed, respectively, as positive when they are in the direction going into the transistor from the electrode. In regard to the base electrode, the direction coming from the interior of the transistor towards the base electrode is expressed as positive.

The following equation can be obtained for the emitter current.

$$I_E = I_{Eo}\left\{\exp\left(\frac{qV_E}{kT}\right)-1\right\}+(I_{ESo}+I_{EMo})\left[\exp\left\{\frac{q(V_E-V_B)}{kT}\right\}-1\right]+I'_{EMo}\left[\exp\left\{\frac{q(V_E-V'_B)}{kT}\right\}-1\right]$$
$$-I_{Eo}\left\{\exp\left(\frac{qV_C}{kT}\right)-1\right\}+g_l V_E \qquad (2)$$

The following equation can be obtained for the collector current.

$$-I_C = I_{Eo}\left\{\exp\left(\frac{qV_E}{kT}\right)-1\right\}-I_{Eo}\left\{\exp\left(\frac{qV_C}{kT}\right)-1\right\}-I_{CSo}\left\{\exp\left(\frac{qV_C}{kT}\right)-1\right\} \qquad (3)$$

From equations (2) and (3), the following equation can be derived for the base current.

$$I_B = I_E + I_C = (I_{ESo}+I_{EMo})\left[\exp\left\{\frac{q(V_E-V_B)}{kT}\right\}-1\right]+I'_{EMo}\left[\exp\left\{\frac{q(V_E-V'_B)}{kT}\right\}-1\right]$$
$$+I_{CSo}\left\{\exp\left(\frac{qV_C}{kT}\right)-1\right\}+g_l V_E \qquad (4)$$

where:

$$I_{Eo} = A_E q\frac{D_p p_o}{W} \qquad (5)$$

$$I_{ESo} = A_s q S p_o \qquad (6)$$

$$I_{EMo} = A_M q \mu_n n_o \left\{\frac{q(V_{Mo}-V_E)q\pi n_o}{K}\right\}^{\frac{1}{2}} \exp\left(-\frac{qV_{Mo}}{kT}\right) \qquad (7)$$

$$I'_{EMo} = A_M' q \mu_n n_o \left\{\frac{q(V_{Mo}-V_E)q\pi n_o}{K}\right\}^{\frac{1}{2}} \exp\left(-\frac{qV_{Mo}}{kT}\right) \qquad (8)$$

$$I_{CSo} = A_C q\frac{D_p p_o}{W'} \qquad (9)$$

In the above equations, V_E is the voltage between the emitter and base, V_C is the voltage between the collector and base, and g_l is the conductance corresponding to the emitter's leak current. I_{Eo} in the first term on the right side of equation (2) is the saturation current through the regular parts of p-n junction of the emitter. Equation (5) is the well known Shockley Equation(1). A_E is the area of the emitter junction. I_{ESO} in the second term on the right side of equation (2) is the saturation current due to the surface recombination around the emitter, and equation (6) is well known(1). A_S is the surface area at which the positive holes injected from the emitter recombine. The equation for A_S can be obtained by slightly modifying Webster's treatment(10) of a diode with a p-n junction having a diameter of a.

$$A_s = \pi\sqrt{\frac{WD_p}{2S}}\left(2a+\sqrt{\frac{WD_p}{2S}}\right) \qquad (10)$$

In regard to surface recombination at inperfact p-n junctions, it is necessary to consider not only around the edge but also around inperfect parts inside. Also, if area of high surface recombination velocity exist locally as in 4.1 (e), the effective value of A_S may ecome still larger.

I_{EMo} in the second term of equation (2) is he saturation current of the *m-n* junctions f compartively large area (diameter of larger han 1 μ) explained in 4.1 (c), and equation 7) is given by Schottky(11), where A_M is the otal area of such *m-n* junctions. In the same nanner, I_{EMo}' in the third term of equation 2) is the saturation current of the *m-n* juncions of small area (diameter of about 1 μ or ess) which have been explained in 4.1 (c). A_M' in equation (8) is the total area of such *n-n* junctions. The fourth term on the right ide of equation (2) is the current component lue to the extraction(2)(12) at the collector unction. The fifth term expresses the leak urrent due to the ohmic contact explained n 4.1 (d). I_{CSO} in the third term on the right ide of equation (3) is the collector's saturaion current. In the present case, the colector is considered to be a complete junction nd no excess current components are assumd. A_C in equation (9) is the area of the colector junction. V_B is the voltage drop due o internal resistance r_{bb}' of the germanium ase. V_B' is the voltage drop due to the spreading resistance through a small area. q is the electron charge, D_P is the diffusion oefficient of the positive holes in the *n* type ermanium, and p_o is density of the positive oles which are in the thermal equilibrium n the *n* type germanium. W is the base vidth between the emitter and collector, vhile W' is the effective base width consilered for the collector junction and generaly differs from W. S is the surface recombiation velocity of the positive holes. μ_n is he mobility of the electrons in the *n* type ermanium. n_o is the density of the electrons vhich are in the thermal equilibrium in the *n* type germanium. K is the dielectric consant of germanium, k is Boltzmann's constant, nd T is the absolute temperature. V_{Mo} is he so-called diffusion potential of the *m-n* unction. The irregular structure described n 4.1 (a) presents no problem because no urrent flows. The irregular structure descried in 4.1 (b) has not been taken into consileration in the foregoing treatment, but there s a possibility that reverse current may flow lue to tunnel effect or breakdown when the everse voltage becomes high.

4.3 *Equation for voltage-current characteristics of actual transistors*

For the actual cases undertaken by the author, the equations (2), (3) and (4) can be simplified further. We shall now consider the case where a sufficiently large negative bias is applied on the collector and a positive bias is applied on the emitter. Let us first consider the equation (2). The voltage V_B in the second term on the right side can be expressed as follows

$$V_B=(I_B+I_{CSO})r_{bb'} \tag{11}$$

r_{bb}' is the internal resistance of the transistor. As for the third term on the right side of equation (2), the voltage drop of the junction is comparatively small, while in comparison, the voltage drop due to the spreading resistance in the base germanium through the small *m-n* junctions, r_s, would be large. Therefore, it can be expressed as follows.

$$I'_{EMO}\left[\exp\left\{\frac{q(V_E-V_B')}{k\mathrm{T}}\right\}-1\right]$$
$$=\frac{V_B'}{r_s}\fallingdotseq\frac{V_E}{r_s} \tag{12}$$

The fifth term can be neglected. This is clearly seen by the fact that no leak current component is detected as shown in Fig. 11 and 13. In order to get the expression for the forward characteristics of the emitter, the above results are combined and equation (2) is replaced by the following.

$$I_E=I_{EO}\exp(\beta_E V_E)+(I_{ESo}+I_{EMo})$$
$$[\exp\{\beta_{ESM}(V_E-V_B)\}-1]+\frac{V_E}{r_s} \tag{13}$$

In this case, q/kT in the first term and second term on the right side of equation (2) are replaced by β_E and β_{ESM} respectively.

Next, in considering the collector current, if we assume V_C is negative and sufficiently large, equation (3) can be simplified as follows.

$$-I_c=I_{EO}\exp(\beta_E V_E)+I_{CSO} \tag{14}$$

As for the base current, equation (4) can be simplified as follows.

$$I_B=(I_{ESo}+I_{EMo})[\exp\{\beta_{ESM}(V_E-V_B)-1]$$
$$+\frac{V_E}{r_s}-I_{CSO} \tag{15}$$

When we consider the emitter's reverse characteristics applying a sufficiently negative bias upon the collector, V_B and V_B' can be neglected. In this case equation (2) can be expressed as follows.

$$I_E = I_{Eo}\exp(\beta_E V_E) + (I_{ESo} + I_{EMo} + I'_{EMo})\{\exp(\beta'_{ESM} V_E) - 1\} \quad (16)$$

In this case, q/kT in the second term and third term on the right side of equation (2) are replaced by mean value β'_{ESM}.

Next the collector's reverse characteristics, when a sufficiently large negative bias is applied, can be expressed as follows by simplifying equation (3).

$$-I_C = -I_{Eo}\exp(\beta_C V_C) - I_{CSo}\{\exp(\beta_{CS} V_C) - 1\} \quad (17)$$

q/kT in the second term and third term on the right side of equation (3) are replaced by β_C and β_{CS} respectively.

Current amplification factor α_{ce} can be expressed as follows from equations (13), (14), (15) and (11).

$$\alpha_{ce} = \frac{\partial I_c}{\partial I_E} = \frac{\beta_E I_{Eo}\exp(\beta_E V_E)}{\beta_E I_{Eo}\exp(\beta_E V_E) + \beta_{ESM}(I_{ESo} + I_{EMo})\exp\{\beta_{ESM}(V_E - V_B)\}\left(1 - r_{bb'}\dfrac{\partial I_B}{\partial V_E}\right) + \dfrac{1}{r_s}} \quad (18)$$

where:

$$\frac{\partial I_B}{\partial V_B} = \frac{\beta_{ESM}(I_{ESo} + I_{EMo})\exp\{\beta_{ESM}(V_E - V_B)\} + \dfrac{1}{r_s}}{1 + r_{bb'}\,\beta_{ESM}(I_{ESo} + I_{EMo})\exp\{\beta_{ESM}(V_E - V_B\})} \quad (19)$$

For the floating potential V_f, the value of V_E for $I_E = 0$ in equation (13) is equal to V_f. In this case β_E and β_{ESM} are expressed in the original form as q/kT respectively. This is permissible because β_E and β_{ESM} are almost equal to q/kT in all cases as will be explained later.

$$\exp\left(\frac{qV_f}{kT}\right) = \frac{I_{ESo} + I_{EMo}}{I_{Eo} + I_{ESo} + I_{EMo}} - \frac{V_f}{(I_{Eo} + I_{ESo} + I_{EMo})r_s} \quad (20)$$

4.4 *Analysis of the voltage-current characteristics*

In order to analyze the characteristics for the case where a sufficient large negative bias is applied upon the collector and a suitable positive bias is applied upon the emitter, Fig. 8 and Fig. 9 shall be compared respectively with equation (14) and equation (15). It should be possible to analyze I_E by using the relation $I_E = I_B - I_C$. From equation (14) we obtain the following.

$$-I_c - I_{CSo} = |I_c| - I_{CSo} = I_{Eo}\exp(\beta_E V_E) \quad (14)'$$

The values of $|I_C| - I_{CSo}$ are obtained from the results of Fig. 8 and the measured values of I_{CSo}. Fig. 17 shows the relation between V_E and these values of $|I_C| - I_{CSo}$. Differing from the relation of V_E and I_C in Fig. 8, each curve is nearly a straight line even into the region of negative V_E and their slopes are almost equal, satisfying equation (14)′ quite well.

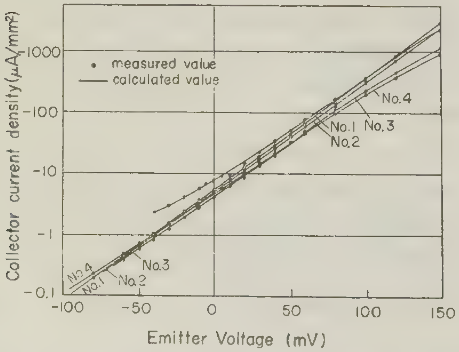

Fig. 17. Relation between V_E and $|I_C| - I_{CSO}$ when collector bias is negative and sufficiently large (collector bias, -6V)

Table IV. Various constants of equation (14)

Specimen	I_{CSO}	I_{EO}	β_E
	μA/mm²	μA/mm²	Volt⁻¹
No. 1	2.96	5.12	41.3
No. 2	4.67	4.94	40.5
No. 3	4.75	4.40	40.2
No. 4	8.02	4.86	36.6
No. 5	44.3	7.02	39.2

The measured values of I_{CSo}, and the I_{Eo} and β_E values obtained from Fig. 17 are shown in Table IV. The I_{Eo} value is reasonable nce it corresponds to the value where W in quation (5) is 0.1~0.07 mm. Since $q/kT=39.19$ olt^{-1} at 23°C, it can be seen that the values f β_E are very close to the theoretical one. $_E$ of No. 3, No. 4 and No. 5 are quite diffeent from those in Table II. Next, we shall onsider Fig. 9 in terms of equation (15). ccording to equation (15), it should be posible to obtain an approximate value of r_S rom the characteristics of the small current egion of the net base current I_B+I_{CSO} which ould be obtained when the collector cut-off urrent is added to the observed base current. he approximate values of r_S obtained from he slopes of the small current region in Fig. 0 are given in Table V.

Table V. Approximate r_s value obtained from minute current part of I_B+I_{CSO}.

No. 4	23.2	37.9	1.11	10.5
No. 5	2.45	38.6	0.987	12.4

Table VI shows the values of the three onstants, $(I_{ESo}+I_{EMO})$, β_{ESM} and r_S determined to best fit equation (15) to the curves in ig. 9. In this case, the values of V_B were btained from equation (11) using the experimental values of $r_{bb'}$. Fig. 9 also shows the esults obtained by computing the relation etween V_B and I_B+I_{CSO} using equation (15) ogether with these constants. As can be een the values thus calculated agree quite ell with the experimental results. It can also be seen that the r_S values in Table 5 are approximately equal to those given in Table VI. It is seen that the saturation current $I_{ESo}+I_{EMO}$ differs to quite a degree among these specimenns.

Next, we shall estimate the value of I_{ESo} using equations (6) and (10) When following values are assumed,

$W=0.008$ cm, $D_p=48.5$ cm^2/sec., $S=100$ cm/sec. and $a=0.056$ cm

we obtain the following from equations (6) and (10)

$$I_{ESo}=0.22\mu A \tag{21}$$

Consequently, the value of $I_{ESo}+I_{EMO}$ of specimen No. 1 in Table 6 can be considered as one in which the contribution from I_{ESO} predominates. In the cases of other specimens, when the indium becomes thinner I_{ESO} can be also supposed to become somewhat larger because of the increase in the effective values of A_S in equation (6) as seen from Fig. 2 and Fig. 4. Although the value of No. 4 is extremely large, it is probably due to the fact that the I_{EMO} value became large owing to formation of a relatively large *m*-*n* junction.

Next, we shall examine an *m*-*n* junction of small area. As explained in regard to Fig. 5 and Fig. 16, the diameter $\varDelta$ of a small area junction may be considered to be about 1 μ. If it is assumed that the existing number of such junctions is n/mm^2, r_S of equation (12) will be as follows.

$$r_S=\frac{M\rho}{2n\varDelta} \tag{22}$$

The current flowing in the base germanium from the emitter towards the base tab does not spread semi-infinitely but spreads only in the comparatively small solid angle which glances the base tab from the emitter. M is the compensating factor for this difference in spreading condition. For the present case, the ratio of this solid angle to the semi-infinitely spreading one is about 0.04. Assuming that the current flow will spread somewhat more than this, we shall approximate the value as $M=10$. When we consider specimens No. 4 and No. 5 as examples, the experimental values of their r_S are about 1000Ω. If $\rho=2.55\Omega$ cm and $\varDelta=1\,\mu$ in equation (22), we get; $n=130$. When the value of A_M' is computed using these values of n and $\varDelta$, and is substituted into equation (8) together with the following figures,

$n_o=6{,}28\times 10^{14}\mathrm{cm}^{-3}$(13) $T=295°K$, $\mu_n=3900\mathrm{cm}^2/\mathrm{sec.\,volt}$ $V_{Mo}=0.05$ volt, $K=16$,

$$\text{we get } I_{EMO}'=178\,\mu\mathrm{A/mm}^2 \tag{23}$$

And if we examine the case where $V_E=20$ mV;

$$V_E-V_B'=2.40\,\mathrm{mV}$$

Therefore

$$\frac{V_E-V_B'}{V_E}=0.120 \tag{24}$$

When V_E becomes larger than 20 mV, the above ratio will become still smaller, showing that the aproximate equation (12) is nearly correct. In the case of No. 4, although the value of $I_{ESo}+I_{EMO}$ is much greater than those of other specimens, the r_S Value is almost equal to that of No. 5. This is believed to be due to the fact that $I_{ESo}+I_{EMO}$ contains a current component which flows through a *m-n* junction of rather large area. In the cases of specimens No. 2 and No. 3, it can be assumed that n is several/mm². In the case of specimen No. 1, it may be considered that, practically there exist no such defect.

Next, the emitter's reverse characteristics when a sufficiently negative bias is applied on the collector and the collector's reverse characteristics when a sufficiently negative bias is applied on the emitter can be analyzed by comparison of Fig. 13 and 14 with equations (16) and (17) respectively. The values given in Table IV were used for β_E of the first term on the right side of equation (16). The value of I_{Eo} was determined for the range where V_E is small, and $(I_{ESo}+I_{EMO}+I_{EMO}')$ and β_{ESM}' were determined for the other range. The various constants obtained in this manner are listed in Table VII.

Table VII. Various constants obtained from the reverse characteristics of the emitter

Specimen	I_{EO}	$I_{ESO}+I_{EMO}$ $+I'_{EMO}$	β'_{ESM}
	μA/mm²	μA/mm²	Volt^{-1}
No. 1	5.12	0.45	42.4
No. 2	6.09	3.52	28.1
No. 3	4.54	2.44	38.4
No. 4	7.86	49.5	36.8
No. 5	10.0	105	9.12

Fig. 13 also shows the results obtained by computing the relation between V_E and I_E by using these constants. The computed values match the experimental results very well. Next, the collector's reverse characteristics can be analyzed by comparison of equation (17) and Fig. 14. The value given in Table 7 was used for the constant I_{Eo} in the first term on the right side of equation (17). The average of β_E and β_{ESM} in equation (13) was used for β_C. The other constants I_{CSO} and β_{CS} in equation (17) can also be determined. The values of these constants are listed in Table VIII.

Table VIII. Various constants obtained from the reverse characteristics of the collector

Specimen	I_{CSO}	β_C	β_{CS}
	μA/mm²	Volt^{-1}	Volt^{-1}
No. 1	2.17	41.9	42.8
No. 2	3.00	40.0	40.0
No. 3	3.95	38.2	36.5
No. 4	7.03	37.3	38.1
No. 5	21.5	38.9	10.7

Fig. 14 shows the results of the voltage-current characteristics computed by using these constants. They agree with the experimental results very well. These results shall now be discussed. In the cases of No. 1, No. 2 and No. 3, the I_{Eo} values in Table VII obtained for the reverse characteristics of emitters are about equal to those in Table IV obtained for the forward characteristics, but in the cases of No. 4 and No. 5, the formers are about 40~50% larger than the latters. This, as will be explained below, is believed to be the results of a condition in which a portion of the positive holes produced near the imperfect junction flow into the emitter instead of flowing as the collector's cut-off current, (I_{CSO} in equation (17)), when the sufficiently large negative bias is applied on the collector and suitable smaller negative bias is applied on the emitter. As the collector junction can be considered to be complete, I_{CSO} in Table VIII which is the saturation current of the collector junction may be mainly a positive hole current through the collector junction owing to the generation of hole-electron pairs at the germanium surface and the ohmic contact etween the base tab and germanium. In he case of specimens No. 4 and No. 5 whose mitter junctions are much more irregular, his value is quite high. As mentioned above ı respect to I_{EO}, this high value is believed ɔ be the result of a condition where the ositive holes appearing near the emitter unction are not all collected into the emitter, ut some of them flow into the collector vhen the sufficiently large negative bias is pplied on the emitter and a suitable smaller egative bias is applied on the collector. uch mutual effect of the emitter and collector as been known heretofore, to a certain exent(10)(11).

The value of I_{EMO}' can be obtained by comaring the values of $I_{ESo}+I_{EMO}+{}_{EMO}'$ in Table II with the value of $I_{ESo}+I_{EMO}$ in Table VI. he values of I_{EMO}' obtained by this method re given in Table 9.

Table IX. I_{EMO}' values

Specimen	I'_{EMO} μA/mm^2
No. 1	0.22
No. 2	2.52
No. 3	−0.16
No. 4	26.3
No. 5	103

$_{EMO}'$ of specimen No. 5 nearly matches the he value 178 μA/mm^2 of equation (23). As or specimen No. 4 I_{EMO}' less matches equaion (23) but when we consider that equation 23) is only an order estimation, the agreenent of this degree is what one can hope for. ince the measurements for Table VI and Table were made on different days, some change ı the surface conditions resulting in the uctuation of I_{ESo} could not be avoided. This probably the reason why I_{EMO}' of No, 3 ecame slightly negative. The same can be aid for No. 2, but the value of 2.52 μA/mm^2 iven for I_{EMO}' can be believed to be correct ithin an order. According to equations (22) nd (8), r_S is inversely proportional to n, the umber of the m-n junctions of small area, ut I_{EMO}' should be proportional to n. It can e seen from Table VI and Table IX that r_S nd I_{EMO}' of specimens No. 1, No. 2, No. 4 nd No. 5 are roughly inversely proportional each other. As it can be assumed that the collector junctions of all specimens are complete, β_C of equation (17) is expected to be near the value of q/kT and in this respect the values in Table VIII are reasonable. β_{ESM}' in Table VII seems smaller than q/kT when $I_{EMO}'/(I_{ESo}+I_{EMO}+I_{EMO}')$ is large, i. e. when there is a large percentage of reverse current passing through the m-n junctions of small area in the second term of the right side of equation (16). The values of $I_{EMO}'/(I_{ESo}+I_{EMO}+I_{EMO}')$ are given in Table X.

Table X. Values of $I'_{EMO}/(I_{ESO}+I_{EMO}+I'_{EMO})$

Specimen	$I'_{EMO}/(I_{ESO}+I_{EMO}+I'_{EMO})$
No. 1	0.49
No. 2	0.72
No. 3	——
No. 4	0.53
No. 5	0.93

In respect to No. 5 for which this ratio is very near 1 in Table X, the β_{ESM}' in Table VII has a very small value of 9.12 Volt^{-1}. In respect to specimen No. 2 for which this ratio is 0.72, the β_{ESM}' value in Table VII is 28.1 Volt^{-1}. These values are much smaller than q/kT. The above results show that the rectifying effect of small area m-n junction is very incomplete and the value of β becomes much smaller than q/kT. It has been known that, if the contact between n type germanium and indium metal is complete, β will be near the value of q/kT(15). Since a rather large m-n junction probably corresponds to this case being discussed, the β_{ESM} of all specimens in Table VI may have approximately q/kT value whereas the small area m-n junctions, possessing imperfect contact, probably have smaller β values as stated before. In respect to β_{CS} in Table VIII, the positive holes generated near the imperfect structure part of the emitter junction can be considered to have a large effect for those specimens having a large I_{CSO} value, as explained previously concerning I_{CSO} in reference to equation (17). Then if we assume that most of such positive holes are drawn to the emitter due to the sufficiently large reverse bias of the emitter and only a small portion flows as the collector's reverse current and that it does not increase much with the increase of the collector's reverse voltage, it can be understood why the β_{cs} value of specimen No. 5 is very small.

Lastly Fig. 11 shows that with the increase of the emitter's reverse voltage, the current of the specimens No. 1 and No. 2 is approximately saturated but that of No. 3 gradually increases despite of the fact that the comparison of the characteristics of the specimens No. 1, No. 2 and No. 3 in Table VII shows little difference. Also in the cases of No. 4 and No. 5, the current increases with the increase of emitter voltage. Such increase of current is believed to be caused, not by the aforementioned surface recombination or *m-n* junctions, but by the irregular structure of the *p-n* junction due to the thinness of the indium layer as indicated in Fig. 4. This reasoning is certified by the fact that the reverse current increases rapidly when the indium layer becomes less than 30 μ in Fig. 6. This condition is believed to occur when the indium and *n* type germanium are contacting via an insulation film of oxide, etc. and the increase in the voltage results in the increase of the current flow through this part due to tunnel effect or local breakdown. On the other hand, because of the absence of such irregular structure of the collector junction, the reverse currents of all specimens are saturated with the increase of collector voltage in Fig. 12.

4.5 *Current amplification factor*

Fig. 15 shows the computed results of the dependency of the current amplification factor, α_{ce}, upon the emitter current by using the constants given in Tables IV and VI for equation (18). The results show that the measured values and computed values agree relatively well. In the cases of such transistors as No. 4 and No. 5 whose emitters are incomplete and r_S values in Table VI are small; α_{ce} has a very small value when the emitter's forward voltage is low and the emitter current is small, because the current flowing through r_S is comparatively larger than the current flowing through a normal *p-n* junction. However, when the emitter voltage becomes comparatively high the positive hole current through the emitter's *p-n* junction increases as an exponential function of the voltage while the current due to r_S is of a linear function and consequently the ratio of the current through r_S to that of the positive holes becomes gradually small and α_{ce} approaches to unity. In the case of specimen No. 1 which has a practically perfect emitter junction, α_{ce} has a constant value.

4.6 *Floating potential*

The floating potential of the emitter, when a sufficiently large reverse bias is applied on the collector, has been known to satisfy the following relation⁽²⁾.

$$V_f=-\frac{kT}{q}\log(1-\alpha_{ce})$$ (25

The value of α_{ce} when $I_B \to 0$ should be used for equation (25). Table III gives the α_{ce} values measured when $I_B=1\ \mu$A and the floating potentials computed from equation (25) by using these values. The table also gives the V_f values derived from equation (20) and the V_f values obtained by measurement. When we compare the V_f obtained by equation (20 and the V_f obtained from equation (25) in the Table, the former is closer to the measured value in the case of specimens No. 4 and No 5 whose r_S are small.

The author wishes to thank Mr. T. Tokuyama and Mr. K. Uehara for their aid in the experiments.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 15, No. 7, JULY, 1960

Note on the Field Dependence of the Mobility in Semiconductors

By Masumi HATTORI
Department of Physics, University of Nagoya
and Hisanao SATO
Research Department, Wireless Division, Matsushita
Electric Industrial Co. Ltd., Kadoma, Osaka

(Received March 19, 1960)

By assuming that the mobility μ can be expanded in powers of the field strength F as $\mu=\mu_0(1-\nu F^2)$, ν is calculated for non-polar and polar semiconductors. The electron-electron interactions are neglected completely and the Boltzmann equation is solved by means of the variation method. It is shown that ν calculated in this way differs significantly from that calculated in the previous paper and in Stratton's particularly at low temperatures. The electric field dependence of the Hall coefficient is also estimated.

1. Introduction

One of the authors investigated the electric
eld dependence of the electron mobility in
-Ge in the preceding paper(1), which we shall
all I in this paper. There was assumed the
oltzmann distribution which was displaced a
onstant magnitude in the direction of the
lectric field in momentum space. But in low
lectron density, the electron-electron interac-
ion may be so weak that the above assump-
ion seems to be wrong. In this paper we
alculate the mobility of electrons in semi-
onductors neglecting the collisions between
lectrons. The Boltzmann equation will be
olved by means of the variation method(2),
hich is shown to be useful at high electric
eld even in the presence of the static magne-
c field. The variational approach to the
igh field problem is also proposed by
dawi(3).

At relatively low field, the mobility μ can
e expanded in powers of the field strength
as follows:

$$\mu=\mu_0(1-\nu F^2). \tag{1}$$

In this paper we evaluate the coefficient ν,
ough the method is applicable to cases of
arbitrary field strength. In §2 the value
ν for n-Ge is compared with that calcula-
d in I. The mobility for non-polar semi-
nductors was investigated by Yamashita(4)
a different way. It is shown in §3 that
e Hall coefficient of n-Ge, where the spheri-
l energy surface is assumed, decreases sli-
ghtly with the electric field strength. The field dependence of the Hall coefficient is found to be sensitive to the scattering mechanism(5). In §4 the mobility in polar semiconductors is computed and compared with the calculation of Stratton(6).

§2. Non-Polar Semiconductors

In I the rate of the change of the electron distribution due to electron-phonon interactions in n-Ge was investigated. Letting the electric field be directed in x axis, we assume here that the electron distribution function $f(\boldsymbol{k})$ in the following from:

$$f(\boldsymbol{k})=f_0(w)+k_x\chi(w), \tag{2}$$

where w is the energy of an electron E divided by k_0T (k_0, the Boltzmann constant). As shown in Appendix A, the Boltzmann equation is separated into two equations, (3) and (4),

$$-w^{3/2}\frac{d}{dw}(e^{-w}g)=e^{-w}w^{3/2+n}c(w), \tag{3}$$

$$-M\frac{d}{dw}(w^{3/2}e^{-w}c)=e^{-w}L_N[g], \tag{4}$$

$$f_0(w)=e^{-w}g(w), \tag{5}$$

$$\chi(w)=-\frac{e\hbar F}{mk_0T\xi q}e^{-w}c(w), \tag{6}$$

where M and $L_N[g]$ are defined by (A11) and (A10) respectively, and n, ξ, and q the constants which may depend on temperature. Changing the sum over $\boldsymbol{k}$ to an integral

$$\sum_k \to A\int w^{1/2}dw,$$

the electric current density j is given by, using (2) and (6),

$$j=\frac{2e^2FA}{3m\xi q}\int_0^\infty w^{3/2}e^{-w}c(w)dw. \tag{7}$$

Let N be the number of electrons per unit volume, and it follows that

$$N=A\int w^{1/2}e^{-w}g(w)dw. \tag{8}$$

We expand $g(w)$ and $c(w)$ in terms of electric field F up to the second order

$$g(w)=g_0\{1+g_1(w)\}, \tag{9}$$

$$c(w)=c_0(w)+c_1(w), \tag{10}$$

where g_0 and c_0 are independent of F, and g_1 and c_1 are propotional to F^2. In the first approximation, $g=g_0$ and $c=c_0$, we have from (8)

$$Ag_0=N/\Gamma(3/2), \tag{11}$$

where $\Gamma(n)$ is the gamma function.

From (3) we get

$$c_0(w)=g_0w^{-n} \tag{12}$$

so that, corresponding to c_0, j_0 is given by, using (7) and (11),

$$j_0=\frac{Ne^2F}{m\xi q}\cdot\frac{\Gamma(5/2-n)}{\Gamma(5/2)q}, \tag{13}$$

and the zero-field mobility μ_0 becomes

$$\mu_0=\frac{e}{m\xi q}\cdot\frac{\Gamma(5/2-n)}{\Gamma(5/2)}, \tag{14}$$

In the next approximation g_1 is obtained by replacing c by c_0 in (4), namely

$$e^{-w}L_N[g_1]=-M\frac{d}{dw}(e^{-w}w^{3/2-n}). \tag{15}$$

As to the properties of L_N, the symmetry relation

$$\int e^{-w}h(w)L_N[g(w)]dw=\int e^{-w}g(w)L_N[h(w)]dw$$

and the inequality

$$\int e^{-w}gL_N[g]dw\geq 0$$

are easily proved, so we can apply the variation method to solve the equation (15). Expanding g_1 in powers of w

$$g_1=\sum_{r=0}^{\infty}b_rw^r, \tag{16}$$

it can be shown that the coefficients b_r ($r\geq 1$) satisfy the infinite set of linear equations(2)

$$\sum_{s=1}^{\infty}l_{rs}b_s=\alpha_r,\quad (r=1,2,\cdots) \tag{17}$$

where

$$l_{rs}=\int e^{-w}w^rL_N[w^s]dw,$$

$$\alpha_r=-M\int w^r\frac{d}{dw}(e^{-w}w^{3/2-n})dw. \tag{18}$$

b_0 is determined by the condition

$$\sum_{\mathbf{k}}e^{-w}g_1(w)=0, \tag{19}$$

which follows from the definition of g_0, (11).

From Eqs. (3), (9), (10) and (12) we have

$$w^{3/2}e^{-w}c_1(w)=-g_0w^{3/2-n}\frac{d}{dw}(e^{-w}g_1) \tag{20}$$

Let j_1 be the current density due to c_1, then we get from (7) and (20)

$$j_1=\frac{Ne^2F}{m\xi q\Gamma(5/2)}\left(\frac{3}{2}-n\right)\left\{\sum_{r=0}^{\infty}b_r\Gamma\left(\frac{3}{2}-n+r\right)\right\}, \tag{21}$$

where the coefficients b_r are not all independent, but is there a relation

$$\sum_{r=0}^{\infty}b_r\Gamma\left(\frac{3}{2}+r\right)=0, \tag{22}$$

which is derived from (19) and (16). Then from (21), (22), and (14) we have the mobility μ:

$$\mu=\mu_0\left[1-n\left\{b_1+(4-n)b_2+\left(\frac{71}{4}-\frac{15}{2}n+n^2\right)b_3+\cdots\right\}\right] \tag{23}$$

We shall evaluate ν in the following approximations.

(i) As the simplest assumption we put

$$g_1=b_0+b_1w. \tag{24}$$

Then from (23)

$$\mu=\mu_0(1-nb_1), \tag{25}$$

where

$$b_1=\alpha_1/l_{11}$$

Accordingly we have

$$\nu=\frac{n\alpha_1}{l_{11}F^2}=\frac{4nq\left[\Gamma\left(\frac{5}{2}\right)\right]^2}{3\Gamma\left(\frac{5}{2}-n\right)l_{11}}\left(\frac{\mu_0}{v_T}\right) \tag{26}$$

where $v_T^2=2k_0T/m$ and ξ is replaced in terms of μ_0.

We write ν_B as the value of ν calculated in I, which is given in Appendix B. Comparing (26) with (B11), we find

$$-\frac{\nu}{\nu_B}=\frac{[\Gamma(5/2)]^2}{\Gamma(5/2-n)\Gamma(5/2+n)}=\frac{9\pi}{32}, \qquad (27)$$

here we put $n=1/2$ and equated μ_0 in (26) that of (B11) as being replaced by the ex- rimental value, although two have the di- erent meanings from each other.

) In the next approximation we assume

$$g_1=b_0+b_1\,w+b_2\,w^2$$

The numerical results are given in Table I the case of $n=1/2$ and $a=0.2$, where ν_1 d ν_2 are the values of approximations (i) d (ii), respectively. For the numerical lues of other parameters, the same values in I are used.

As shown in Table I, at high temperatures e result of (ii) is not so different from that (i), but at low temperatures it is rather fferent, so that it may be said that the ap- oximation (i), and ν_B also, becomes not good relatively low temperatures: the tempera- res at which $u\gg1$.

Hall Coefficient for Non-Polar Semiconductors

Let us assume that the uniform magnetic ld H is directed in z axis and the electric ld F is in xy plane. To obtain the Hall efficient in the limit $H\rightarrow0$, it is sufficient to iow the distribution function up to the linear rms in H.

We assume the followings similar to (2)

$$f=f_0(w)+k_x\,\chi_x(w)+k_y\chi_y(w), \qquad (28)$$

$$\chi_x=\chi_x^0+\chi_x^1, \qquad (29)$$

$$\chi_y=\chi_y^0+\chi_y^1,$$

iere $\chi^0{}_{x,y}$ and $\chi^1{}_{x,y}$ are zero and first order H, respectively. Since $f_0(w)$ should not ve the linear term in H, we obtain from e linear terms in the Boltzmann equation

$$\omega_H\,\chi_y^0=-\xi q\,w^n\,\chi_x^1, \qquad (30)$$

$$-\omega_H\,\chi_x^0=-\xi q\,w^n\,\chi_y^1,$$

here $\omega_H=(eH/mc)$ and χ_x^0 or χ_y^0 is given by), in which F is to be replaced by F_x or F_y.

If we define $s(w)$ by the following equations

$$\chi^1{}_x=\left(\frac{e\hbar F_y}{mk_0T\xi q}\right)\left(\frac{\omega_H}{\xi q}\right)e^{-w}s(w), \qquad (31)$$

$$\chi^1{}_y=-\left(\frac{e\hbar F_x}{mk_0T\xi q}\right)\left(\frac{\omega_H}{\xi q}\right)e^{-w}s(w)$$

(30) is reduced to

$$s(w)=w^{-n}\,c(w) \qquad (32)$$

The Hall coefficient R becomes after some elementary calculations

$$|RNec|=g_0\,\Gamma(5/2)\,p_1/p_0^2 \qquad (33)$$

where

$$p_0=\int e^{-w}w^{3/2}c(w)dw,$$

$$p_1=\int e^{-w}w^{3/2-n}c(w)dw, \qquad (34)$$

which become from (12) and (20)

$$p_0=g_0\Gamma\left(\frac{5}{2}-n\right)[1-n\{b_1+(4-n)b_2+\cdots\}], \qquad (35)$$

$$p_1=g_0\Gamma\left(\frac{5}{2}-2n\right)[1-2n\{b_1+(4-2n)b_2+\cdots\}] \qquad (36)$$

As b_1, b_2, $\cdots$ are of order of F^2, we can expand (33) with regard to them:

$$|RNec|=\frac{\Gamma(5/2)\Gamma(5/2-2n)}{[\Gamma(5/2-n)]^2}(1+2n^2b_2+\cdots\cdot) \qquad (37)$$

Comparing (37) with (23), we find that the field dependence of the mobility is determined almost by b_1, while that of the Hall coefficient is determined by b_2, which is far smaller than b_1 as shown in Table I. For n-Ge b_2 is negative so that the Hall coefficient decreases as the field increases, but its magnitude is far less than that of the mobility. Besides, including both optical and acoustical mode scatterings, b_2 becomes very much small in magnitude compared with the case including only acoustical mode scattering. It should be noted, however, that we have assumed the spherical energy surface.

§ 4. Polar Semiconductors

The interaction between a free electron and the optical vibration in ionic crystals was investigated in detail by Fröhlich(7) and the mobility was calculated by means of the variation method by Howarth and Sondheimer(8). Stratton(6) calculated the mobility in strong electric field, assuming the distribution function to be $\exp\{-(\boldsymbol{p}-\boldsymbol{p}_0)^2/2mk_0T_e\}$, where T_e is the electron temperature.

As shown in Appendix *C*, the equation corresponding to (3) and (4) become in this case

$$-w^{3/2}\frac{d}{dw}(e^{-w}g)=e^{-w}L[c], \tag{38}$$

$$-M'\frac{d}{dw}(w^{3/2}e^{-w}c)=e^{-w}L_p[g]. \tag{39}$$

Since L and L_P both satisfy the symmetry relation and the inequality as L_N, we can apply the variation method to solve (38) and (39).

We assume that g and c are expanded in powers of w:

$$g(w)=\sum_{r=0}^{\infty} g_r w^r, \tag{40}$$

$$c(w)=\sum_{r=0}^{\infty} c_r w^r \tag{41}$$

To evaluate ν, it will be sufficient to take first few terms. The more terms consider we, in the stronger field will it be valid.

Substituting (40) and (41) into (38) and (39), multiplying both sides of them by w^r, and integrating over w, we have the two sets of linear equations, from which g_r $(r\geq 0)$ and c_r $(r\geq 0)$ can be determined:

$$\sum_{s=0}^{\infty} d_{rs}c_s=\alpha'_r, \quad (r=0,1,2,\cdots) \tag{42}$$

$$\sum_{s=1}^{\infty} l'_{rs}g_s=\beta_r \quad (r=1,2,\cdots) \tag{43}$$

where

$$d_{rs}=\int w^r L[w^s]e^{-w}dw, \tag{44}$$

$$\alpha'_r=-\int w^{3/2+r}\frac{d}{dw}(e^{-w}g)dw, \tag{45}$$

$$l'_{rs}=\int w^r L_p[w^s]e^{-w}dw, \tag{46}$$

$$\beta_r=-M'\int w^r\frac{d}{dw}(w^{3/2}e^{-w}c)dw. \tag{47}$$

and g_o is related to g_r by the total number N,

$$\sum_{\mathbf{k}} e^{-w}g(w)=N \tag{48}$$

Setting the mobility $\mu=\mu_o[1-\delta_n(\mu_o F/v_T)^2]$, numerical values of δ_n is given in Table 2, where δ_n means that first n terms are taken into account as the variation parameters:

$$g=g_0+\sum_{r=1}^{n} g_r w^r,$$

$$c=\sum_{r=0}^{n-1} c_r w^r.$$

δ_s is the value calculated by Stratton's method which is explained in Appendix *D*, since Eq. (2.24) in his paper is mistaken.

As we can see from Table II, the difference between δ_s and δ_n is significant at low temperatures. Moreover, we must take more parameters at $u=3$, since the difference between δ_2 and δ_3 is serious.

Table II.

$u=(\hbar\omega/k_0T)$	δ_s	δ_2	δ_3
1	0.139	0.179	
2	1.71	0.405	0.49
3	3 14	0.186	0.43

In conclusion, we can estimate in some cases the difference of the two approximations: one assumes that the electron-electron interaction plays the dominant role and the other neglects it completely. In order to analyse the recent experiment on InSb of Kanai(9), we must know the Hall coefficient of polar semiconductors, the calculation of which requires more parameters to be considered than in this section as seen from the discussion of § 3. Moreover, it seems desirable to take the electron-electron interaction into consideration more accurately.

Appendix A

When the static electric field F is directed in x axis, the Boltzmann equation is

$$\frac{eF}{\hbar}\frac{\partial f}{\partial k_x}+\left(\frac{\partial f}{\partial t}\right)_L=0 \tag{A1}$$

where $(\partial f/\partial t)_L$ means the change of the distribution function per unit time due to electron-phonon collisions.

We expand $f(\boldsymbol{k})$ in terms of spherical harmonics and take the first two terms:

$$f=f_0+f_1, \tag{A2}$$

$$f_0=f_0(w), \quad f_1=k_x\chi(w), \tag{A3}$$

where $w=(E/k_0T)$ and k_0 is the Boltzmann constant.

From Eqs. (42), (A17), (A13), and (A19) in I, we can easily show that

$$\begin{aligned}\left(\frac{\partial f_0}{\partial t}\right)_L=\xi\,[\lambda w^{1/2}\Big\{2\left(f_0+\frac{df_0}{dw}\right)\\ +w\left(\frac{df_0}{dw}+\frac{d^2f_0}{dw^2}\right)\Big\}+\eta\{[f_0(w+n)e^u\\ -f_0(w)](w+u)^{1/2}+\Delta(w)[f_0(w-u)\\ -f_0(w)e^u](w-u)^{1/2}\}],\end{aligned} \tag{A4}$$

$$\left(\frac{\partial f_1}{\partial t}\right)_L = -\xi[w^{1/2}+\eta\{(w+u)^{1/2} + \Delta(w)e^u(w-u)^{1/2}\}]k_x\chi(w), \quad \text{(A5)}$$

here ξ is a product of Γ of I and $(k_0T)^{1/2}$ nd therforefore has the inverse dimention of me. Besides we used the following notaons:

$$\lambda=(2ms^2/k_0T), \qquad \Delta(w)=\begin{cases}1; w\geq u\\ 0; w<u\end{cases}$$

$$u=(\hbar\omega/k_0T)$$

$$n_0=(e^u-1)^{-1}$$

$$\eta=n_0au$$

here s is the sound velocity, $\hbar\omega$ is the nergy of an optical phonon and a is a consnt which represents the ratio of magnitudes optical-mode scattering to that of acousticalode scattering. In order to simplify the lculation, we replace (A5) by the approxiate equation

$$\left(\frac{\partial f_1}{\partial t}\right)_L = -\xi q w^n k_x\chi(w). \quad \text{(A5')}$$

n-Ge a being small (~ 0.2), η becomes egligible at low temperatures and we may it $n=1/2$ and $q=1$. At high temperatures $>u$, $n\sim 1/2$ and q becomes a constant also. ut in cases $u\sim 1$, the approximation (A5) ay not be good.

Expanding the drift term in (A1) in terms spherical harmonics we get

$$-w^{3/2}\frac{d}{dw}(e^{-w}g)=e^{-}w^{3/2+n}c(w), \quad \text{(A6)}$$

$$-M\frac{d}{dw}(w^{3/2}e^{-w}c)=e^{-w}L_N[g], \quad \text{(A7)}$$

here

$$f_0(w)=e^{-w}g(w), \quad \text{(A8)}$$

$$\chi(w)=-\left(\frac{e\hbar F}{mk_0T\xi q}\right)e^{-w}L_N[g], \quad \text{(A9)}$$

$$L_N[g]=\lambda w(-2g'+wg'-wg'')$$
$$+\eta[\{g(w)-g(w+u)\sqrt{w(w+u)}$$
$$+\Delta(w)e^u\{g(w)-g(w-u)\}\sqrt{w(w-u)}] \quad \text{(A10)}$$

$$M=(2e^2F^2/3mk_0T\xi^2q) \quad \text{(A11)}$$

ppendix B

Let the electron temperature and the drift locity be $T+\Delta T$ and p_0/m, respectively, and e distribution function is written as

$$f=B\exp\left\{\frac{-|\boldsymbol{p}+\boldsymbol{p}_0|^2}{(mk_0(T+\Delta T)}\right\}. \quad \text{(B1)}$$

Expanding this in terms of p_0 and $(\Delta T/T)=\gamma$, we can obtain⁽¹⁾

$$f_0(w)=B_0e^{-w}\left(1-\frac{3}{2}\gamma+\gamma w\right), \quad \text{(B2)}$$

$$k_x\chi(w)=\frac{p_xp_0}{m}\frac{\partial f_0}{\partial E}=$$
$$-\left(\frac{\hbar k_xp_0}{mk_0T}\right)B_0e^{-w}\left(1-\frac{5}{2}\gamma+\gamma w\right). \quad \text{(B3)}$$

Comparing (B2) with (5) and (B3) with (6), we have

$$g(w)=B_0\left(1-\frac{3}{2}\gamma+\gamma w\right), \quad \text{(B4)}$$

$$c(w)=(p_0\xi q/eF)B_0\left(1-\frac{5}{2}\gamma+\gamma w\right). \quad \text{(B5)}$$

Substituting (B4) and (B5) in (3), integrating over w, the following equation results

$$\Gamma\left(\frac{5}{2}\right)=(p_0\xi q/eF)\Gamma\left(\frac{5}{2}+n\right)(1+n\gamma). \quad \text{(B6)}$$

Setting $p_0=m\mu F$, we obtain for the mobility μ

$$\mu=(e/m\xi q)\left(\Gamma\left(\frac{5}{2}\right)\Big/\Gamma\left(\frac{5}{2}+n\right)\right)(1-n\gamma) \quad \text{(B7)}$$

Therefore we have the zero-field mobility μ_0 in this case as

$$\mu_0=(e/m\xi q)\left(\Gamma\left(\frac{5}{2}\right)\Big/\Gamma\left(\frac{5}{2}+n\right)\right), \quad \text{(B8)}$$

which is of course different from (14).

The electron temperature, γ, is determined in the same way as b_1. Multiplying (4) by w and integrating, we obtain

$$M(p_0\xi q/eF)\Gamma\left(\frac{5}{2}\right)=\gamma l_{11} \quad \text{(B9)}$$

We can put $p_0=m\mu_0F$ in (B9), where μ_0 is given by (B8), then

$$\gamma=\frac{\left(\Gamma\left(\frac{5}{2}\right)\right)^2}{\Gamma\left(\frac{5}{2}+n\right)}\cdot\frac{M}{l_{11}}. \quad \text{(B10)}$$

ν_B, which means ν in this aprroximation, is given by

$$\nu_B=\frac{4nq\Gamma\left(\frac{5}{2}+n\right)}{3l_{11}}\left(\frac{\mu_0}{v_T}\right)^2 \quad \text{(B11)}$$

where

$$v_T^2=(2k_0T/m).$$

Appendix C

Since $(\partial f/\partial t)_L$ in polar semiconductors due to optical-mode scattering is given by Stratton(6) (Eqs. (2.2), (2.3), and (2.4) in his paper), we can immediately obtain the following equations

$$-w^{3/2}\frac{d}{dw}(e^{-w}g)={}^{-w}L[c], \tag{C1}$$

$$-M'\frac{d}{dw}(w^{2/2}e^{-w}c)=e^{-w}L_p[g], \tag{C2}$$

where

$$f_0=e^{-w}g(w), \tag{C3}$$

$$\chi(w)=-(e\hbar t_0F/mk_0T)e^{-w}c(w),$$

$$L[c]=w\phi(w)c(w)-c(w+u)\left\{\left(w+\frac{u}{2}\right)\phi(w)-\sqrt{w(w+u)}\right\}+\Delta(w)e^u\left[w\phi(w-u)c(w)-c(w-u\left\{\left(w-\frac{u}{2}\right)\phi(w-u)-\sqrt{w(w-u)}\right\}\right], \tag{C4}$$

$$L_p[g]=\{g(w)-g(w+u)\}\phi(w)+\Delta(w)e^u\{g(w)-g(w-u)\}\phi(w-u), \tag{C5}$$

$$\phi(w)=ln\frac{\sqrt{w+u}+\sqrt{w}}{\sqrt{w+u}-\sqrt{w}}, \tag{C6}$$

$$M'=\frac{2(eFt_0)^2}{3mk_0T}, \tag{C7}$$

and t_0 is equal to $(2mk_0T)^{1/2}/(eF_0N_0)$ in Stratton's notation.

Appendix D

g and c are defined in Appendix B. Let ξq be equal to t_0^{-1}, (B4) and (B5) become

$$g(w)=B_0\left(1-\frac{3}{2}\gamma+\gamma w\right), \tag{D1}$$

$$c(w)=(p_0/eFt_0)B_0\left(1-\frac{5}{2}\gamma+\gamma w\right), \tag{D2}$$

By using the above two equations and integrating both sides of (38) over w, the following results

$$\Gamma\left(\frac{5}{2}\right)=(p_0/eFt_0)\left\{\left(1-\frac{5}{2}\gamma\right)d_{00}+d_{10}\gamma\right\}. \tag{D3}$$

Putting $p_0=m\mu F$, we obtain

$$\mu=\left(\frac{et_0}{m}\right)\frac{\Gamma\left(\frac{5}{2}\right)}{d_{00}}\left[1-\gamma\left\{\frac{d_{10}}{d_{00}}-\frac{5}{2}\right\}\right], \tag{D4}$$

so that

$$\mu_0=\frac{et_0}{m}\cdot\frac{\Gamma\left(\frac{5}{2}\right)}{d_{00}} \tag{D5}$$

Next, by multiplying both sides of (39) by w and integrating, we have

$$M'(p_0/eFt_0)\Gamma\left(\frac{5}{2}\right)=\gamma l_{11}$$

Setting $p_0=m\mu_0F$ and rewriting t_0 in terms of μ_0, we obtain

$$\gamma=(4d_{00}/3l_{11})(\mu_0F/v_T)^2, \tag{D6}$$

$$\mu=\mu_0\left\{1-\frac{4}{3l_{11}}\left(d_{01}-\frac{5}{2}d_{00}\right)(\mu_0F/v_T)^2\right\}, \tag{D7}$$

$$\delta_s=(4/3l_{11})\left(d_{01}-\frac{5}{2}d_{00}\right), \tag{D8}$$

Dynamic Behaviour of Twinning in Tin Crystals at Various Temperatures and Strain Rates

By Saiyu MARUYAMA

Department of Physics, Osaka Women's University

(Received April 6, 1960)

Twinning behaviour of tin was investigated as a function of temperature and strain rate. The resolved shear stress for twin became large and the scatter of individual values was pronounced, as the temperature was lowered and strain rate was increased. The observed twinning stress was not so large as to expand the stacking-fault across the crystal, but it was sufficient to trigger twin nucleus if local stress concentration was produced, say, by dislocation pile-ups. As the temperature was raised and strain rate was decreased, deformation by slip preceding twin became dominant, and twin formation was finally prohibited. The activation energy derived from the ductile-brittle transition temperatures is approximately that of self diffusion, suggesting that recovery due to dislocation climb releases local stress and prohibits twin nucleation. Hardening of twin boundary migration was found at low temperatures or at high strain rates, while the initial migration stress was not raised by these factors but raised by prestrain. It was about one order of magnitude smaller than that for twin initiation, and too small for the creation of twin dislocation ring on the existing twin layer. A mechanism of sweeping and climbing of the twin dislocation around a pole dislocation is necessary to explain the observedvalue.

§ 1. Introduction

Although the crystallography of mechanical twinning has considerably been investigated, he dynamic behaviour of twinning has very ittle been examined. Even the critical shear stress criterion for mechanical twinning has ot yet been established well, at least in h. c. p. metals. In the earlier experiments, as was shown by Cahn1),2), the values of 'critical hear stress' obtained by different investigaors for material of similar purity were quite different, and the values in any one series of xperiments usually had a large scatter.

As for f.c.c. metals, however, it has been eported3) that the critical shear stress crierion holds in the initiation of the twins, he value of the stress depending closely on he energy of the stacking fault.

Later, Bell and Cahn4) measured a resolved hear stress for twin initiation (r.s.s.t.) by arefully handling the zinc specimen and by eeping away from using pin chucks, in order o prevent the specimen from containing any win nucleus and local stress concentration rior to the test. The value thus obtained was about one order of magnitude larger than that obtained by the earlier investigators. They concluded that the earlier investigators had measured not the stress to start twinning but the stress to spread the already existing twins. Further, they found that the value of their r.s.s.t. was altered noticeably by changing the specimen orientation slightly or by changing the specimen length, and concluded that r.s.s.t. is determined simply by the tensile stress required to bring the specimen to the point of double slip, which would raise the local stress.

The necessity for local stress concentration, which would not be consistent with a critical shear stress criterion at the onset of twinning, is supported by the following experimental facts: burst of twinning by the indentation under the applied tensile stress4), lowering of the r.s.s.t. of the indented crystals5), twin initiation at the bending plane6) or by double slip4), delayed twinning with the aid of residual high strain of a surface layer produced in the crystal growth7), initiation of the secondary twin at the twin intersection8), etc. The precise picture of this stress concentration presented by Bilby and Entwisle[9] on the basis of semi-quantitative calculations is that dislocations piled up against a barrier generate a high local stress, large enough to trigger the twin nucleation, on one or more of the twinning planes.

The mechanism of twin nucleation by the local stress concentration might be assured by the aid of recovery phenomena. In the circumstances where either static or dynamic recovery in Zeeger's sense[10] is substantial in the process of deformation, the local stress will not be enhanced high enough for twin nucleation, slip and other mode of ductile deformation will then be preferred, and *vice versa* when the recovery is insignificant. The well known preference to mechanical twinning under impact loading at low temperature may be the latter case.

In this work, tin crystals were used. White tin shows significant recovery even at room temperature and at moderate strain rate[11]. It is considered to be static recovery by dislocation climb, because tin has low activation energy for self diffusion. The crystals were tested under the various temperatures and strain rates, to confirm the influence of recovery phenomena upon the twin nucleation and to discern the modes of stress concentration and of associated recovery phenomena.

§ 2. Experimental Details

In order to avoid the activation of any other twin plane except the one which has the greatest resolved shear stress (this may also be necessary for the migration stress measurements of the twin boundary) the author ought to use the compression test, although it is less desirable than the tension test. The specimens were grown from the seed crystal and their axes made angles 15°～20.5° with [100] on the [010] great circle. The r.s.s.t. on the most highly stressed twin plane (301) (the angle χ between the specimen axis and the twinning plane is 43.5°～38°) is at least two times higher than that on any other twin planes, and the latter was kept inoperative until the former covered almost entire length of the crystals.

The crystals were grown from the melt of tin containing impurities less than 0.01%, in pyrex glass tubes with inner diameter 4.2 mm. To prevent any slightest deformation in the course of specimen preparation, the pyrex glass tube was dissolved in hydrofluoric acid, and the specimen was acid cut in pieces of length 35 mm. After about 30 hours annealing at 180°C, oxides were removed off chemically. Cooling down after crystal growth and after annealing was slow enough to avoid any thermal stress.

In the earlier stage of the present experiment, the ends of the specimen were ground flat and parallel by emery paper before annealing, and were lubricated with glease before testing the specimen. The mechanical twin started always at the ends and at a lower stress than that found in the later experiment as described below, indicating that fine grains scarcely greater than 1 mm recrystallized at the ends raised local stress to trigger twin nucleation with ease, although the effect was negligible when slip preceding the twin was dominant.

In the later experiment, iron caps were used instead of pin chucks or soldering which might act as local stress raiser. Holding the space between cap wall and specimen closer than 0.1 mm, they were cemented with 'Araldite' which was found more stiff than the tin crystal for the deformation. Special device was made to hold the top surfaces of the caps at right angle with the crystal axis. In this case, twin started at any point excluding the cemented parts at higher stresses than the earlier case.

The compression container in which the specimen was compressed at low temperature was such as used by Kraft *et al*[12]. To record the load-extension curve and vary the strain rate, 'Instron Testing Machine for Textile' with load cell of 500 kg was utilized.

For the measurement of the stress of twin initiation, load was relaxed as soon as the load dropped with a loud twinning click, and the twin lamella just formed was observed. On the other hand, for the measurement of the migration stress of the twin boundary, the compression was continued until the specimen was covered wholly with twinned part, leaving only the gripped ends. In this case, only poor information about twin initiation was obtained because the starting point of the twin formation was uncertain.

Experimental Results

1) *Effects of changing temperature and strain rate upon twin initiation*

xperiments were mainly restricted to the
cimens with $\chi=43.5^\circ\sim38^\circ$. The range of
perature tested was between −80°C∼20°C,
the rate of deformation was between
∼5 cm/min. (Strain rate of 2.5∼
%/min.) The gauge length of the speci-
n was about 20 mm.

xperiments at the temperature lower than
room temperature (20°C) was carried out
dipping the specimens into the mixture of
thyl alcohol and solid carbon dioxide. The
thyl alcohol atmosphere was used even at
room temperature in order to avoid, if
, secondary contributions of the surround-
atmosphere.

he rate of deformation was controlled by changing the head speed and the chart speed of the Instron machine proportionally. The rate of deformation higher than 5 cm/min. was not applied because the speed of the recording pen did not follow the deformation.

The typical load-extension curves in the various circumstances are shown in Fig. 1a∼1e.

The effect of changing temperature and strain rate upon the stresses at which twinning starts (solid circle), and the magnitude of deformation before twinning plane operates (horizontal line) are illustrated in Fig. 2a,b,c. The cross mark indicates that the twinning did not start within the magnitude of deformation here illustrated.

To summarize briefly the general features:

i) As the temperature is raised and the strain rate is diminished, the magnitude of the deformation necessary to start twinning increases, and the mechanical twinning becomes hard to realize.

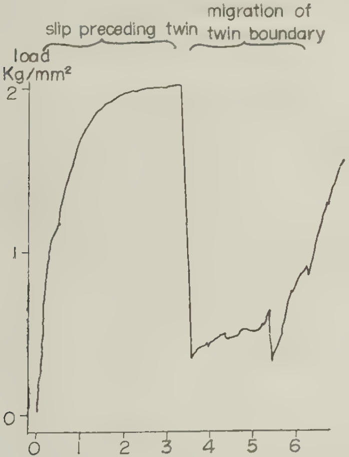

Fig. 1a. Temperature: −30°C
Strain rate: 25%/min.

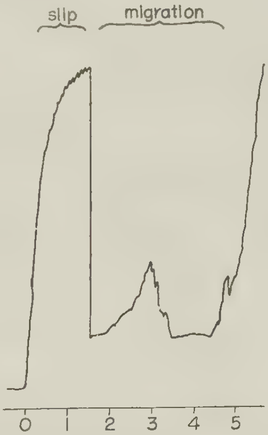

Fig. 1b. Temperature: −60°C
Strain rate: 2.5%/min.

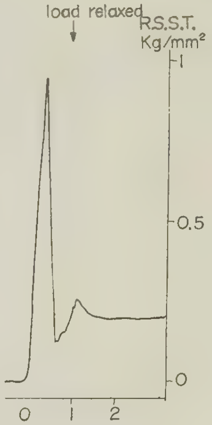

Fig. 1c. Temperature: −80°C
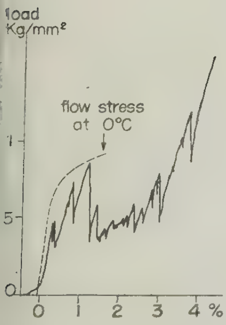
Strain rate: 25%/min.

ii) In the range of twin formed under a dominant slip, the twinning shear stress gives a constant value and it becomes higher as the temperature is lowered or the strain rate is increased. Whereas in the case of the twin formed under an insignificant slip, a large scatter of the value of the twinning stress is found.

(2) *Effect of changing specimen orientation*

As for the slip system in tin, there is very little literature. According to the old litera-



1d. Temperature: −195°C
ain rate: 2.5%/min.

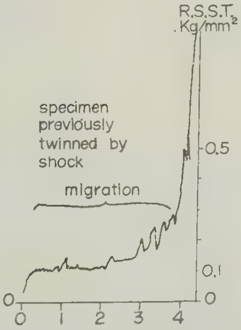


Fig. 1e. Temperature: 20°C
Strain rate: 2.5%/min.

ture, written by Obinata and Schmid[11], the main slip system in white tin is $t=[001]$ $T=\{100\}$ or $\{110\}$ at room temperature. Occasionally, the system $t=[10\bar{1}]$, $T=\{101\}$ or $\{121\}$ was observed. The critical shear stresses for these four systems were 189, 133, 160 and 170 gm/mm², respectively. As the glide strain increases, the flow stress of the main slip system increases only slightly, becaus tin crystals show substantial recovery ever at room temperature. On the other hand the hardening of the system $t=[101]$ is rapid This is the reason why the system operates only in exceptionally rare cases.

In the present experiment, to see the effe of changing specimen orientation upon tw nucleation, the specimens with $\chi=53.5°$ were prepared. (The specimen is noted as B hereafter, whereas the other specimen with $\chi=43.5°\sim38°$ is noted as A.) The axis of these specimens made an angle of 85° with the main silp direction [001]. The resolved shear stress for main slip [001]/(100) is about three or four times higher than that in the specimen A, but the resolved shear stress for twin is nearly equal in the magnitude. The load-extension curve in crystal B was raised, however, only about 25% than in crystal A, suggesting that the secondary slip system was operative in either case, although the temperature range and strain rate was not the same as in the case of Obinata and Schmid.

The stress for the twin initiation in speci-

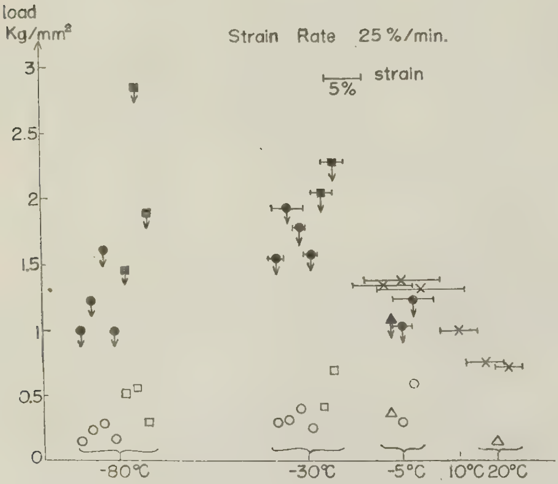

Fig. 2b.

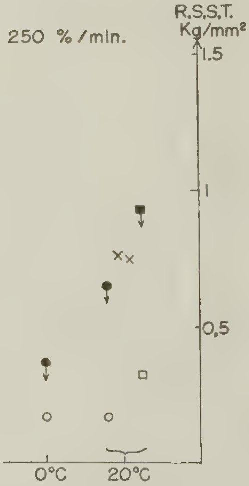

Fig. 2c. (Deformation prior to twin is not recorded.

n B was always somewhat higher than t in A. This is in accord with the Bell l Cahn's hypothesis. Because in the speci-n B, the r.s.s. for [001]/(100) main slip is ıch larger than that in A, and the point double slip which is supposed to begin h the secondary slip [10$\bar{1}$]/(101), followed the main slip [001]/(100), may be delayed ın the case in A. This results in the raise twinning stress.

The precise discussion must, of course, be sed on the observations of slip traces by metallographic treatment of the specimen face, but they failed chiefly because of the ıallness of the strain preceding twin.

3) *Migration of the twin boundary*

Bell and Cahn[4] measured the resolved shear ess of the twin boundary migration (r.s.s.) in zinc about one order of magnitude ıaller than the r.s.s.t., the magnitude of ıt stress being comparable with that served by the earlier investigators as twinn-g stress.

In the present work, the initial r.s.s.m. is own by open mark in Fig. 2, and again rresponds to about one order of magnitude ıaller than that of the r.s.s.t.

Effect of changing temperature and strain te upon migration stress is not substantial. is not the temperature or the strain rate elf, but the magnitude of deformation eceding twin, which affects the migration ess.

At a low temperature, -80°C, prestrain is small that the r.s.s.m. shows the lowest lue 70 gm/mm^2. As the temperature is ised and the strain rate is decreased, pre-rain becomes considerable magnitude, r.s.s. . then increases. When a kink band was rmed at the strain rate of 25%/min. and at e temperature -30°C or -5°C, the r.s.s.m. as raised about four times higher than the west value. Further, even at room tem-rature, when the crystal had been twinned advance by impact shock, the prestrain in is case being very small[5], the r.s.s.m. ıowed then the lowest value 70 gm/mm^2 ig. 1e).

On the other hand, the hardening in the undary migration process is affected by mperature and probably by strain rate. At om temperature, the specimen twinned in advance by impact does not show hardening through the whole process of twinning. In the liquid nitrogen experiment, however, a serrated curve was recorded (Fig. 1d). Loud twinning crick was heard at every moment of the fall of stress. At this temperature, the migration stress in the true sense is not recorded, but rapid hardening of the twin boundary movement and twin nucleation assisted by the local stress of the operating twin itself appears alternately. These results show that the recovery process in the tin crystals is operative at room temperature even in the twin boundary movement.

§ 4. Considerations and Discussions

It is supported by this experiment that the mechanism of twin nucleation by the local stress concentration in zinc holds in tin crystals as well, and the criterion for the critical shear stress for the initiation of twin does not hold in both metals. The twinning process is therefore excluded, under the condition in which crystal recovery is dominant and the local stress is insignificant. The results of the experiments which support these hypotheses are as follows:

i) As the temperature is raised and the strain rate is decreased, the deformation by slip should be large before the twin initiation.

ii) At low temperature, -80°C, the twinning stress is very sensitive to the crystal imperfection. Even under the constant temperature and constant strain rate and for the same crystal orientation, the observed twinning stress is not regarded as constant.

iii) The r.s.s.t. varies appreciably by changing specimen orientation. It is affected by the operating slip systems.

The theory for the twin formation to explain these results will be discussed somewhat quantitatively below:

1) *Model of spreading a stacking fault*

The critical shear stress for the twin initiation is, following Friedel[13], the applied shear stress to develope a stacking fault across a crystal. This model is applicable in the case where the energy of stacking fault is low and the applied stress is high. For example, in the case of f.c.c. metals, Suzuki and Barrett[3] expressed the critical shear stress for twin initiation,

$$\sigma=\frac{\gamma}{2b}+\frac{2T}{lb}$$

using double stacking fault model. Here γ is the stacking fault energy, b is the Burgers vector of a half-dislocation, T is the tension of the half-dislocation line, and l is the mean distance between the intersecting dislocations. The equation was in accord with their observed values.

But in our case on tin crystals, taking

$$\gamma=20 \text{ ergs/cm}^2,\ b=0.2\times10^{-8} \text{ cm},$$

and neglecting the resisting force due to the intersecting dislocations

$$\sigma=50 \text{ Kg/mm}^2$$

In other words, the applied shear stress of about 50 times larger than that observed in this experiment is expected by this model. The model is obviously not adequate in the case of tin.

2) *Model of twin nucleation by the aid of local stress*

The other model for twin initiation was proposed by Orowan[14)], and somewhat modified and applied by Bell and Cah[4)] in zinc crystals. If the applied stress is in some way magnified 'locally' to the theoretical twinning stress, a twin nucleus of the critical diameter will be triggered. This nucleus will be able to grow further by the applied stress of the order of the observed value[5)]. Because the local stress at the top of the nucleus will be enhanced to the twinning stress by its own twin dislocation array along the periphery of the twin nucleus.

Now, the mechanism of the local magnification of the applied stress is uuknown. But the most probable mechanism which might occur in such an early stage of deformation is the piling up of the slip dislocations against a barrier, as in the case of brittle fracture. The number of pile-ups necessary for the twin nucleation is that which magnifies the applied shear stress on the piled up slip plane to the theoretical twinning shear stress throughout the twin nucleus of the critical diameter. The calculation is made by Bell and Cahn[4)] in zinc, in which the twin nucleus is calculated by the method of Orowan, and the magnification of the applied stress is estimated by the expressions derived by Frank, Eshelby and Nabarro[15)]. In the present case, we take the self energy of twinning dislocation $\Gamma=Gb_t$ where G is appropriate shear modulus and b_t is Burgers vector of the twinning dislocation, applied shear stress on the slip plane 4.4×10^7 dynes/cm², and the theoretical twinning stress $(G/2\pi)\gamma$ following Orowan where γ is the twinning shear. The estimated number of the pile-ups of the slip dislocations is then approximately one hundred, which is not unreasonable value. Here, of course, the estimation is very approximate. For example, the theoretical twinning stress will be smaller if the atomic force is considered more precisely[16)]. The stress distribution function should be used along the dimensions of twin nucleus. These abbreviations make the number of the pile-ups too overestimated. Whereas, the interaction energy of the twin dislocations is neglected. This makes the number of the pile-ups too underestimated.

3) *Twin prohibition by recovery*

These piling-ups of the slip dislocations may be released with the aid of thermal activation, and the twin nucleation will be prohibited, if the temperature is raised and the strain rate is decreased. On the contrary, under the reversed condition, the probability for the release will diminish and twin nucleation will be operative.

The situation is analogous to the case of the ductile-brittle transition in iron polycrystals. The following treatment is essentially that of Stroh[17)] except that the release occurs by recovery process instead of the operation of Frank-Read source in the neighbouring grain, and the activation energy U for the stress release is then the energy corresponding to the recovery process, not to the breaking up of Cottrell locking.

The mean time for stress release is, in the atmic scale,

$$\tau=\frac{1}{\nu}\exp\{U/k\mathrm{T}\}.$$

The probability that the release does not occur in a time interval t will be

$$\begin{aligned}p&=\exp\{-t/\tau\}\\&=\exp[-\nu t\exp\{-U/k\mathrm{T}\}].\end{aligned}$$

Owing to the form of double exponential, p falls abruptly from 1 to 0 as the temperature is raised. The transition temperature is, taking $p=1/e$,

$$T_c = U/k \log \nu t\ .$$

he effect of strain rate is introduced through t is the order of time elapsed before the train reaches $\mathcal{E}_t$ necessary for the twin initia-on. Apart from numerical factor, we expect

$$t = \mathcal{E}_t/\dot{\mathcal{E}}$$

lere, being different from the case of fra-ture both $\mathcal{E}_t$ and $\dot{\mathcal{E}}$ are the values beyond he elastic region. The transition tempera-ure is related to the strain rate in the from

$$1/T_c = -(k/U)\log\dot{\mathcal{E}} + (k/U)\log \nu\mathcal{E}_t$$

og $\dot{\mathcal{E}}$ is plotted against $1/T_c$ in Fig. 3. The ark △ shows the transition point, and lines p with the inclination giving an activation nergy of about 0.58 eV (13 kcal). This is ompared with the activation energy for the elf diffusion in tin, 10.5 kcal in c direction[18], uggesting that twinning is prohibited by the islocation climb. Here, the self diffusion in direction is rejected, for it involves ring echanism[19]. According to Mott's theory[20], e rate of climbing is

$$\nu \exp\{-(E-\gamma n b^3\sigma)/kT\}$$

here ν is atomic frequency, γ is a numeri-al constant of order of unity, σ is the flow tress and n is the number of pile-ups. E is e activation energy for a free dislocation nd of the order of that for the self diffusion. ut if the jogs is not supplied enough, it in-olves the formation energy of jogs which is qual to about one half of the energy for the elf diffusion. Taking into account the formation energy of the jogs, the obtained activation energy U corresponds to that for climbing, *i. e.*, $E-\gamma n b^3\sigma$, which is weakly dependent on stress for $n \simeq 100$. U will also correspond to the activation energy for creep in tin, 11 kcal[19], interpreted by the climb mechanism.

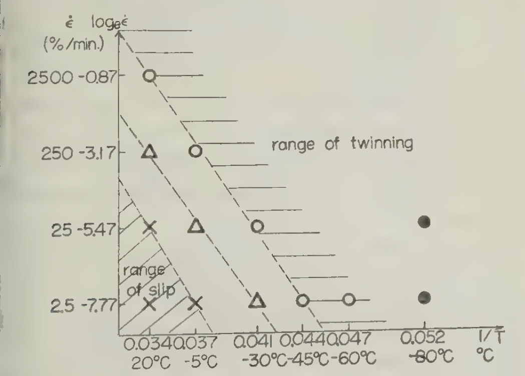

Fig. 3. Probability for twinning under varied temp. and strain rate.
- ●: twin formed under insignificant slip
- ○: twin formed after flow stress reach a constant value
- △: transition point
- ×: twin inhibited

As for the other mode for the release, for example, the operation of *F-R* source from Cottrell locking or cross slip by the breaking up of Lomer-Cottrell barrier, nothing decisive can be said, because the activation energy for them can hardly be estimated. But the former is hard to conceive because the transition point illustrated is well beyond the elastic region, and the latter is also put aside because the cross slip in tin has not been reported.

4) *The nature of barriers*

The nature of barriers dumming up the dislocation array is left to be discussed. At an elevated temperature and a decreased strain rate, it is expected that double slip generates barriers resulting the pile-ups of dislocations, as was shown by Bell and Cahn. This is because, in the present experiment, twins start simultaneously at many points along the gauge length of the specimen under such conditions.

While, at low temperature and at high strain rate, the above model is not reasonable. Because twin operates under the applied stress not far from elastic limit, with insignificant lattice rotation. Instead, other types of stress concentrators are expected. For xeample, Frank partial sessile dislocations[21], dislocation arrays of opposite sign on neighbouring slip planes[22], segregation of impurity atoms during annealing, etc. Even the constraint at the cemented part seems to act as stress raiser. Here, we put aside nucleation by thermal stress or phase transformation at -80°C, because nucleation click was not heard, and the specimen kept -80°C for 2.5 hrs did not show any traces of phase transformation by *X*-ray examination.

5) *The stress values for twin initiation*

If we admit the nature of stress concentrators as described above, the variation of the stress for twin initiation is understood as follows. Under the condition of dominant slip, the stress for twin initiation, if it occurs, is determined simply by the magnitude of the flow stress at the point of double slip forming barriers. The raise of the twinning stress by the lowering of temperature and by increasing strain rate as well as the marked change of the r.s.s.t. with crystal orientation is a natural consequence. Whereas, in cases with insignificant slip, twin initiates in the course of rapid hardening of the flow stress. Thus the large scatter of the twinning stress results. The scatter of the r.s.s.t. in the orientation of insignificant slip was also observed under impact test[5]), which would correspond to the low temperature experiment.

6) *The resolved shear stress for boundary migration*

Last of all, the magnitude of the r.s.s.m. is referred to. Let us estimate the r.s.s.m. necessary for successive nucleation of a twin dislocation ring on the twin surface. Here, a new stacking fault energy or twin boundary energy is not required. The shearing stress necessary to form a hill of one atomic height on a coherent twin boundary is therefore calculated like that required to form a slip dislocation ring in a perfect crystal[23]). The critical radius of the hill under the observed minimum r.s.s.m., 70 gm/mm^2, is 3400 Å, the activation energy of 25.5 eV is then required. If the creation is allowed under the activation energy of the order of 0.4 eV, the r.s.s.m. required is 1.6 Kg/mm^2, much larger than the stress for the 'twin initiation'. The nucleation of this ring by the piling up of slip dislocations against the twin boundary is also rejected. Because the applied stress giving the minimum migration stress is far from giving a critical shear stress for any slip, and the constancy of minimum r.s.s.m. at various temperatures and strain rates refuses the process which requires the thermal activation.

The most probable model for the migration of twin boundary is the continuous growth on an atomic scale by the sweeping twin dislocation around a pole dislocation, such as presented by Cottrell and Bilby[24]). The migration stress is then the resisting force to the moving twin dislocation. The resisting force will be dependent on the crystal perfection. In crystals prepared by recrystallization, the minimun r.s.s.m. was reported[25]) to be 50 gm/mm^2, somewhat lower than the present experiment. The raise of of the stress by the deformation preceding twin is a natural consequence. But the resisting force will be only weakly dependent on temperature and strain rate, because a jog in the twin dislocation does not necessarily drag vacancies. Of course, accomodation process accompanying incoherent twin boundary movement will be necessary in the later stage of migration, this will result in the hardening of the migration stress at low temperature.

In conclusion, the author wishes to express his cordial thanks to Prof. K. Tanaka, Kyoto Univ., for his cotinuous encouragement and criticism on this subject. He also wishes to thank to Prof. J. Takamura, Kyoto Univ. for his instructive suggestion, and to Prof. T. Sugeno, Tokyo Univ., for his criticism. His thanks are especially due to Dr. H. Kiho, Kyoto Univ., for his stimulating discussions throughout this work. He is much indebted to Master T. Kishimoto and Mr. H. Ito, Japan Synthetic Textile Inspection Institute Foundation, for kindly utilizing Instron Machine.

Study on the Ordered Alloys of Gold-Manganese System by Electron Diffraction, II. Au_4Mn*

By Denjiro WATANABE

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai, Japan

(Received February 23, 1960)

The ordered Au_4Mn alloy has been investigated by electron diffraction, using oriented, evaporated films. This ordered alloy has been found below about 400°C to have the body-centred tetragonal unit cell which is 2.5 times as large as the fundamental cell in volume. The structure is isomorphous to that of Ni_4Mo and belongs to the space group $I4/m-C_{4h}^5$. This structure is not the so-called anti-phase domain structure. Some qualitative discussions have been given of the structural transition between the ordered Au_4Mn and Au_3Mn and of the origin of ferromagnetism in Au_4Mn, on the basis of the proposed structure model.

§1. Introduction

In Part I of the present study[1], the structure f the ordered Au_3Mn alloy was investigated y electron diffraction, using thin single-rystalline films prepared by evaporation, and t was shown that this alloy possesses a two-limensional anti-phase domain structure of a ew kind, whose fundamental lattice consists f a face-centred orthorhombic cell with the tomic arrangement similar to Cu_3Au. On he other hand, it was found by Kussmann nd Raub[2] that the alloy Au_4Mn has an rdered face-centred tetragonal lattice ($c/a<1$) elow about 420°C, but its atomic arrangenent has as yet been unknown. According o the said authors and Meyer[3], the ordered u_4Mn alloy is ferromagnetic below about 8°C. The structure determination of this rdered alloy, therefore, seemed to be necesary from the crystallographic as well as from the magnetic points of view. The present author studied the superlattice of Au_4Mn by electron diffraction, using thin single-crystalline films, and was able to determine its complex ordered structure.

In the present paper, it will be shown that the ordered Au_4Mn phase has not the so-called anti-phase domain structure but a body-centred tetragonal lattice with a unit cell of Ni_4Mo-type which is 2.5 times as large as the disordered unit cell in volume.

§ 2. Experimental Results

In the present study, the experimental procedures involving preparation of specimens, heat treatment and electron diffraction technique were quite the same as those in Part I.

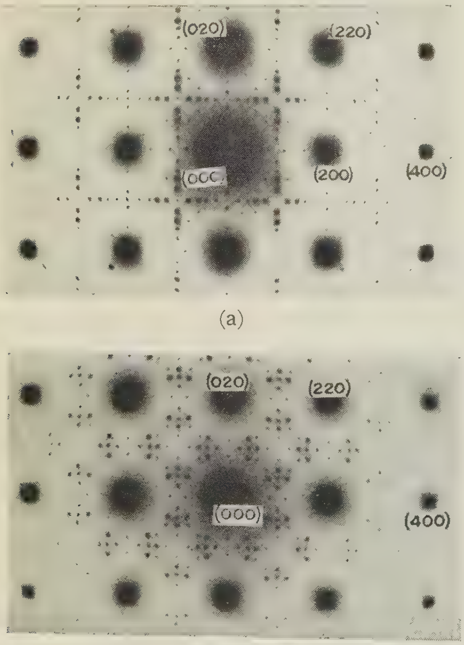
The alloy films containing manganese less than 25 per cent** showed diffraction patterns of Au_3Mn-type superlattice after quenching from temperatures above 400°C. When they were annealed for a long period below 400°C, however, the patterns changed their aspects as follows: The specimen giving the pattern as shown in Photo. 1 (a) ($a_1=4.09$, $a_2=4.06$, $a_3=4.04\pm0.01$ Å, $M_1=1.18$, $M_2=2.23$*) after quenching from about 400°C showed the pattern as shown in Photo. 1 (b) after annealing at 360°C for 24 hrs. In this pattern, we can see a new kind of superlattice spots besides those of Au_3Mn-type. The longer the annealing time, the stronger the intensity of new spots became, and the superlattice spots consisted of those of a new kind alone after further annealing at 350°C for 40 hrs., as shown in Photo. 1 (c). Photo. 1 (d) shows the pattern of the same film as in Photo. 1 (c) taken at oblique incidence, the angle between the incident electron beam and the film normal being several degrees. The further annealing below 350°C did not change the aspect of the pattern any more. The pattern changed almost reversibly when the specimen was again heated at higher temperatures, and the spots of Au_3Mn-type structure entirely recovered their intensity at about 400°C.

---

* A short note concerning this work has been ublished in Acta Cryst. **10** (1957) 483.

** In the present paper, all percentages refer to atomic per cent.

The above observation enables us to suggest that the alloys containing manganese less than 25 per cent possess below 400°C an ordered structure different from that of Au_3Mn-type. Moreover, it was found by Kussmann and Raub that the alloy Au_4Mn has an ordered lattice below 420°C which is different from the Au_3Mn-type lattice, as already mentioned, and therefore it seems that the ordered structure observed in the present experiment is identical with that of Au_4Mn. In fact, the lattice spacings measured from all the diffraction spots agree well with those obtained from an X-ray Debye photograph by Kussmann and Raub, as shown in Table I, and so it is sure that such patterns as shown in



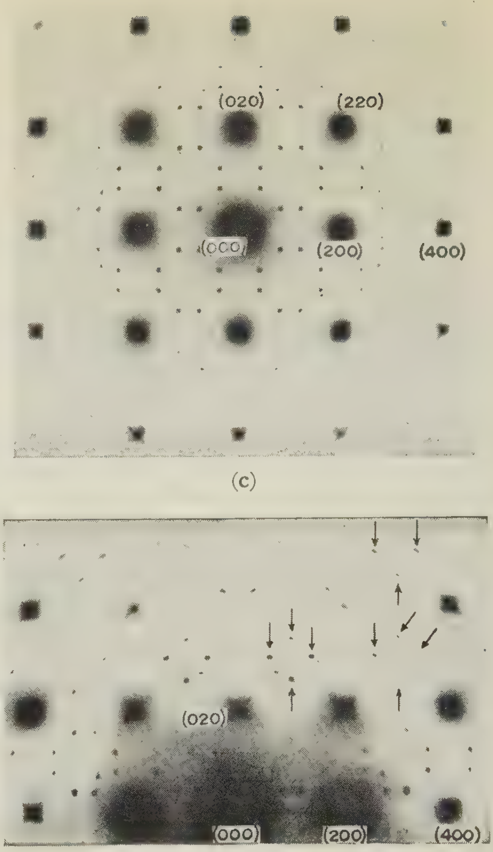


Photo 1. Electron diffraction patterns obtained after annealing at various temperatures from thin alloy films containing about 20% Mn. Indices assigned to main reflections are referred to the disordered cubic system.

(a) Annealed at 400°C; normal incidence.

(b) Annealed at 360°C for 24 hr.; normal incidence.

(c) Further annealed at 350°C for 40 hr.; normal incidence.

(d) Diffraction pattern of the same film as in (c); oblique incidence.

---

* M_1 and M_2 have the same significance as in Part I.

hoto. 1 (c) and (d) are obtained from the rdered structure of Au_4Mn. The fundamental ell of the alloy referring to the original disrdered unit cell is face-centred tetragonal, ith the lattice constants

$${}_1=a_2=4.08, \quad a_3=4.03\pm0.01\,\text{Å}, \quad a_3/a_1=0.988.$$

he pattern in Photo. 1 (b) is considered to eveal the transition state from the ordered u_3Mn-type structure to the ordered Au_4Mn-ype structure.

3. Determination of the Ordered Structure

The superlattice reflections in the patterns hown in Photo. 1 (c) and (d) appear as if ey are formed as a result of the splitting f the reciprocal lattice points with mixed ntegers, h_1, h_2 and h_3†, and it may be susected that the alloy Au_4Mn possesses some ind of anti-phase domain structure. Figs. (a) and (b) are illustrations of the patterns in Photo. 1 (c) and (d) respectively. It was found from the fine splits of main reflections as well as from the positions of the superlattice reflections in Figs. 1 (a) and (b) that the patterns correspond to a superposition of such three orientations that the tetragonal axis of the ordered lattice distributes into three directions of the original disordered cubic axes. After a careful examination the intensity distribution in reciprocal space which corresponds to one orientation can be induced, as shown in Fig. 2 (a). Since a set of four spots which are considered to be split from (100) or (101) is superposed on a set split from (010) or (011), respectively, when the reciprocal lattice is rotated by 90° around the h_3-axis, some of the superlattice spots depicted in Fig. 2 (a) may not be necessary in the fundamental intensity distribution. But, as this is unknown from the observation, we cannot help utilizing Fig. 2 (a) in order to proceed the analysis. There are two values of separation, "m_1" and "m_2", in the split, as shown in Figs. 1

---

† h_1, h_2 and h_3 are used in terms of the fundaental lattice.

and 2 (a), and they satisfy the following relations,

$$m_1/2=a_1^*/2.5\,,\qquad m_2/2=a_1^*/5\,,$$

where a_1^* is a reciprocal lattice constant corresponding to $\boldsymbol{a}_1$. If the split is formed as a result of the formation of anti-phase domains, the alloy $\mathrm{Au_4Mn}$ is likely to possess a two-dimensional anti-phase domain structure because of the appearance of two values of separation in the split, and the sizes of the domains have to be $1.25a_1$ and $2.50a_1$, respectively. But these values in the present alloy never changed with a change of the composition, unlike the ordered alloys with anti-phase domains, CuAu(II)[4], $\mathrm{Cu_3Pd}$[5], $\mathrm{Ag_3Mg}$[6] and $\mathrm{Au_3Mn}$[1], and moreover, we cannot explain the intensity distribution by any kind of anti-phase domain structure based upon the $\mathrm{Cu_3Au}$-type atomic arrangement.

(b)

Fig. 1 (a). Illustration of Photo. 1 (c).
(b). Illustration of Photo. 1 (d).

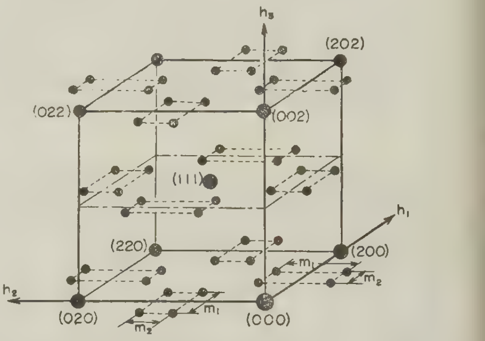

Fig. 2 (a). Intensity distribution in reciprocal space induced from diffraction patterns of $\mathrm{Au_4Mn}$ film.

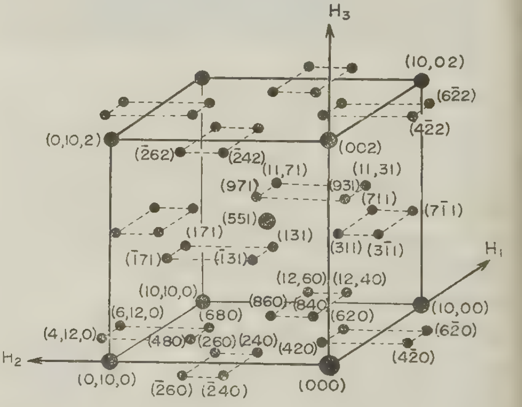

Fig. 2 (b). Indexing of the reciprocal lattice points in Fig. 2 (a).

We shall carry out the structure analysis on the basis of the space group. In order that all the reflections may be indexed with integers, a large unit cell must be taken, the size being $5a_1\times5a_2\times a_3$, and the indexing of the reciprocal lattice points corresponding to this unit cell is shown in Fig. 2 (b)†. The possible space group satisfying the extinction rule is C_{4h}^4-$P4_2/n$. The large unit cell is 25 times as large as the fundamental cell and there are 100 atoms in the unit cell, i.e. 20 manganese and 80 gold atoms. Since the fundamental lattice of this ordered alloy is face-centred as in the case of $\mathrm{Au_3Mn}$, we can easily determine the positions of atoms as follows: 4 atoms must be situated on 4 (c) ositions (000; $\frac{1}{2}\frac{1}{2}0$; $0\frac{1}{2}\frac{1}{2}$; $\frac{1}{2}0\frac{1}{2}$) and the remaining 6 atoms on twelve kinds of 8 (g) positions

---

† In Fig. 2 (b), indices, $(H_1H_2H_3)$, are used in order to distinguish from $(h_1h_2h_3)$ in Fig. 2 (a).

$$(x_i, y_i, z_i:\ \tfrac{1}{2}-x_i, \tfrac{1}{2}-y_i, z_i:\ \bar{y}_i, \tfrac{1}{2}+x_i, \tfrac{1}{2}+z_i:$$
$$\tfrac{1}{2}+y_i, \bar{x}_i, \tfrac{1}{2}+z_i:\ \bar{x}_i, \bar{y}_i, \bar{z}_i:\ \tfrac{1}{2}+x_i, \tfrac{1}{2}+y_i, \bar{z}_i:$$
$$y_i, \tfrac{1}{2}-x_i, \tfrac{1}{2}-z_i:\ \tfrac{1}{2}-y_i, x_i, \tfrac{1}{2}-z_i)$$

ith $z_i=0$. Twelve kinds of parameters, x_i nd y_i, are given by

$$\begin{array}{ll} x_1=0.1,\ y_1=0.1\ ; & x_7=0,\ \ y_7=0.4 \\ x_2=0.2,\ y_2=0\ \ ; & x_8=0.6,\ y_8=0.2 \\ x_3=0.2,\ y_3=0.2\ ; & x_9=0.2,\ y_9=0.6 \\ x_4=0.1,\ y_4=0.3\ ; & x_{10}=0.6,\ y_{10}=0.4 \\ x_5=0.3,\ y_5=0.1\ ; & x_{11}=0.8,\ y_{11}=0.2 \\ x_6=0.4,\ y_6=0\ \ ; & x_{12}=0,\ \ y_{12}=0.2 \end{array}$$

: is most reasonable to arrange 4 and 16 anganese atoms on 4 (c) positions and two inds of 8 (g) positions, respectively. The tructure amplitudes are given by

$$\text{(i)}\quad F=4E_{\mathrm{Mn}}+8\sum_{i=1}^{12}E_i \cdot\cos\pi[(H_1-H_2)x_i+(H_1+H_2)y_i] \cdot\cos\pi[(H_1+H_2)x_i-(H_1-H_2)y_i]\ ,$$

or $H_1+H_2=2n$, $H_2+H_3=2n$;

$$\text{(ii)}\quad F=-8\sum_{i=1}^{12}E_i \cdot\sin\pi[(H_1-H_2)x_i+(H_1+H_2)y_i] \cdot\sin\pi[(H_1+H_2)x_i-(H_1-H_2)y_i]\ ,$$

or $H_1+H_2=2n$, $H_2+H_3=2n+1$;

$$\text{(iii)}\quad F=0,$$

or $H_1+H_2=2n+1$, $H_2+H_3=2n$, and $H_1+H_2=2n+1$, $H_2+H_3=2n+1$,

here E_i is the atomic scattering factor for lectrons of i-th atom. After a detailed trial, it was found that there is no atomic arrangement which can completely explain the intensity distribution in Fig. 2 (b) by itself. But kinds of we consider the following two kinds of positions of manganese: (A), $(x_4, y_4, 0)$ and $(x_9, y_9, 0)$, (B), $(x_5, y_5, 0)$ and $(x_8, y_8, 0)$. The former arrangement can explain only one half of the superlattice spots and the latter only the remaining superlattice spots. Fig. 3 shows the atomic arrangement corresponding to (A). It is readily understood that the arrangement corresponding to (B) is crystallographically identical with that in Fig. 3, that is to say, we can produce the former, (B), by rotating clockwise the latter, (A), about the a_3 axis by ~53°. Here, we shall call these two types of lattice "A-lattice" and "B-lattice", respectively. The intensity distribution in reciprocal space corresponding to the model in Fig. 3 (A-lattice) is derived as shown in Fig. 4. It should be noted that the reciprocal lattice shown in Fig. 2 corresponds not to a true single crystal lattice of Au_4Mn but to a superposition of the A- and B-lattices.

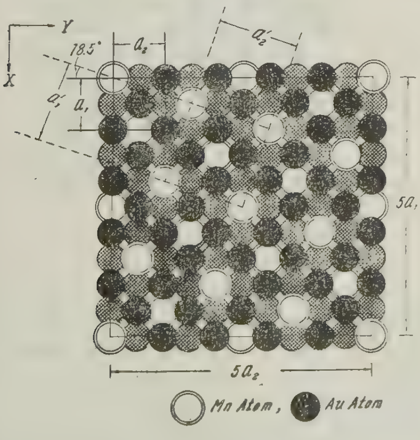

Fig. 3. The Au_4Mn structure corresponding to (A)-lattice, viewed along [001].

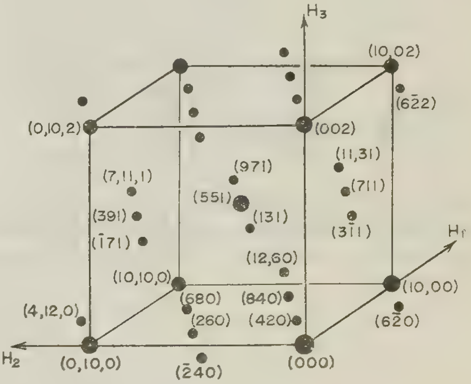

Fig. 4. Intensity distribution in reciprocal space corresponding to Fig. 3.

Although the unit cell with the size of $5a_1\times 5a_2\times a_3$ was adopted in the above analysis, it is known from Fig. 3 that a true unit cell of the ordered lattice is represented by the small cell indicated by the broaken lines in Fig. 3. It is body-centred tetragonal and 2.5 times as large as the fundamental cell in volume, the lattice constants being

$$a_1'=a_2'=\sqrt{5/2}\ a_1=6.45\text{Å}\ ,\quad a_3'=a_3=4.03\text{Å}\ ,$$
$$a_3'/a_1'=0.625\ .$$

Atoms included in the cell are ten, i.e. eight gold and two manganese atoms. The space group for this cell is $I4/m-C_{4h}^5$, and two manganese atoms are placed in 2 (*a*) at 0, 0, 0 and $\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$ and eight gold atoms in 8 (*h*) $\{(0, 0, 0;\ \frac{1}{2}, \frac{1}{2}, \frac{1}{2}) + x', y', 0;\ \bar{x}', \bar{y}', 0;\ \bar{y}', x', 0;\ y', \bar{x}', 0\}$ with parameters $x'=0.2$, $y'=0.4$. The structure amplitudes are given by

$$F'=2E_{\mathrm{Mn}}+4E_{\mathrm{Au}}\{\cos 2\pi(H_1'x'+H_2'y') + \cos 2\pi(H_1'y'-H_2'x')\}\ . \qquad (2)$$

The relation between the reciprocal lattice corresponding to the new cell and that in Fig. 4 is shown in Fig. 5, where indices refer to the true cell. The calculated intensities, using Eq. (2), are tabulated in Table I and agree satisfactorily with the present observation and also with the X-ray result obtained by Kussmann and Raub[2].

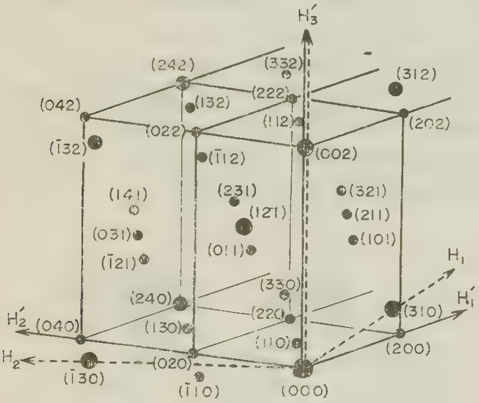

Fig. 5. The relation between the reciprocal lattice corresponding to the body-centred tetragonal cell and that in Fig. 4. Indices refer to the b.c.t. cell.

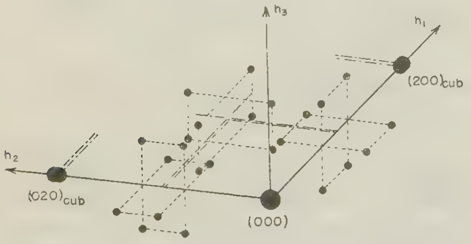

Fig. 6. Sixfold superposition of the intensity distribution in reciprocal space.

While Fig. 4 or 5 represents the intensity distribution in reciprocal space corresponding to one orientation of the lattice, there are six possible orientations in an actual ordered alloy, because, first, the a_1' axis in Fig. 3 can take either position making a positive or negative angle of 18.5° to one of the original cubic axes, corresponding to the above-mentioned *A*- or *B*-lattice and, secondly, the tetragonal axis can lie along any of the three original cubic axes, as already considered in the introduction of Fig. 2 (a). In Fig. 6, the sixfold superposition of intensity distribution is given. Photo. 1 (c) corresponds to the intensity distribution in the plane of coordinates of Fig. 6, while the arrows in Photo. 1 (d) indicate the intensities not lying in this plane.

§ 4. Discussion

In the present electron diffraction study it was elucidated that the ordered Au_4Mn alloy has not the so-called anti-phase domain structure in spite of the resemblance between the diffraction patterns of the present alloy and those of the ordered alloys CuAu (II)[4], Cu_3Pd[5] and Au_3Mn[1] but a body-centred tetragonal lattice belonging to the space group $I4/m-C_{4h}^5$, as described in the preceding chapter. This type of ordered structure has already been found by Harker[7] in the alloy Ni_4Mo.

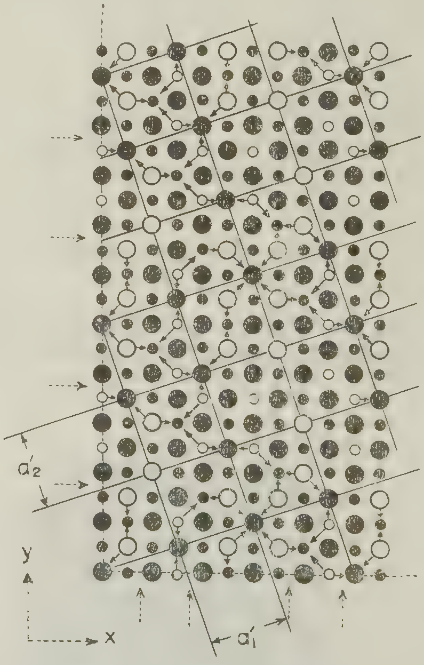

Fig. 7. The relation between the ordered Au_3Mn-type structure and the ordered Au_4Mn-type structure. The open and closed circles represent Mn and Au atoms, respectively. Out-of-steps in the Au_3Mn structure occur at places indicated by dotted arrows. The full arrows show the possibility of interchange between nearest neighbor atoms.

He determined this structure, analyzing X-ray Debye patterns, and called the fifth ordered structure of the face-centred cubic lattice. Subsequently, Epremian and Harker[8] found the same type of structure also in the alloy Ni$_4$W. It seems noticeable that the Ni$_4$Mo-type ordered structure was confirmed in the present case, using single-crystalline patterns of evaporated films.

As seen from the patterns in Photo. 1, the Au$_4$Mn alloy possesses the ordered Au$_3$Mn-type structure above about 400°C. Here, we shall consider the mechanism of the structural transition between the ordered Au$_4$Mn and Au$_3$Mn in terms of both the present model and the atomic arrangement elucidated in Part I. One of examples of the atomic arrangement of Au$_3$Mn-type corresponding to the pattern in Photo. 1 (a) is shown in Fig. 7, where M_1 and M_2 are assumed to be 1.2 and 2.2 respectively, the dotted lines represent the line-up directions of anti-phase domains and the full lines correspond to the directions parallel to a_1' and a_2' axes of Au$_4$Mn lattice. It is readily known that the transformation can be done only by the interchange of nearest neighbor atoms, as shown by full arrows in Fig. 7. While the above model corresponds to the 25 per cent manganese alloy, the circumstances seem to be much the same for 20 per cent manganese alloy.

Manganese atoms are farther distant from one another in the present ordered structure than in the ordered Au$_3$Mn: all the twelve first nearest neighbors* of a manganese atom are gold atoms, and among the second and third nearest neighbors there are only two and eight manganese atoms, respectively, manganese-manganese distance being 4.03 and 4.99 Å, which are far larger than in metallic manganese. These circumstances may be responsible for the occurrence of ferromagnetism in the ordered Au$_4$Mn alloy.

The present author wishes to express his sincere thanks to Professor S. Ogawa for the kind guidance and encouragement. His thanks are also due to Dr. M. Hirabayashi whose discussion was very useful.

The present investigation has partly been supported by the fund of the Ministry of Education in Aid of Scientific Researches.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 15, No. 7, JULY, 1960

The Binding Energy of the σ Bond, II. Application to the Diamond Crystal.

By Kiyosi O-OHATA

Physics Department, Tokyo Institute of Technology
O-okayama, Meguro-ku, Tokyo

(Received November 17, 1959)

A calculation of the cohesive energy of the diamond crystal has been carried out by using the general scheme which is derived by the Heitler-London approximation in the preceding article. It has been found that the value of the binding energy is about 3.26 eV per a bond in rather good agreement with the observed one.

§ 1. Introduction

In the preceding article[1] we have derived the general scheme for calculating the binding energy of the σ bond. The aim of this article is to apply this scheme to the calculation of the binding energy of the C–C bond in the diamond crystal.

§ 2. Atomic Wave Functions and Energy Leaves

We will use the following atomic orbitals of the Slater type:

$$\left.\begin{aligned} (1s)&=\sqrt{\frac{\delta_0^3}{\pi}}\exp(-\delta_0 r)\,,\\ (2s^\circ)&=a\sqrt{\frac{\delta^5}{3\pi}}\,r\exp(-\delta r)+b(1s)\,,\\ (2px)&=\sqrt{\frac{\delta^5}{\pi}}\,x\exp(-\delta r),\ \text{etc.}\end{aligned}\right\} \qquad (2.1)$$

where δ_0 and δ are parameters of which values are here taken to be 5.70 and 1.60, respectively. These values are chosen so as to be approximately equal to the corresponding ones given by Slater and Zener.[2] The small difference of these values may not yield any serious change to the following results. a and b are parameters determined by the condition of the orthogonalization between $1s$ and $2s$ functions. The total energy of the ground state and the energies of the excited states relative to that of the ground state are calculated, of the carbon atom, by the use of the atomic orbitals (2.1). The results are given in Table I, where the comparison is made with the corresponding experimental ones.

As a whole, the agreement between the calculated values and the observed ones is satisfactory in spite of the somewhat arbitrary choice of the parameters. The calculated value of the total energy of the ground state is 6.4 eV larger than the experimental one.

Table I. The total energy of the ground state and the energies of the excited states relative to the ground state of the carbon atom.

Electron configurations	States	Calc. values (in eV)*	Exp. values[3] (in eV)
	^3P	0.00 (−1023.4)**	0.00 (−1029.8)**
s^2p^2	^1D	1.84	1.26
	^1S	4.59	2.68
	^5S	2.70	4.16
	^3D	8.83	7.94
sp^3	^3P	10.66	9.33
	^3S	15.58	—
	^1D	16.20	13.12
	^1P	17.41	—

* We take 1 a.u. as 27.204 eV.

** The values in brackets are the total energy of the ground state.

This state of affairs does not change appreciably, even if we use the Hartree wave functions.[4] As seen from Table I the calculated excitation energy to the ^5S state is smaller than the experimental one by about 1.5 eV. This can be expected from the fact that the correlational energy in the ^5S states is smaller than that in the ^3P state. Thus we take the ^5S state as a reference level in the calculated atomic energies, and assume that the ground state ^3P lies by 4.16 eV below the ^5S state, taking into account the exerimental value for the energy separation between these states. The energy of the ground state determined in such a way is also about 5 eV larger than the experimental one. This difference is mainly due to the correlational energy between the two electrons in the 1*s* orbital. The detail discussion on this problem was reported by Arai and Onishi.[5] The discrepancy between the calculated and experimental values above mentioned may not give rise any any serious error in the calculation of the binding energy, since it might be legitimate to treat the two electrons in the 1*s* orbital as the core electrons and to assume the same correlational energy in both of the free and bound atoms. The tetrahedral valence state V_{4t} of the carbon atom is calculated to be 4.15 eV above the ^5S state. Thus we assume 8.31 eV for the excitation energy of V_{4t} state from the ground state. This value corresponds to the promotional energy for the infinitely separated atom in diamond in the Heitler-London approximation.

Table II. The ionization potentials and electron affinities in the valence state of the carbon atom.

		Calc. values	Estimated values
Ionization potentials	$E(C^+,\ p^3,\ V_3)-E(C,\ sp^3,\ V_4)$	19.74 eV	21.06 eV
	$E(C^+,\ sp^2,\ V_3)-E(C,\ sp^3,\ V_4)$	9.54	11.17
Electron affinities	$E(C,\ sp^3,\ V_4)-E(C^-,\ sp^4,\ V_3)$	−7.50	0.69
	$E(C,\ sp^3,\ V_4)-E(C^-,\ s^2p^3,\ V_3)$	4.31	8.79

We have also calculated the ionization potential and the electron affinity for the valence state $V_4(sp^3)$ of the carbon atom. These correspond to the case where one electron is subtracted from or added to the electron configuration $1s)^2 2s)^1 2px)^1 2py)^1 2pz)^1$. The result is listed in Table II, where the values estimated by Mulliken[6] are given for comparison. As seen from this table, our atomic orbitals are suitable to compute the ionization potential, but not to the electron affinity. This is familiar fact suggested by Moffitt,[7] but we do not adopt any particular treatment to avoid this defect. For necessity in the calculation of the later section, we have also computed the ionization potential for the tetravalent state $V_{4t}(sp^3)$ to be 13.24 eV.

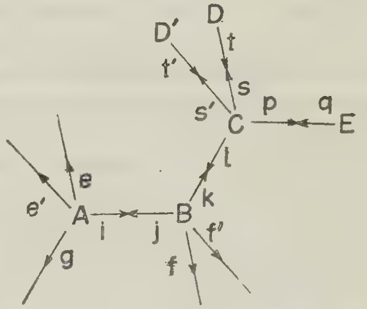

Fig. 1. Structural Diagram of the Diamond lattice. Capital letters show the constituent atoms and small letters denote the directional valence orbitals.

§ 3. The Binding Energy of Diamond Crystal

Diamond consists of the equivalent carbon atoms liked together by the equivalent C–C σ bonds and can be considered as a saturated giant molecule. The spatial arrangement of the atoms in the diamond crystal is shown in Fig. 1. We assume the nuclear distance between the nearest neighbour atoms to be 1.54 A. The method for the calculation of the binding energy of the σ bond with the Heitler-London method was given in I. The binding energy $D(AB)$ of a bond A–B in a saturated molecule was given by Eq. (6.1) in I, that is,

$$
\begin{aligned}
D(AB)=Q(AB)&+\sum_{C}\frac{1}{n_A+n_C}Q(AC)\\
&+\sum_{D}\frac{1}{n_B+n_D}Q(BD)+J(ij)\\
&-\frac{1}{4}\sum_{(kl)\neq(ij)}J(ij,\ kl)\\
&+\left\{\frac{1}{n_A}(E_A{}^*-E_A)+\frac{1}{n_B}(E_B{}^*-E_B)\right\},
\end{aligned}
\tag{3.1}
$$

where n_A, n_B, n_C and n_D are the total numbers of the valence orbitals of the atoms A, B, C and D, respectively, and all of them are equal to 4 in the diamond. $E_A{}^*-E_A$ and $E_B{}^*-E_B$, being the promotional energy from the ground state to the tetravalent state in the carbon atom, are taken, from the preceding paragraph, as

$$E_A{}^*-E_A=E_B{}^*-E_B=8.31\ \text{eV}. \tag{3.2}$$

The expressions of $Q(AB)$, $Q(AC)$, $Q(BD)$, $J(ij)$ and $J(ij,\ kl)$ are given in I in terms of the overlap and molecular energy integrals, of which values can be obtained by using the tables given by Kotani et al..[8] After a tedious calculation we get

$$D(AB)=-3.54\ \text{eV} \tag{3.3}$$

as the binding energy of a C–C bond in the diamond crystal. To obtain the value (3.3) from Eq. (3.1), we took the summations $\sum_{C}$ and $\sum_{D}$ in Eq. (3.1) only over the second neighbour atoms from the atoms A and B, respectively, since the total contribution from the third neighbours is very small ($\simeq -0.005$ eV). We also took the summation $\sum'_{(kl)}$ in Eq. (3.1) over the nearest and second nearest neighbour bonds with respect to the bond (ij), since the value of $\Delta(ij,\ kl)$, which is found in the expression of $J(ij,\ kl)$ and manifests the effect of the non-orthogonality between the two bonds (ij) and (kl), may be exceedingly small in the case that the two bonds (ij) and (kl) are the third or more remote neighbours. The values of $\Delta(ij,\ kl)$ are listed in Table III for the first and second neighbour bonds, and the values of the corresponding $J(ij,\ kl)$ are listed in Table IV. The values of the other terms in Eq. (3.1) are

$$Q(AB)=-5.773\ \text{eV},\quad J(ij)=-4.50\ \text{eV}$$

and

$$\frac{1}{8}\left\{\sum_{C}Q(AC)+\sum_{D}Q(BD)\right\}=-0.317\ \text{eV}.$$

In the evaluation of the value of $J(ij,\ kl)$, we assumed that the values of the many center energy integrals can be estimated by the Mulliken approximation analogous to Eq. (5.6) in I, and further $J(ij,\ kl)$ involves the operator depending only on the potential of the atoms to which the orbitals ϕ_i, ϕ_j, ϕ_k and ϕ_l belong. The latter assumption is approximately warranted by the former assumption. This is explained in the following.

The original form of $J(ij,\ kl)$ can be written so as to involve the potential of the whole molecule, that is, it is seen from Eq. (4.6) in I that the terms of the following two types

Table III. The values of Δ's.

	Nearest neighbour	Second neighbours*	
		gauche	trans
$\Delta(ij,\ kl)$	0.05555 34	0.01248 76	0.01407 17

* There are two kinds of the second neighbour bonds with respect to a bond (ij), as seen from Fig. 1. The first locates at the gauche position and the second at the trans position for the bond (ij).

Table IV. The values of $J(ij,\ kl)$. (in eV)

	Nearest neighbour	Second neighbours	
		gauche	trans
$J(ij,\ kl)$	−1.543	−0.161	−0.066

$$\alpha_i = I_{ii} + \sum_{(pq)}'' \frac{1}{1+S_{pq}^2}(C_{ip}+C_{iq}+2S_{pq}D_{i,pq}) \tag{3.4}$$

and

$$\beta_{ij} = I_{ij} + \sum_{(pq)}'' \frac{1}{1+S_{pq}^2}(D_{p,ij}+D_{q,ij} + 2S_{pq}N_{pq,ij}) \tag{3.5}$$

are involved in $J(ij, kl)$, where $I_{ij}=(\phi_i|h|\phi_j)$, h is the part of the total Hamiltonian depending only on one electron, $C_{ip}=(\phi_i\phi_i;\ \phi_p\phi_p)$, $D_{i,pq}=(\phi_i\phi_i;\ \phi_p\phi_q)$, $N_{pq,ij}=(\phi_p\phi_q;\ \phi_i\phi_j)$, and the summation extends over all the orbital pairs other than the two pairs (ij) and (kl). Using the Mulliken approximation, we can estimate the above two terms as

$$\left.\begin{aligned} \alpha_i &= I_{ii} + \sum_{(pq)}'' (C_{ip}+C_{iq})\ , \\ \beta_{ij} &= I_{ij} + \sum_{(pq)}'' (D_{p,ij}+D_{q,ij})\ . \end{aligned}\right\} \tag{3.6}$$

These involve the potential $\mathscr{V}^X$ of the atom X which is expressed as

$$\mathscr{V}^X = V^X + \sum_x C_x\ , \tag{3.7}$$

where V^X denotes the core potential of the atom X, C_x represents the Coulomb potential due to the electron in the orbital ϕ_x, ϕ_x is a valence orbital of the atom X. This potential is the one due to the neutral atom X, and its expectation value will, of course, be small. In terms of $\mathscr{V}^X$ Eq. (3.6) are rewritten as

$$\left.\begin{aligned} \alpha_i &= \mathscr{K}_{ii} + \sum_X \mathscr{V}_{ii}^X - (C_{ii}+C_{ij}+C_{ik}+C_{il})\ , \\ \beta_{ij} &= \mathscr{K}_{ij} + \sum_X \mathscr{V}_{ij}^X - (D_{i,ij}+D_{j,ij}+D_{k,ij}+D_{l,ij}), \end{aligned}\right\} \tag{3.8}$$

where

$$\mathscr{K}_{ij} = \left(\phi_i \left| -\frac{1}{2}\varDelta \right| \phi_j\right),$$

and the summation $\sum_X$ extends over all the atoms of the molecule. Furthermore, we use the Mulliken approximation for the many center energy integrals involved in β_{ij}:

$$\mathscr{V}_{ij}^X = \frac{1}{2}S_{ij}(\mathscr{V}_{ii}^X + \mathscr{V}_{jj}^X)\ , \tag{3.9}$$

if the atom X is the one other than the atoms to which ϕ_i and ϕ_j belong. If we apply the above treatment to the other α's and β's appearing in the expression of $J(ij, kl)$, it is easily seen that the potential of the atoms to which the orbitals ϕ_i, ϕ_j, ϕ_k and ϕ_l do not belong drops out from the expresssion of $J(ij, kl)$. If $J(ij, kl)$ is the exchange term between adjacent bonds and ϕ_j and ϕ_k are the different orbitals of the same atom, we cannot use the Mulliken approximation in the second step. In this case, it may be plausible to assume that the value of $\mathscr{V}_{jk}^X$ is small enough to be neglected because of the orthogonality between ϕ_j and ϕ_k. If we adopt the notations for the atoms and orbitals as shown in Fig. 1, we must take into account, for the computation of $J(ij, kl)$, only the atoms A, B, and C, and the orbitals belonging to these atoms, for that of $J(ij, st)$, only the atoms A, B, C and D and the atomic orbitals belonging to these atoms, and so on.

As the result of the above calculation, we have found that the value of the binding energy depends considerably on the exchange terms between the nearest neighbour bonds, but not appreciably on those between the second neighbour bonds. We note here that hitherto we followed the definition (5.6) in I for $J(ij)$. If, however, we assume that the valence orbitals fulfil Eq. (5.8) in I and adopt the definition (5.9) in I for $J(ij)$, we obtain the value of the exchange terms between adjacent bonds to be -0.124 eV. This value is very small compared with the one listed in Table IV. This apparent discrepancy comes mainly from the difference of the subtraction of the exchange integrals from $J(ij, kl)$ in the above two treatments. In the latter treatment, we obtain -4.38 eV as the value of $D(AB)$, by neglecting the contribution of the second or more remote neighbour bonds, as it may be much smaller than that of $J(ij, kl)$. This value of $D(AB)$ is somewhat different from that in (3.3), but this discrepancy seems not be so serious as that of $J(ij, kl)$. Although it must be kept in mind that the atomic wave function used here is not a good approximation for the eigenfunction of the Hartree-Fock type equation (5.8) in I, particularly at the region distent from the atomic nucleus, the above fact suggests that the effect of the exchange terms can be reduced if the appropriate atomic orbitals are used and the intra-atomic exchange integrals are taken into account adequately.

§ 4. Discussion

In the estimation of the molecular energy integrals in the preceding section, we assumed that the core potential of an atom can be replaced by the nuclear potential with an effective nuclear charge, that is,

$$V_{ij}{}^{A}=\int \phi_i(1)\,\frac{4}{r_{A1}}\,\phi_j(1)dv_l\ . \tag{4.1}$$

The effect of the extension of the 1s orbital was discussed by Nagahara,[9] who suggested that the contribution from this effect to the binding energy is by no means unimportant even at the equilibrium nuclear distance. There are two reasons which affect the value of the binding energy from this effect. The one comes from the fact that we must orthogonalize the valence orbital to 1s orbital of the other atoms. The second comes from we must consider the exchange terms between the two orbitals mentioned above. To study the first point, though it is preferable that we orthogonalize each valence orbital to the core orbitals of all the other atoms, it may be sufficient, as discussed in § 3 of I, that we orthogonalize the valence orbital only to the core orbitals of the atom bonded with the considering valence orbital, because of the smallness of the other overlap integrals in our case. For the bond A–B between the atoms A and B the revised valence orbitals are

$$\left.\begin{aligned}\tilde{\phi}_i{}^{A}&=\frac{1}{\sqrt{1-T_{i\nu}{}^2}}\,(\phi_i{}^{A}-T_{i\nu}\phi_\nu{}^{B})\ ,\\ \tilde{\phi}_j{}^{B}&=\frac{1}{\sqrt{1-T_{j\mu}{}^2}}(\phi_j{}^{B}-T_{j\mu}\phi_\mu{}^{A})\ ,\end{aligned}\right\} \tag{4.2}$$

where $\phi_i{}^{A}$ and $\phi_j{}^{B}$ are the valence orbitals of the atoms A and B, respectively, and are responsible for the construction of the bond A–B, $\phi_\mu{}^{A}$ and $\phi_\nu{}^{B}$ are the 1s orbitals of the atoms A and B, respectively, and $T_{i\nu}$ is the overlap integral between $\phi_i{}^{A}$ and $\phi_\nu{}^{B}$. In the molecular integrals involving these modified valence orbitals (4.2), can be calculated by expanding the integrals as a power series of $T_{i\nu}$. We neglected the third and higher order terms of this series due to the smallness of the value of $T_{i\nu}$. Following the above treatment, it is found that the effect of the overlap reduces the binding energy by about 0.67 eV per a bond. To study the second point, we calculated $-K_{i\nu}-K_{j\mu}$, where $K_{i\nu}$ and $K_{j\mu}$ are the exchange integrals between the valence orbital of one atom and the core orbital of another in the bond (ij). The method of calculation is the same as that in Kotani's Table.[8] The values of the auxiliary functions are found by interpolating the ones given by this table. The result is found to be -0.39 eV per a bond. Thus the total effect of the extension of the 1s orbitals on the binding energy is about 0.28 eV per a bond. This result seems to be somewhat different from Nagahara's result. With the value (3.3), the resultant binding energy of the C–C bond in the diamond crystal is found to be 3.26 eV, while the experimental one is 3.712 eV, although several different experimental values are reported.[10]

Nagahara also calculated the binding energy of the C–C bond in the investigation of the electronic state of a C–C radical. The fundamental equation (30) in his articale shows that the normalization factor of the total wave function is $(1+k-ks^2)^{-1/2}$, where k is the square of the overlap integral between bonded orbitals and s^2 is the sum of the square of the overlap integrals between unpaired orbitals. It seems to be rather strange that the normalization factor does not involve the term which depends on s^2 alone. Schmid[10] also calculated the binding energy of the diamond crystal with the use of the orthogonalized atomic orbitals, where the effect of non-orthogonality was considered up to the second order of all the overlap integrals. Such treatment seems not to be legitimate as there are some large overlap integrals, of which third order terms are unable to be neglected. On the other hand, in our treatment the overlap integrals are classified into two classes by utilizing the directional character of the valence orbitals. The overlap integral between paired orbitals is very large: $S\simeq 0.7$, and that between unpaired orbitals is very small: $T\simeq 0.1$. Then, S should be throughly taken into account, while T^3 and higher order terms can be neglected. Through this treatment, Eq. (3.1) was derived in I. From the actual calculation in the preceding section, we found that we can obtain a good approximate value for the binding energy of the σ bond, if we take the Coulomb and exchange terms between bonded orbitals and the exchange terms between the nearest neighbour bonds, since the contribution of the exchange terms between the second neighbour bonds is not appreciable. It, then, seems to be plausible that we neglect the exchange terms between the third or more remote neighbour bonds. As to the Mulliken approximation (5.6) in I we already discussed in § 6 of I. Furthermore, as seen from the discussion in the preceding section, the use of the Mulliken approximation served to show that the potential of the effectively neutralized atoms cancel out in the expression of $J(ij, kl)$. Then in our calculation a significant error may not arise from the use of the Mulliken approximation for the estimation of the values of the many center energy integrals. Furthermore we assumed that the orthogonalized $2s$ atomic orbital can be replaced by the non-orthogonal one in the calculation of the two electron molecular integrals other than some of Coulomb integrals. This may be serious but the order of magnitude of each term discussed in the preceding section seems not to vary radically by this approximation.

It will be reported in the next article of this series to revise the calculated value of the binding energy with the inclusion of the ionic terms of the bond.

The author wishes to express his sincere thanks to Professor K. Niira for his incessant encouragement and also for his kind reading of the manuscript, and to Professor E. Ishiguro for his valuable suggestions. The author is indebted to the Ministry of Education for the research grant.

(Received March 26, 1960)

The magnetic susceptibilities and the g-values of the Pd and Pt group transition metal complexes are calculated by means of the intermediate coupling scheme. Crystalline field with cubic symmetry is assumed to be strong, so that the effect of $d\gamma$ orbitals is neglected. The effect of Coulomb repulsion is considered to be comparable with that of the spin-orbit interaction. The results are expressed by functions of parameters $\eta=\zeta_d/(3B+C)$ and kT/ζ_d, where B and C are Racah's parameters and ζ_d the coefficient of spin-orbit coupling of a d-electron. Comparison with available experimental data is also made.

§ 1. Introduction

As the result of growing interest in the magnetic properties of the Pd($4d$) and Pt($5d$) group transition metal compounds, several experimental works have recently been carried through concerning the electron spin resonance and the susceptibility on these salts. It is well known that the general aspect of the magnetic moments (some are very near to the free ion values but some are much lower than those) are well accounted for by the Van Vleck and the Pauling models. Kotani[1] explained the behaviour of the low magnetic moments and their temperature variations quantitatively by taking the spin-orbit coupling of the d-electrons into account. He obtained good agreements with experiments as far as the first ($3d$) transition metal complexes are concerned.

Quite recently, Figgis et al[2] have applied the Kotani theory to the magnetic susceptibility of the Pd and Pt group transition metal complexes and found remarkable discrepancies between their experimental values and those obtained by the Kotani theory. For example, the ions with $(5d\varepsilon)^3$ configuration have the effective Bohr magneton numbers fairly smaller than the values expected from the theory. According to the theory all the octahedral complex ions with $d\varepsilon^3$ configuration should have the temperature independent value 3.88 of the effective Bohr magneton number, which is fairly large compared with the experimental values mentioned in Table I. For comparison, those of the iron group complexes, which agree very well with the Kotani theory, are also listed in the table.

Table I.

Iron Group	$n_{300°K}$	Platinum Group	$n_{300°K}$	n'_{eff}	ϑ(°K)
$K_3[Cr(CN)_6]$	3.74β	K_2ReF_6	3.32β	3.50β	40
$[Cr(NH_3)_6]I_3$	3.80β	K_2ReCl_6	3.25β	3.70β	86
$[Cr(NH_3)_6]Br_3$	3.77β	K_2ReBr_6	3.19β	3.70β	105
$[Cr(OC(NH_2)_2)_6]Cl_3$	3.64β	K_2ReI_6	3.32β	3.70β	100
$[Cr(OH_2)_6]Cl_3$	3.78β	K_2OsF_6	3.2 β		

In order to clarify the reason of the discrepancies, let us mention the basic assumptions of the Kotani theory:

(i) the effects of the ligand field are much greater than those of the Coulomb repulsion between the d-electrons;

---

* Present address: Bell Telephone Laboratory, Murray Hill, N.J., U.S.A.

(ii) the Coulomb repulsion is much stronger than the spin-orbit coupling;

(iii) the ligand field is of perfectly cubic symmetry; and

(iv) the magnetic interaction between ions is negligible.

Recent experiments on the electron spin resonance yield the evidence that the charge clouds of the $4d$- and $5d$-electrons spread much more widely than the $3d$-electrons. The assumption (iv) is, therefore, not correct in the former case.

The spin-orbit coupling is also very strong for the $4d$- and $5d$-electrons, and has the strength comparable to the Coulomb repulsion. Therefore, the assumption (ii) is also invalid for these electrons. Thus we may conclude that the discrepancies arise from the assumptions (ii) and (iv) which are not satisfied by the $4d$- and $5d$-electrons.

In fact, Figgis et al have measured the susceptibilities of the salts mentioned in Table I over the temperature region 80° to 300°K and found that the observed values of the susceptibilities obey the Curie-Weiss law $\chi = C/(T+\vartheta)$. Thus they attribute a part of the enormous lowering of the magnetic moments to the anti-ferromagnetic interaction between ions. If one considers, after Figgis et al, that the effects of such interaction are all involved in the Weiss constant ϑ, then the effective Bohr magneton number will be given by the expression $n'_{eff} = 2.84\sqrt{\chi(T+\vartheta)}$. The values of n'_{eff} obtained in this manner are listed in Table I. These may be regarded as the magnitudes of the magnetic moments of the individual ions, and the deviation of their values from those predicted by the Kotani theory may be due to the break-down of the assumption (ii). From this standpoint we will pay attention only to the values of n'_{eff} and examine the interplay between the Coulomb interaction and the spin-orbit coupling.

In the present work, therefore, we shall calculate the energy eigenvalues and the magnetic susceptibilities for each of the electron configurations $d\varepsilon^n$ ($n=1, 2, \cdots, 5$) assuming only (i) and (iii).

Since the effect of the spin-orbit interaction is comparable to that of the Coulomb repulsion for the $4d$ and $5d$ transition group complexes, the intermediate coupling scheme has to be adopted for our purpose. For the configuration $d\varepsilon^1$, however, there is no Coulomb repulsion. Hence we need not consider the effect of the Coulomb interaction in this case. Since $d\varepsilon^5$ is regarded as the configuration in which there remains one hole in the closed shell $d\varepsilon^6$, the level scheme is the same as that of the $d\varepsilon^1$ configuration. The Kotani theory can, therefore, be applied to $d\varepsilon^1$ and $d\varepsilon^5$ even in the case of very strong spin-orbit coupling. The configuration $d\varepsilon^4$ can also be treated in the same scheme as $d\varepsilon^2$ except for changing the sign of the spin-orbit coupling parameter. After all, we have only to calculate the energy eigenvalues for the configurations $d\varepsilon^2$ and $d\varepsilon^3$.

§ 2. Energy Levels

The Hamiltonian of a transition metal ion in an external magnetic field is given by

$$\mathscr{H} = \mathscr{H}_0 + V_{\text{cubic}} + \sum_{i>j} \frac{e^2}{r_{ij}} + \zeta_d \sum_i \boldsymbol{l}_i \cdot \boldsymbol{s}_i + \beta \boldsymbol{H} \cdot \sum_i (\boldsymbol{l}_i + 2\boldsymbol{s}_i) \quad (1)$$

where $\mathscr{H}_0$ stands for the sum of the kinetic- and the potential energy of d-electrons moving in the field due to the atomic core of the ion. The third term denotes the Coulomb repulsion between the d-electrons, and the fourth term is their spin-orbit interaction. The last term expresses the Zeeman energy due to the external magnetic field. As is emphasized in § 1, the purpose of the present paper is to show the joint effects of the spin-orbit interaction and of the Coulomb repulsion on the magnetic properties of the complex ion. Hence, for simplicity, the ligand field expressed by the second term of (1) is assumed to be completely cubic and the field components with lower symmetry will be neglected. Besides we assume that all the effects of the magnetic interaction between ions are included in the Weiss constant ϑ.

According to the assumption (i), the ligand field is so strong that the splitting between $d\varepsilon$ and $d\gamma$ levels is sufficiently large and we shall disregard the effect of the latter orbitals. In the following, therefore, the effect of the ligand field will be implicitly involved in that we merely consider the configurations $d\varepsilon^n$ ($u=2$, 3 and 4). Thus the contribution of $\mathscr{H}_0 + V_{\text{cubic}}$ will not appear explicitly in the calculation because it only gives a constant term common to all the diagonal elements of the energy matrix.

For the configurations $d\varepsilon^2$ and $d\varepsilon^4$, the Coulomb repulsion between d-electrons gives rise to four levels ${}^3\mathrm{T}_1$, ${}^1\mathrm{E}$, ${}^1\mathrm{T}_2$ and ${}^1\mathrm{A}_1$. After Tanabe and Sugano[3], the eigenfunctions of these states will be denoted by the following:

$$\begin{array}{llll} {}^3\mathrm{T}_1: & |\alpha(M_s)\rangle, & |\beta(M_s)\rangle, & |\gamma(M_s)\rangle \qquad (M_s=1,0,-1)\,. \\ {}^1\mathrm{E}: & |u\rangle, & |v\rangle, & \\ {}^1\mathrm{T}_2: & |\xi\rangle, & |\eta\rangle, & |\zeta\rangle \\ {}^1\mathrm{A}_1: & |e\rangle\,. & & \end{array}$$

$d\varepsilon^2$: The matrix elements of the spin-orbit interaction with respect to the eigenfunctions mentioned above are given in Appendix I. We shall first omit the Zeeman energy term and diagonalize the Coulomb repulsion plus the spin-orbit interaction. The eigenvalues and the eigenfunctions thus obtained are the following:

$$W_1=\zeta_d/2 \qquad \text{(Triply degenerate)}$$

$$\psi_{10}=\frac{1}{2}[i\{|\alpha(1)\rangle+|\alpha(-1)\rangle\}+|\beta(1)\rangle-|\beta(-1)\rangle]$$

$$\psi_{1\pm1}=\frac{1}{2}\{i|\alpha(0)\rangle\mp|\beta(0)\rangle\}-\frac{i}{\sqrt{2}}|\gamma(\pm1)\rangle$$

$$\left.\begin{matrix}W_2\\W_3\end{matrix}\right\}=\frac{\zeta_d+Q}{2}\pm\frac{1}{2}\sqrt{(\zeta_d-Q)^2+8\zeta_d^2} \qquad \text{(the upper and lower signs correspond to } W_2 \text{ and } W_3 \text{ respectively)}$$

$$\left.\begin{matrix}\psi_2\\\psi_3\end{matrix}\right\}=\frac{1}{\sqrt{2\zeta_d^2+(Q-W_{2,3})^2}}\{\sqrt{2}\,\zeta_d|e(1)\rangle+(Q-W_{2,3})|\varphi_0\rangle\}$$

$$\left.\begin{matrix}W_4\\W_5\end{matrix}\right\}=\frac{P}{2}-\frac{\zeta_d}{4}\pm\frac{1}{2}\sqrt{\left(\frac{\zeta_d}{2}+P\right)^2+2\zeta_d^2} \qquad \text{(each has five-fold degeneracy specified by } \gamma_J)$$

$$\left.\begin{matrix}\psi_4(\gamma_J)\\\psi_5(\gamma_J)\end{matrix}\right\}=\frac{1}{\sqrt{\frac{\zeta_d^2}{2}+\left(\frac{\zeta_d}{2}+W_{4,5}\right)^2}}\left\{-\frac{\zeta_d}{\sqrt{2}}|\varphi_1(\gamma_J)\rangle+\left(\frac{\zeta_d}{2}+W_{4,5}\right)|\varphi_2(\gamma_J)\rangle\right\}$$

$$(\gamma_J=2,1,0,-1,-2)\,.$$

Here

$$P=2(3B+C) \quad \text{and} \quad Q=5(3B+C)\,,$$

B and C being the Racah parameters, and

$$|\varphi_0\rangle=\frac{1}{\sqrt{6}}\{i|\alpha(1)\rangle-i|\alpha(-1)\rangle+|\beta(1)\rangle+|\beta(-1)\rangle\}-\frac{i}{\sqrt{3}}|\gamma(0)\rangle$$

$$|\varphi_1(0)\rangle=\frac{1}{2\sqrt{3}}[i\{|\alpha(1)\rangle-|\alpha(-1)\rangle\}+\{|\beta(1)\rangle+|\beta(-1)\rangle\}]+\sqrt{\frac{2}{3}}\,i\,|\gamma(0)\rangle$$

$$|\varphi_1(\pm2)\rangle=\frac{1}{\sqrt{2}}\{i|\alpha(-1)\rangle\pm|\beta(-1)\rangle\}$$

$$|\varphi_1(\pm1)\rangle=\frac{1}{2}\{i|\alpha(0)\rangle\pm|\beta(0)\rangle\}+\frac{1}{\sqrt{2}}|\gamma(\mp1)\rangle$$

$$|\varphi_2(0)\rangle=|u\rangle$$

$$|\varphi_2(\pm 2)\rangle = \frac{1}{\sqrt{2}}\{|\zeta\rangle \pm i|v\rangle\}$$

$$|\varphi_2(\pm 1)\rangle = \frac{1}{\sqrt{2}}\{|\xi\rangle \pm i|\eta\rangle\}$$

$d\mathcal{E}^4$: All the expressions can be derived from those of $d\mathcal{E}^2$ by changing the sign of the spin-orbit interaction parameter ζ_d, i.e. $\zeta_d \to -\zeta_d$. The energy levels are shown in Fig. 1.
$d\mathcal{E}^3$: The Coulomb repulsion gives rise to four levels $^4A_2$, ^2E, $^2T_1$ and $^2T_2$ in this case. The eigenfunctions of these levels will be denoted by the following:

$$^4A_2: \quad |e^{++}\rangle, \quad |e^{+}\rangle, \quad |e^{-}\rangle, \quad |e^{--}\rangle$$

$$^2E\ : \quad |u^{+}\rangle, \quad |u^{-}\rangle, \quad |v^{+}\rangle, \quad |v^{-}\rangle$$

$$^2T_1: \quad |\alpha^{+}\rangle, \quad |\alpha^{-}\rangle, \quad |\beta^{+}\rangle, \quad |\beta\rangle, \quad |\gamma^{+}\rangle, \quad |\gamma^{-}\rangle$$

$$^2T_2: \quad |\xi^{+}\rangle, \quad |\xi^{-}\rangle, \quad |\eta^{+}\rangle, \quad |\eta^{-}\rangle, \quad |\zeta^{+}\rangle, \quad |\zeta^{-}\rangle$$

Here the plus and the minus signs correspond to the M_z values 1/2 and $-1/2$ respectively, and the double signs to those of 3/2 and $-3/2$ respectively.

The non-vanishing matrix elements of the spin-orbit interaction with respect to the above functions are given in Appendix II. By reducing the energy matrix without the Zeeman term, we can immediately determine eight of the eigenstates as:

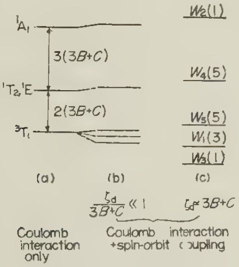

Fig. 1. A schematic energy-level diagram for $(d\varepsilon)^4$. Figures in parentheses represent degeneracy of each energy level.

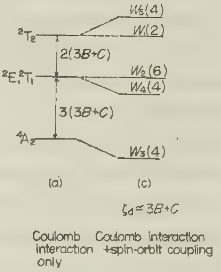

Fig. 2. A schematic energy-level diagram for $(d\varepsilon)^3$.

$W_1 = 15B + 5C$:

$$\frac{1}{\sqrt{3}}\{\pm i|\xi^{\pm}\rangle + |\eta^{\pm}\rangle - i|\zeta^{\mp}\rangle\}$$

$W_2 = 9B + 3C$

$$\frac{1}{\sqrt{5}}\{3|u^{\pm}\rangle - i|\alpha^{\mp}\rangle \mp |\beta^{\mp}\rangle\}$$

$$\frac{1}{\sqrt{2}}\{|v^{\pm}\rangle \pm i|\gamma^{\pm}\rangle\}$$

$$\frac{1}{\sqrt{10}}\{|v^{\pm}\rangle \mp i|\gamma^{\pm}\rangle - 2i|\alpha^{\mp}\rangle + 2|\beta^{\mp}\rangle\}.$$

In order to determine the remaining twelve states, we have to diagonalize the following three-dimensional matrix. The eigenvalues and the eigenfunctions are obtained numerically. Each of the three eigenvalues is of four-fold degeneracy. Energy levels are (schematically) given in Fig. 2.

$\pm\frac{1}{\sqrt{2}}\{i\|\xi^{\pm}\rangle\mp\|\eta^{\pm}\rangle\}$	$\frac{1}{\sqrt{10}}\{\pm 2\|v^{\mp}\rangle+2i\|\gamma^{\mp}\rangle\pm i\|\alpha^{\pm}\rangle+\|\beta^{\pm}\rangle\}$	$\|e^{\pm\pm}\rangle$
$\mp\frac{1}{\sqrt{6}}\{i\|\xi^{\pm}\rangle\pm\|\eta^{\pm}\rangle\pm 2i\|\zeta^{\mp}\rangle\}$	$\pm\frac{1}{\sqrt{10}}\{2\|u^{\mp}\rangle+\sqrt{3}\,i\|\alpha^{\pm}\rangle\mp\sqrt{3}\,\|\beta^{\pm}\rangle\}$	$\|e^{\mp}\rangle$
$15B+5C$	$\sqrt{5}\,\zeta_d/2$	ζ_d
	$9B+3C$	0
		0

§ 3. Magnetic Susceptibilities and g-values

Matrix elements of the Zeeman term can be easily obtained by means of Tanabe-Kamimura's tables[4]. Then the calculation of magnetic susceptibilities is carried out by using the well-known formula based on the perturbational treatment of the Zeeman energy. As easily seen from Figs. 1 and 2, the g-values and the susceptibilities can respectively be expressed in terms of functions of $\eta=\zeta_d/(3B+C)$ and of functions of η and kT/ζ_d. The limiting case of $\eta\rightarrow 0$ is the one given by the Kotani theory.

$d\varepsilon^2$: The result of calculation for the effective Bohr magneton number $n_{eff}=\sqrt{3kT\chi/N\beta^2}$ is plotted as a function of η and kT/ζ_d in Fig. 3. So far there is no experimental data for this configuration. The result shown in Fig. 3 may be used for the future analysis.

$d\varepsilon^3$: Our results for the g-value and n_{eff} are plotted in Fig. 4 and Fig. 5 respectively. As seen in Fig. 4, the g-value decreases with increasing η and becomes smaller than 2. The value of n_{eff} also decreases with increasing η and shows a slight temperature dependence.

$d\varepsilon^4$: The ground level is a singlet in this

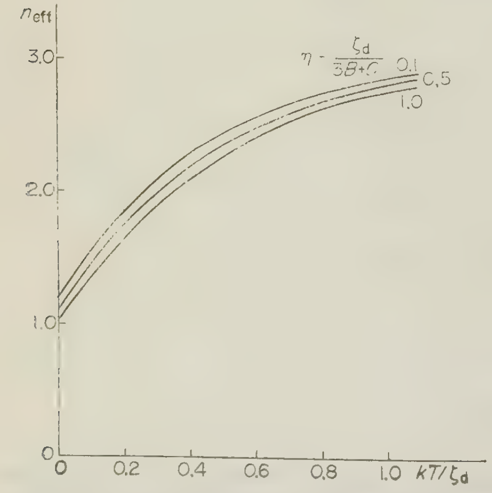

Fig. 3. The effective Bohn magneton number n_{eff} as a function of $\eta=\frac{\zeta_d}{3B+C}$ and $\frac{kT}{\zeta_d}$ for $(d\varepsilon)^2$.

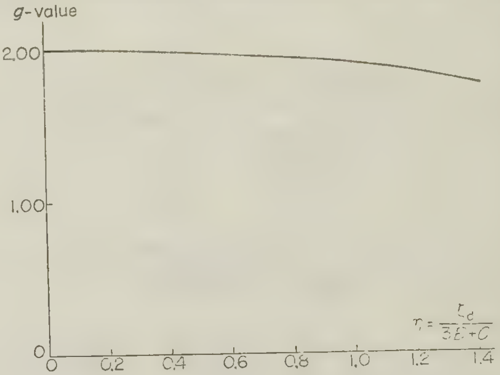

Fig. 4. The g-value as a function of η for $(d\varepsilon)^3$.

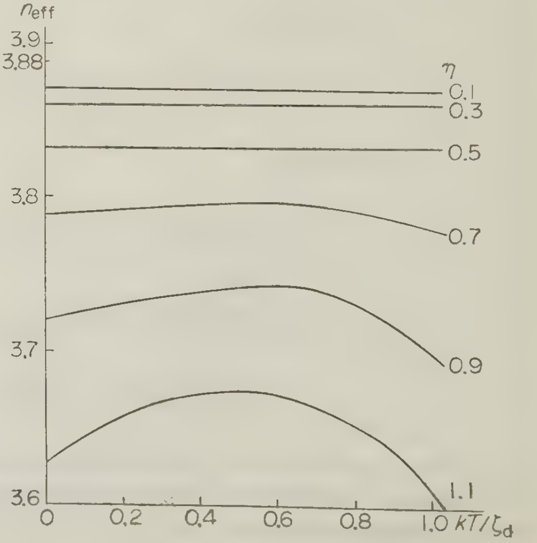

Fig. 5. n_{eff} for $(d\varepsilon)^3$.

case. Hence $g=0$. The behaviour of n_{eff} as a function of η and kT/ζ_d is illustrated graphically in Fig. 6.

§ 4. Comparison with Experiments and Discussions

In comparing the calculated Bohr magneton numbers with experiments, we have to separate the contribution of the interaction between ions from the observed susceptibilities which obey the Curie-Weiss law $\chi=C/(T+\vartheta)$. If the constants C and ϑ are determined so as to get the best fit with experimental values, we may consider the effect of the interaction to be involved in the Weiss constant ϑ. Then the effective Bohr magneton number given by the expression $n'_{eff}=2.84\sqrt{C}$ is regarded as the magnetic moment of a single ion.

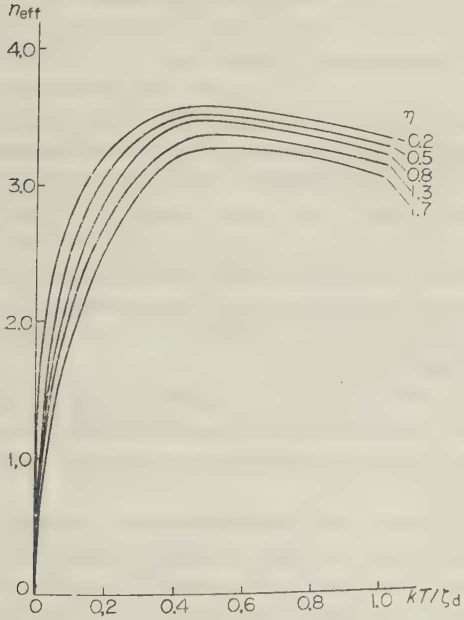

Fig. 6. n_{eff} for $(d\varepsilon)^4$.

$d\mathcal{E}^3$: It is seen in Table I that the effective Bohr magneton numbers of K_2ReX_6, thus obtained (X being halogen atom) have the common value for Cl, Br and I of X. According to our assumption, the effect of the ligands is involved in the cubic field and so is taken care of in considering only the configulation $d\mathcal{E}^n$.

Consequently, there is no room in our treatment for the ligands to exhibit their differences. The above-mentioned experimental result seems to justify our basic assumptions in the case of K_2ReX_6. We cannot, however, determine the values of the parameters η and ζ_d by comparing our theory with the experiments of susceptibilities, because the temperature dependence of n'_{eff} has not been reported yet. However, experimental data of the electron spin resonance are available for K_2ReCl_6 [5] and gives a provisional value of $g=1.8$, from which we can determine the value of η as 1.3. Using this value and the value 3.70 of n'_{eff} at room temperature, we obtain $\zeta_d=2600\,\text{cm}^{-1}$ and $3B+C=2000\,\text{cm}^{-1}$.

Using the intermediate coupling scheme, Jørgensen[6] estimated the values of these parameters from the splitting of the optical absorption peak due to the spin-orbit interaction. His results, $\zeta_d=2250\,\text{cm}^{-1}$ and $3B+C=2800\,\text{cm}^{-1}$, have the same order of magnitude as those obtained above.

If we adopt the same procedure as the Kotani theory and take account of the effect of the spin-orbit coupling on the ground state ^4A by perturbation method, then we get the expression for n'_{eff} as

$$n'_{eff}=n_{\text{spin only}}\left(1-\frac{4\zeta_d}{30Dq}\right),$$

where $10Dq$ stands for the energy difference between $d\mathcal{E}$ and $d\gamma$ orbits. If we use the value of $10Dq=27000\,\text{cm}^{-1}$, which is determined from the optical absorption data, and adjust the value of ζ_d so as to get a good fit of n'_{eff} to experiment, then we obtain $\zeta_d=1350$

Table II.

	ζ_d (cm^{-1})			$3B+C$ (cm^{-1})	
	Present calculation	Jørgensen	Kotani	Present calculation	Jørgensen
K_2RuCl_6	1400	—	1610	3500	—
K_2OsCl_6	3600	3600	6700	2770	2100

cm^{-1}. As is seen in Fig. 5, temperature variation of n'_{eff} is expected to some extent from our calculation.

$d\varepsilon^4$: Temperature variation of the magnetic susceptibilities has been observed for K_2RuCl_6 and K_2OsCl_6.[7] In Table II the values of the parameters determined so as to get the best fit of the calculated temperature variation with the experiments are set out in the second and fifth column. In Fig. 7 it may be seen that the magnitude and temperature dependence of the magnetic susceptibilities of these complex ions are fairly well reproduced by our theoretical results with parameters shown in Table II. The values determined by Jørgensen from the optical absorption data are also listed. The figures in the fourth column show the values of ζ_d which we obtain by fitting the limiting value of the susceptibility at 0°K to the one calculated by means of the Kotani theory; $\chi_0=24N\beta^2/\zeta_d$, where N is Avogadro's number and β is the Bohr magneton.

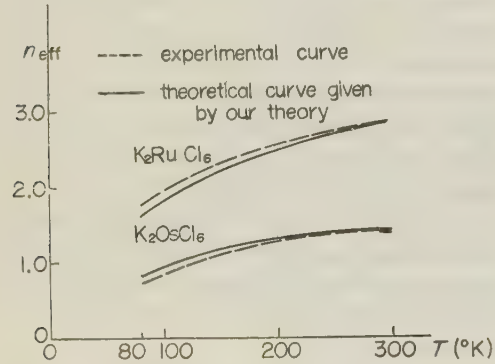

Fig. 7. Variation with temperature of n_{eff} for K_2RuCl_6 and K_2OsCl_6.

As seen in this table, our results agree quite well with those obtained by Jørgensen from the optical absorption data. The values of ζ_d obtained by the Kotani theory are larger than ours. In particular the value for K_2OsCl_6 is twice as large as those given by Jørgensen and by the present calculation. As is pointed out by Figgis et al, the jj-coupling scheme yields the expression of the magnetic susceptibility at 0°K as $\chi_0=8N\beta^2/\zeta_d$. Hence, if we determine ζ_d by comparing the observed χ at 0°K with the expression derived by means of the intermediate coupling scheme, its value is one-third of that by the Kotani theory. According to the results by Figgis et al, the values of ζ_d obtained in this way are 2500 cm^{-1} for Os^{4+} and 2900 cm^{-1} for Ir^{5+}. The Kotani theory gives 8700 cm^{-1} for the latter. Recent numerical calculation on the value of ζ_d for the Ir^{4+} ion by one of the present authors[8] gives $\zeta_d(Ir^{4+})=2400\,\mathrm{cm}^{-1}$. Cooke et al[9] also determined $\zeta_d\simeq 2000\,\mathrm{cm}^{-1}$ from the temperature dependence of the susceptibility of the complexes ion $[IrCl_6]^{2-}$.

It is seen from these values that the Kotani theory is not applied to the $4d$- and $5d$ group ions and that the spin-orbit interaction is as important as the Coulomb repulsion between the d-electrons in these ions.

As seen in the above, the comparison of our results with experiments gives reasonable values of the parameters and our assumptions seem to be justified as far as the available experimental data are concerned. The observed data are, however, still too few to confirm the validity of our basic assumptions in more general cases. Improvement might be required with respect to the following points:

(1) We have assumed perfectly cubic ligand field. The field with lower symmetry should be taken into consideration for more detailed analysis.

(2) There are some evidences showing the importance of the covalency effect in the cases of $4d$- and $5d$-electrons. It would therefore be necessary to introduce another parameter which represents the amount of this effect.

(3) We have neglected the effect of the $d\gamma$ orbitals. This is also one of the assumptions to be examined in the future investigations.

We expect, however, that the present work would give an important clue in more detailed analyses of the future experiments.

The authors wish to express their sincere thanks to Professor Masao Kotani for his much instructive advice and continual encouragement during the course of this work. They would like also to thank Miss H. Takeda and Miss S. Kosugi for their assistance in the numerical work.

Microwave Spectrum of Ethyl Iodide, II.

By Takahiro KASUYA

Departmeut of Physics, Faculty of Science,
University of Tokyo, Tokyo

(Reveived, March 26, 1960)

The potential barrier which hinders the internal rotation in ethyl iodide molecule was studied. If the potential energy is assumed to be of the sinusoidal form $\frac{H}{2}$ (1−cos 3x), the barrier height is determined as $H=3.22\pm0.5$ kcal/mole from the Q^b-type transition in the first excited torsional state. The torsional frequency is about 230 cm^{-1}. The effect of internal rotation on the quadrupole hyperfine structure of $K=1$ levels was analyzed.

§ 1. Introduction

In the previous paper[1)*], the microwave spectrum of ethyl iodide molecule in the ground vibrational state was studied by the rigid rotor treatment. The analysis of the quadrupole hyperfine structure of the spectrum due to the quadrupole moment of iodine nucleus was described there. The object of the present paper is to discuss the hindered rotation about the *C-C* bond, and to determine the precise magnitude of the hindering barrier height.

§ 2. Experimental Results

Since the barriers to the internal rotation in ethyl halide molecules are very high, the microwave spectrum of the transitions for the ground vibrational state is essentially the

same as normal rigid rotor pattern. It is well known that even in the molecules with very high barrier the effect of internal rotation can be expected to exert a detectable influence on the energy levels in the excited torsional state. For example, R^a-type transitions involving nearly degenerate $K=2$ levels in the first excited torsional state were adopted for the determination of barriers in C_2H_5Br, C_2H_5Cl and C_2H_5CN[2),3)].

In the case of ethyl iodide, however, the analysis of the torsional satellite lines had to be given up, because the spectral lines of transitions involving levels with $K \geqq 2$ overlapped with each other, and the spectral pattern was found to be quite complicated by the quadrupole hyperfine structure due to the large coupling constant along the C-I bond. On the other hand, if the torsional satellites of Q^b-type transitions are observed the larger

Here, $\varDelta$ indicates the discrepancies between the observed and the calculated frequencies carried out without the consideration of the effects of internal rotation.

effect of internal rotation can be found than in the case of R^a-type transitions. A rough estimation[*] shows that each hyperfine component of Q^b-type transition split into doublet of about 1 Mc/sec.

The spectrometer and the sample used were the same as were reported in (I). The observed frequencies are listed in Table I. The intensity of these Q^b-type lines are weak as the electric dipole moment is nearly along the a-axis.

Some additional observed frequencies of R^a-type transitions involving $K=1$ levels, omitted in (I), are listed in Table II.

§ 3. Discussions

The magnitude of splittings $\Delta\nu$ listed in Table I averages 1.74 Mc/sec for $J=6$ transitions and 1.61 Mc/sec for $J=5$ transitions. These values give the barrier height of about 3.25 kcal/mole. The theoretical treatment used in the interpretation of the observed splitting was that of Hecht and Dennison[6].

Table III. Molecular constants used in calculation.

A	180.91 amu. A^2	$(C_2/C)^*$	0.141
B	91.23 〃	$\frac{2\pi}{3}(C_1/C)^*$	1.797 rad.
C	86.27 〃	$\frac{\hbar^2}{2}(C/C_1C_2)^*$	5.770 cm^{-1}
D	75.99 〃		
C_2	3.28 〃	β	0.0923

The data was also interpreted by another approach according to Herschbach[5], and the same results were obtained. The molecular constants necessary in the analysis of internal rotation problem were derived from those reported in (I) and they are shown in Table III.

It can be seen in Table I that the magnitude of splitting corresponding to each quadrupole hyperfine component varies considerably with each other. Hence, the effects of internal rotation on the quadrupole interaction must be taken into account. The matrix elements of S of reference (6), which transforms the coordinate axis to the principal axis system, and performs the Wang's transformation to the rigid rotor part of the Hamiltonian referred to the principal axis, can be expanded in power series of geometrical parameter β[8]. The expansion accurate to the order of β^2 is:

$$<K|K>=<K|-K>=<-K|K>$$

$$=-<-K|-K>=[1-\beta^2(J^2+J-K^2)/4]/\sqrt{2}$$

$$\text{(for } K>1)$$

$$<\pm K|\pm(K+1)=-<\pm(K+1)|\pm K>$$

$$=\mp<\mp K|\pm(K+1)>=\pm<\pm(K+1)|\mp K>$$

$$=-\beta\sqrt{(J-K)(J+K+1)}/2\sqrt{2} \quad \text{(for } K>1)$$

$$<0|\pm 1>=\mp\beta\sqrt{J(J+1)}/2, \quad <-1|0>=0,$$

$$<-1|0>=\beta\sqrt{J(J+1)/2},$$

$$<0|0>=1-\beta^2 J(J+1)/4,$$

$$<1|\pm 1>=[1-\beta^2(J-1)(J+2)/8]/\sqrt{2}$$

$$<-1|\pm 1>=\pm[1-\beta^2(3J^2+3J-2)/8]\sqrt{2}.$$

The wave function in the rigit rotor limit can be written by symmetric rotor basis $S_K{}^{\pm}$ as,

$$\begin{aligned}\Phi_K{}^{\pm}=&[1-\beta^2(J^2+J-K^2)/4]S_K{}^{\pm}\\&\pm\beta g_{\mp K}S^{\pm}{}_{K\mp 1}\mp\beta g_{\pm K}S^{\mp}{}_{K\pm 1}\end{aligned} \qquad (2)$$

and

$$\Phi^+{}_1=[1-\beta^2(J^2+J-2)/8]S^+{}_1-\beta g_1 S^-{}_2$$

$$\Phi^-{}_1=[1-\beta^2(3J^2+3J-2)/8]S^-{}_1+\beta g_1 S^+{}_2+\beta g_0\Psi_0$$

$$\Phi_0=[1-\beta^2 J(J+1)/4]\Psi_\theta-\beta g_0 S^-{}_1,$$

where $g_K=\sqrt{(J-K)(J+K+1)}/2,$

$$S_K{}^{\pm}=(\Psi_K\pm\Psi_{-K})/\sqrt{2}.$$

Then the quadrupole interaction term for symmetric top limit is given as[**],

$$\frac{eq'Q}{(J+1)(2J+3)}\Big[\{3_K{}^2-J(J+1)\}(1+2\xi'\beta)$$

$$-\Big\{\frac{J^2(J+1)^2+J(J+1)(4K^2+3)}{2}$$

$$+f(J,K)\eta'\Big\}\beta^2+\cdots\Big] \qquad (K>1)$$

---

[*] According to Kilb, Lin, Wilson[4] and Herschbach's[5] notation, the rotational energy deviates from that of rigid rotor as

$$\Delta W=\partial_A W\Delta+\partial_B W\Delta B+0(\gamma^4) \qquad (1)$$

where $\partial_A W=K^2-\sum_{n=2}(n-1)C_n b^n$

$$\partial_B W=J(J+1)(1-\delta_{K,1}/2)/2-K^2/2+\sum_{n=2}nC_n b^{n-1}.$$

For the expected magnitude of barrier height ($H\sim 3$ kcal/mole),

$\Delta A=F\alpha^2\Delta\eta$ and $\Delta B=F\beta^2\Delta\eta$ are about 2.4 and 0.03 Mc/sec, respectively.

[**] For C_2H_5I, $\beta\sim 0.1$ and $b_p\sim -0.003$, the correction to quadrupole interaction coming from the molecular asymmetry is negligible as far as the effects of internal rotation is considered.

and

$$\frac{eq'Q}{(J+1)(2J+3)}\Big[3-J(J+1)+\frac{J(J+1)}{2}\eta' -3(J-1)(J+1)\xi'\beta+\frac{(J+1)(J+2)}{4}\left(9-\frac{J(J+1)}{2}\eta'\right)\beta^2+\cdots\Big]$$

$$(K=1,\ \text{even } J+K+\gamma), \qquad (3)$$

$$\frac{eq'Q}{(J+1)(2J+3)}\Big[-J(J+1)(3+\xi'\beta)+\frac{J(J+1)}{2}\left(3-\frac{J(J+1)}{2}\eta'\right)\beta^2+\cdots\Big] \qquad (K=0)$$

Here, quantities q, ξ, and η referring to the "internal axis" coordinate system are denoted by prime. They are written in terms of the diagonalized form of tensor $\boldsymbol{q}$ (q_x, q_y q_z) given in (I):

$$\boldsymbol{q}'=\boldsymbol{R}\boldsymbol{q}\boldsymbol{R}^{-1},\ \boldsymbol{R}=\boldsymbol{R}_z(\rho x)\boldsymbol{R}_x(\alpha).$$

That is,

$$\begin{aligned} q'&=\cos^2\alpha q_z+\sin^2\alpha q_y\\ \xi'&=\sin\alpha\cos\alpha(q_y-q_z)(1-\delta^{(1)})/q' \qquad (4)\\ \eta'&=(q_x-\cos^2\alpha q_y-\sin^2\alpha q_z)(1-\delta^{(2)})/q'. \end{aligned}$$

$\boldsymbol{R}_x(\alpha)$ is the rotation of angle $\alpha=<\mathrm{CCI}+\tan^{-1}D/B$ in the y_z plane, $\boldsymbol{R}_z(\rho x)$ the subsequent rotation about z axis (ρ being $(C_2/C)^*$ in Table III, and x the internal rotation angle), $\delta^{(1)}$ and $\delta^{(2)}$ the barrier dependent small quantities*).

When the K-type splitting of the K level d_K competes with the off diagonal element of Hamiltonian $(S^{-1}HS)_{K,-K}=\delta_K$ which comes from internal rotation, Wang's symmetric limit wave function $S^{\pm}{}_{J,K}$ must be replaced by the mixed form $mS^{\gamma}+nS^{\gamma'}$ ($m^2+n^2\simeq1$). Hence, η' is multiplied by a factor $\mathcal{E}=m^2-n^2$.[7] This effect is not negligible in the particular term $J\eta'/2(2J+3)$ in Eq. (3) which comes from the $K=1\leftrightarrow-1$ interaction of the quadrupole energy and is of zeroth order of magnitude in β. For A state of internal rotation $|\mathcal{E}|=1$, while for E state $|\mathcal{E}|$ takes the value less than unity sensitivively dependent on the barrier height. An approximate form of $\mathcal{E}$ is

$$\mathcal{E}\simeq\delta_1/(d_1{}^2+\delta_1{}^2)^{1/2},$$

$$\delta_1\simeq\frac{1}{\sqrt{3}}\Delta_0{}^{(1)}\sin\frac{2\pi}{3}\left(\frac{C_2}{C}\right)^{*}.^{[8]**} \qquad (6)$$

Though the hindering barrier is very high in C_2H_5I, the molecular asymmetry is sufficiently small ($b_p\simeq-0.003$) and the quadrupole coupling constant along the C-I bond is enormously large (eq$Q\simeq-1770$ Mc/sec), so that the above competition must be considered for each hyperfine component. First, contribution of the above mentioned effect to the splitting of spectrum was evaluated for each hyperfine component using a crude value of barrier height ($H\simeq3.25$ kcal/mole), and was subtracted from the observed splitting. The remaining splitting was then attributed to the coupling between the overall and internal rotation, which permits the determination of barrier height in an improved accuracy. This procedure was successively repeated until the average barrier height converges to a constant value.

The splitting $\Delta\nu$ (corrected) in Table I are those ultimately obtained by this analysis purely corresponding to the coupling between overall and internal rotation. From this, the barrier height in C_2H_5I was determined as

$$H=3220\pm100\ \text{cal/mole}=1130\pm30\ \text{cm}^{-1}.$$

This implies the torsional frequency of methyl group of about 230 cm^{-1}.

The spectrum of R^a-type transitions involving levels with $K=1$ which was omitted in the report on C_2H_5Cl[9] and C_2H_5Br[10] were also analyzed for C_2H_5I by taking into account of the internal rotation (Table II). Since in R^a-type transition this effect is too small to be observed except for a few cases with the resolution available in a conventional microwave spectrometer, the average frequencies calculated for two species of torsional sublevels were compared with the observations. Then the calculated spectrum showed better agreement with the observed spectrum (Table II). The splitting into doublet observed in a

---

*) For the first excited torsional state, $\delta^{(1)}$ and $\delta^{(2)}$ can be expanded in power series of $\chi=(C_2/C)^*H'$, $H'=H/\frac{\hbar^2}{2}(C/C_1C_2)^*$ as $\delta^{(1)}=2\chi-1.11\chi^2+\cdots$, $\delta^{(2)}=0.5\chi-0.07\chi^2+\cdots$. (5)

**) As is well known, Δ_0 is the very sensitive function of barrier height, the functional dependence of which is given for the first excited torsional state in good approximation as,

$$\Delta^{(1)\prime}{}_0=23.93H'^{1.25}\exp-1.307\sqrt{H'},$$

$$\left(\Delta^{(1)\prime}{}_0=\Delta^{(1)}{}_0/\frac{\hbar^2}{2}(C/C_1C_2)^*\right). \qquad (7)$$

few cases (marked * in Table II) could be interpreted fairly well by the consideration of the effect given in Eq. (6).

Though Eq. (7) is expected to be accurate to within ± 2% in the range of $100 \leq H' \leq 250$, the assumption of structural parameters of methyl group introduces another error of about 5% in the determination of barrier height. In conclusion, it can be said that the magnitude of the barrier height to the internal rotation in ethyl iodide is nearly the same as those of the other ethyl halide molecules, 3306 cal/mole for $C_2H_5F^{11)}$, 2560 cal/mole for $C_2H_5Cl^{2)}$ and 3567 cal/mole in $C_2H_5Br^{2)}$.

The author is indebted to Professor Koichi Shimoda for his kind guidance and encouragement throughout the course of this investigation. He is also grateful to Mr. Takeshi Oka for his helpful discussions.

Proton Magnetic Resonance in Hydrogen Bonded Dimers in Solids

By Kiyoshi KUME and Yoshinobu KAKIUCHI

The Institute for Solid State Physics, University of Tokyo

(Received March 29, 1960)

It is concluded through proton magnetic resonance that the positions of protons in boric acid crystals lie considerably away from the lines connecting two hydrogen bonded oxygens, in contrast to the case in potassium bicarbonate crystals, where protons are approximately on the oxygen-oxygen lines. The result is discussed in connection with the difference in strength of the hydrogen bond both cases.

§ 1. Introduction

The determination of the positions of protons in hydrogen bonds are now being widely discussed in various cases$^{(1-7)}$, because of their basic significance in the study of the properties of hydrogen bonds. We have attempted to attack this problem through the proton magnetic resonance of hydrogen bonded dimers in certain crystals. In a hydrogen bonded dimer, protons approximately form, a two proton system and can favorably be treated by this technique, as far as the effect of neighboring dimers is successfully taken into consideration. We have selected two kinds of crystal, namely potassium bicarbonate and boric acid crystals. In the former, the hydrogen bond is relatively short (2.61 Å)$^{(13)}$ among O–H....O bonds and consequently rather strong, whereas in the latter it is relatively long (2.72 Å)$^{(11-12)}$ and weak. We shall discuss the results of the experiment in connection with these features. The fundamental difficulties in experimental technique lies in the fact that these crystals have in general longer T_1, hence is required the extremely high sensitivity of the spectrometer, which has been successfully attained throughout the present investigation.

§ 2. Resonance Technique

In order to determine the shape of the resonance absorption line in these crystals accurately, the r.f. power level H_1 within the sample coil, should be reduced as low as about 50 microgauss, because of their longer T_1 of the order of 10 minutes, otherwise the observed derivative of the absorption curve would become asymmetric. The conventional Pound-Watkins, detector, which cannot maintain sufficiently a low value of H_1 is, therefore, undesirable in our case, and the bridge type detecter is much more preferable. The second problem is to measure the absorption successfully under such a low r.f. level, especially in the case of broad line, and considerable attention should be paid to improve the signal to noise ratio. For example, in boric acid crystals, the calculated signal voltage across the sample coil amounts only to 4.4×10^{-7} volts, at room temperature corresponding to the sample volume of roughly 2 cc, the Q value of the sample coil of about 200, the amplitude of field modulation of 3 Gauss, and the r.f. level of 50 microgauss. The Twin-T bridge(17) is used under the minimum noise figure conditions(18), comined with a low noise preamplifier. The overall noise figure of the whole detecting system is found to be about three, under practical operating conditions(18). Moreover, the overall bandwidth of the detecting system is as narrow as 0.16 cps. The maximum equivalent noise voltage amplitude across the sample coil can thus be reduced to 2×10^{-8} volts. The estimated signal to noise ratio of $4.4 \times 10^{-7}/2 \times 10^{-8}$ is nearly equal to the observed one. (Fig. 7)

The electromagnet built by the Japan Electron Optics Company is operated at about 7060 Gauss (the proton magnetic resonance frequency being 30.00 Mc). The inhomogeneity of the magnetic field over the sample of 2 cc in volume, is less than 100 milligauss, which gives negligible influence on the results. Details of the measuring equipment used is given elsewhere(19).

§ 3. Specimens

The specimens used are either of "guaranteed grade" (boric acid) or of "chemically pure" grade (potassium bicarbonate), available from the Wako Pure Chemical Company. In order to gain as high a signal to noise ratio as possible, samples are pressed into a lozenge under 3 ton/cm^2 pressure. In this case, no evidence for the lattice distortion is detectable through an X-ray powder photograph. The single crystal of potassium bicarbonate is grown from its aqueous solution by lowering its temperature by 10 degrees, at a rate of 0.5 degree per day in the initial stage, and 1 degree per day in the later stage. The crystal thus obtained is about $20 \times 20 \times 8$ cm^3 in size. Although there are several discontinuities, which look like annual rings, it nevertheless forms a perfect single crystal. The X-ray Laue pattern shows orientational distributions of 10 degrees around the "b" axis, but this is fortunately relatively unimportant to our measurements. In order to make size and shape convenient to our measurements, three single crystals having the same crystallographic orientations are cemented together and shaped into a suitable form. All samples used here are 12 mm in diameter and about 20 mm in height.

§ 4. Results

(a) *Potassium bicarbonate powder*

The recorded derivative of the saturation free proton magnetic resonance curve in potassium bicarbonate crystal powder at room temperature is reproduced in Fig. 1. The sharp central peak having a width equal to the full amplitude of field modulation which disappears at low temperatures may safely be attributed to a signal from contaminating free-water. Subtracting graphically the contributions from this contaminating water, we obtain the powder line, characteristic to a two proton system. The second moment of the curve is 3.4±0.1 Gauss^2, which is the average of six independent data, ± indicating standard deviation. Althrough we have made only a qualitative experiment at low temperatures, the absorption seems to have no temperature dependence from −180°C up to the room temperature.

According to the crystal structure of potassium bicarbonate determined through X-ray diffraction studes(13), four carbonate radicals form two dimers in the unit cell. These two dimers are coplaner, and are, roughly speaking, parallel with each other (Fig. 2). Thus far, nothing is known about the positions of protons.

Field: 7060 Gauss
Field sweep: 0.51 Gauss/min
Frequency: 30.0 MC
R.f. field within sample coil: 70 microgauss
Time constant: 12 sec
Temperature: 25°C

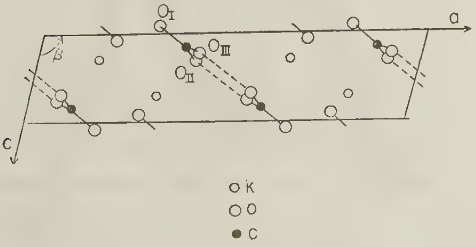

Fig. 2 Crystal structure of potassium bicarbonate

If we make the plausible assumption that configuration of protons also follows the same crystallographic symmetry with that of other kinds of atoms determined by X-ray diffraction, the center of the interproton vector of a pair of protons in each dimer, should coincide with that of the dimer. Further, we shall make another assumption that protons, and consequently the interproton vector, are contained in the plane of the dimer. Then, the results from the powder experiment on the second moment of the absorption curve given above, is quite sufficient in determining the length of the vector. Strictly speaking, the contribution from inter-dimer interactions, which should be subtracted from the total second moment in order to obtain the intra-dimer contribution, will depend upon the orientation of the inter-proton vector. Actually, however, a simple estimation shows that, the resulting ambiguity in inter-proton length amounts only to 0.01 Å, which is indicated by the solid arcs in Fig. 3. Taking also the error involved in the determination of the total second moment into account, the length is finally determined to be 2.27±0.03 Å.

(b) *Potassium bicarbonate single crystal*

Next, we shall proceed to the single crystal measurement, and determine the orientation of the interproton vector, whose length is already fixed by the preceeding powder experiment. It is obvious from the crystal structure shown in Fig. 2, that there are two independent interproton vectors in a unit cell. The resonance line, therefore in general, consists of four lines which can not be well separated, because of rather weak dipole interactions. It is, however, possible to fix the orientation of these two inter-proton vectors relative to the crystal axis, so as to obtain the best fit between calculated and observed line shapes, assuming the inter-proton length obtained above, and taking the crystallographic symmetry into consideration. As is readily seen from Fig. 3, both the OH bond length and the COH bond angle, will be obtained as soon as the orientation of the interproton vector is thus fixed

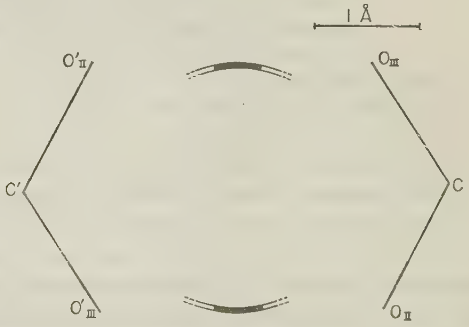

Fig. 3. Experimentally determined positions of protons in potassium bicarbonate. The powder experiment left the arc-shape region as the possible positions for protons, and single crystal experiment reduced it into the shaded portion.

The external magnetic field is applied in a direction making an angle Φ to the "b" axis, and in a plane containing the "b" axis, which is at the same time perpendicular to the "a" plane described in the literature(13). The recorded derivative of the saturation free resonance absorption curve at $\Phi=25$ degrees is reproduced in Fig. 4. The origin for the angle Φ is checked by confirming that the line shape at $\Phi=-25$ degrees coincides with that of $\Phi=25$ degrees within the experimental error. The sharp extra central peak is again subtracted graphically as shown by the broken line. In Fig. 5 is shown by open circles, the absorption obtained by numerical integration of the observed derivative together with the calculated lines, assuming various OH distances ranging from 1.0 Å to 1.3 Å. Owing to the fact that the $C' O'_{II} O_{III} CO_{II} C'_{III} C'$ hexagon is somewhat distorted, the angle between the interproton vector and the crystallographic axes differs a little, according to whether the proton is on the side of O_{II} or of O_{III}, even if we assume the same OH distance; and as a result, the calculated line profile will also be different either for $O_{II}H$ or $O_{III}H$ configurations. In the above calculation, the component lines are assumed to have Gaussian shape, whose second moments are estimated from well-known Van Vleck's formula(8), the normalization being made so as to obtain the best fit between the calculated and observed total intensities. As for the interproton distance we assumed the value 2.27 Å, obtained from the powder measurement, and the possible error of one percent involved in it, will result in an error of about three percents in the calculated width of the line. The figure shows that the OH bond length should approximately be 1.2 Å, the corresponding COH bond angle being 121 degrees when the protons lie on the side of O_{II}, or 116 degrees when on the side of O_{III}. The possibility that the protons exist at the center of the two oxygens, however, cannot entirely be ruled out from this experiment.

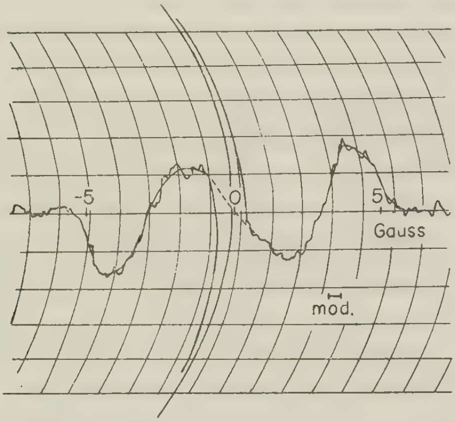

Fig. 4. Derivative of the absorption curve of potassium bicarbonate single crystal at $\Phi=25$ degrees. See the text for the meaning of Φ.

Sample: A single crystal 12 mmφ × 20mm made from the aqueous solution of chemically pure grade specimen of Wako Pure Chemical Company

Field: 7060 Gauss

Field sweep: 0.51 Gauss/min

Frequency: 30.0 MC

R.f. field within sample coil: 70 microgauss

Time constant: 12 sec

Temperature: about 25 degrees

Thus the result of the single crystal measurement restricts the possible proton positions within the range shown by the shaded

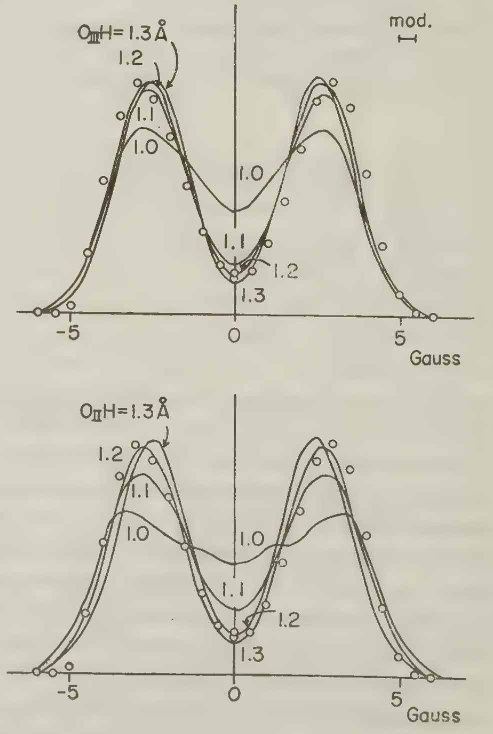

Fig. 5. Absorption line profile of potassium bicarbonate single crystal at $\Phi=25$ degrees. The curves indicate the calculated and the circles indicate the experimental.

area in Fig. 3, and more likely the protons may be located nearer to the side either of of the O_{III} type or of O_{II} type oxygens.

For the purpose of confirmation of the proton configuration obtained above, the comparison between the calculated absorption line positions of a two proton system and general profiles of the experimental curves for various Φ values is made in Fig. 6, the coincidence of which seems quite satisfactory, judging from the accuracies of both measurements and of the method of analysis involved.

(c) *Boric acid powder*

The positions of protons in boric acid crystals have been already inferred, although with somewhat less accuracy, from X-ray(11) as well as electron diffraction studies(12). The X-ray analysis find the protons approximately on the lines connecting oxygens, whereas the electron diffraction studies conclude that they are in much more inward positions. In view of the fact that the X-ray method does not reveal the position of the nuclei, but the distribution of the electrons around them, the accuracy of which is especially poor in the case of the hydrogen atom, the electron diffraction experiment seems to be much more favorable to the situation, although the latter investigation might be handicapped by the assumption involved in processing the data in connection with stacking disorders(12). The authors, however, believe the present investigation will be sufficient to settle this problem.

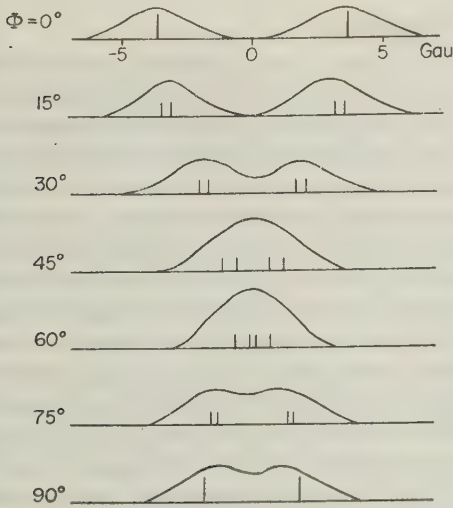

Fig. 6. Line profiles of potassium bicarbonate single crystal for various Φ values. The curves indicate the general behavior of experimental results, and the lines indicate the result of calculation, assuming $r=2.27$ Å and $O_{III}H=1.2$ Å

The recorded derivative of the saturation free proton magnetic resonance curve of the boric acid crystal powder is reproduced in Fig. 7. A somewhat flattened portion is seen at the center. The observed second moment of the curve is found to be 10.6 ± 0.9 Gauss^2, which is again the average of six independent data. The temperature dependence of this value is found to be insignificant, from −180°C up to the room temperature.

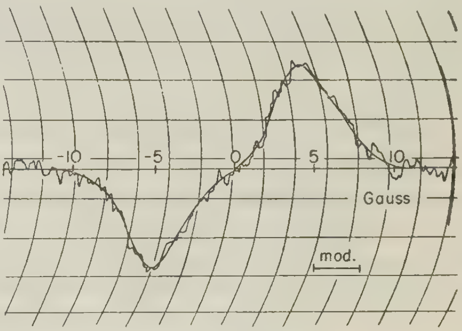

Fig. 7. Derivative of the absorption curve of boric acid powder

Sample: Guaranteed grade specimen from Wako Pure Chemical Company. Compressed powder 12 mmϕ × 20 mm in size
Field: 7060 Gauss
Field sweep: 0.95 Gauss/min
Frequency: 30.0 MC
R.f. field across sample coil: 50 microgauss
Time constant: 12 sec
Temperature: about 30°C

According to the X-ray structure analysis the boric acid crystal is known to have a layer structure. The structure of each layer is reproduced in Fig. 8, all the boron and oxygen atoms being approximately in this plane.

First, we assume the position of the proton as determined by X-ray analysis, in which the protons lie on the lines connecting two oxygens. The resulting second moment amounts only to 7.7 Gauss^2. And even if a somewhat elongated OH distance of 1.02 Å on the average, which has been inferred from the combination of infra-red data(14) and Badgers(9) rule, is assumed, keeping the OH directions as they were, it amounts only to 8.3 Gauss^2. These values are considered to be well outside the range of the experimental error given above. Therefore, the resonance data are not compatible with X-ray results.

Next, we will assume the inward positions of protons as was concluded by electron diffraction studies. When the protons are placed at inward positions, the interaction between the two protons increases, and it would therefore be favorable in explaining the large experimental value. The next problem is to find out the BOH angle compatible with the magnetic resonance experiment, by changing the angle in the layer plane, the OH distance being again 1.02 Å, as was assumed above. The parameters of all atoms beside hydrogen are already given from X-ray data.

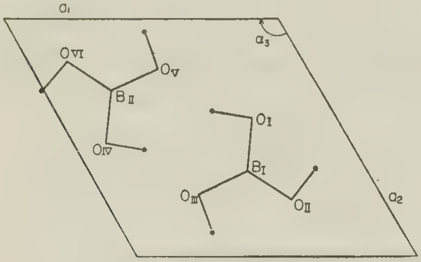

Fig. 8. Crystal structure of boric acid. Proton positions determined through the present work is indicated by the closed circles, their size corresponding roughly to the experimental error.

The summation $\sum_{i>j} 1/r_{ij}^6$ is carried out numerically, for all r_{ij} values shorter than 5 Å. The number of different interproton distances to be considered amounts to as many as about 70 for each BOH angle. The similar calculation is repeated for several BOH angles. The whole process is very long and tedious, and is actually carried out with the parametron computer PC-1 of the University of Tokyo, applying the programming tape originally prepared for calculating interatomic distances r_{ij} in crystal structure analysis$^{(10)}$.

The summation corresponding to r_{ij} longer than 5.0 Å is approximated by integration.

The relation between the BOH angle and the second moment, which is obtained by the above calculation is shown in Fig. 9. When the experimental value of the second moment is assumed, the BOH angle is found to be 96±2 degrees. This could be compared with 95 degrees, obtained from the electron diffraction studies, although there might exist some ambiguities due to the stacking disorder in the sample used for diffraction studies. The result from the present magnetic resonance studies is shown in Fig. 8 by closed circles, whose size represent roughly the experimental error.

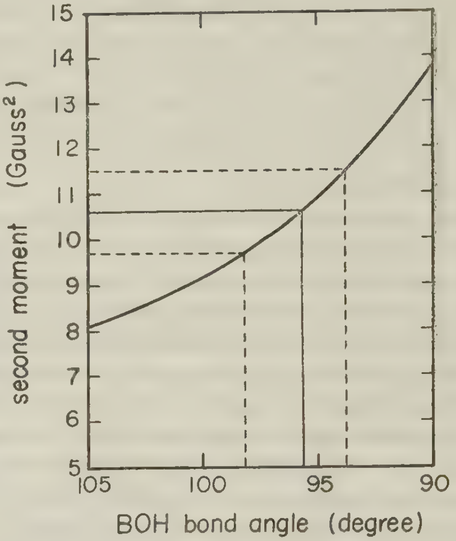

Fig. 9. Relation between BOH bond angle and second moment in boric acid crystal. The solid line indicates the experimental valve for the second moment 10.6 Gauss^2, and the corresponding bond single 95.6°. The broken lines show the allowance due to the experimental error.

§ 5. Discussions

The results of the foregoing experiments may well be summarized schematically in Fig. 10. The striking contrast between boric acid and potassium bicarbonate crystals exists in the fact that in the former the BOH angle is rather small and the OH length is relatively short, whereas in the latter the COH angle is much larger and the OH length is relatively long. This fact suggests that the long (2.72 Å) and weak O–H··O hydrogen bond in boric acid shows only a small deviation from the geometry of the non-hydrogen-bonded radical, whereas in the short (2.61 Å) and strong hydrogen bond in potassium bicarbonate both the XOH angle and the OH bond length are considerably affected by the formation of hydrogen bond. In case of potassium bicarbonate, we should take into consideration another possibility that the double bond character of the bond between C and O-H might tend to increase the COH bond angle. This possibility, however, seems to be largely negated by the fact that in the formic acid monomer(16), which has approximately the same C-O bond length, hence the same order of double bond character with potassium bicarbonate, the COH angle amounts to only 107°48′. The C-O distance is actually 1.31 Å in the former and 1.33 Å in the latter. The above consideration seems to suggest the fact that the COH bond angle in acid dimers largely depends upon the interaction between hydrogen atoms and lone pair electrons of the hydrogen bonded oxygen atoms.

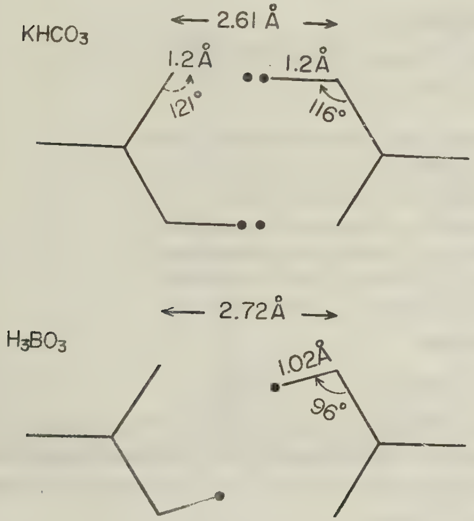

Fig. 10. Summary of our result.

The general tendency that weak hydrogen bonds affect the geometry of the non-hydrogen-bonded radical little, whereas strong ones do considerably, can be seen in other examples. The dependence of OH bond lengths upon interoxygen distances has already been thoroughly studied(15). As for XOH bond angles, they are little affected by weak hydrogen bonds in crystals such as α-resorcinol(3), sodium sesquicarbonate(2) and oxalic acid dihydrate(6), as were studied through neutron diffraction, and also in adipic acid crystal(7) as was found through polarized infra-red spectroscopy. Therefore, protons lie considerably away from the line connecting two oxygens. In cases of strong hydrogen bonds, however, it is difficult to find the case, where protons line considerably away from the lines(1)-(7). Direct confirmation through neutron diffraction studies are also desirable in boric acid and potassium bicarbonate crystals, although the present magnetic resonance method is beleived to have adequate accuracy for our present discussions.

A part of this investigation is a special research program, assisted by the Ministry of Education. The authors express their hearty thanks to Mr. H. Komatsu for his helpful suggestions to our experiments, and also for his giving them detailed informations from his own laboriours preliminary experiments of boric acid under the colaboration of one of the authors (Y. K.), and to Prof. S. Nagakura for his valuable discussions. Their thanks are also due to Mr. T. Sakurai for his X-ray measurements and Mr. R. Shishikura for his courtesy shown during the single crystal development. Their special gratitude is given to Prof. H. Takahashi, who offered them the chance of using the parametron computer PC-1, and to Mr. E. Wada for his preparing the programming tape as well as for his actual operation.

Microwave Spectrum of Methyl Mercaptan

By Takeshi KOJIMA

Faculty of Literature and Science, Toyama University

(Received April 8, 1960)

Two new series of $\Delta J=0$ transitions in the first excited torsional state as well as one series of the S^{34} isotopic molecule were found in the range up to 37 Gc/sec besides those reported in the previous paper. The two series in the first excited torsional state are discussed, confirming the potential barrier height $V_3=443.9\pm1.0\,\mathrm{cm}^{-1}$ which were determined from $\Delta J=\pm1$, $\Delta K=\mp1$ lines in the ground torsional state. Moreover, the hindering potential is considered to be sinusoidal with an accuracy of better than one percent from those analyses.

§ 1. Introduction

Methyl alcohol, methyl mercaptan and methyl-amine form an interesting class of molecules for the study of hindered internal rotation. They are characterized by the structural similarity and the barrier of intermediate height. The potential barriers of methyl alcohol[1] and methyl-amine[2],[3],[4] have been precisely determined from the analysis of the series of lines which correspond to the transitions $\Delta J=0$, $\Delta K=\pm1$. In a previous paper[5] we have determined the potential barrier of methyl mercaptan to be 444 ± 10 cm^{-1} from the analysis of the $\Delta J=\pm1$, $\Delta K=\mp1$ lines in the ground torsional state, because the series of $\Delta J=0$ lines in the ground torsional state have their origins in the higher frequency region outside the observed range. However, three series in the first excited torsional state and one series in the second excited torsional state have been observed. The validity of the assumption that the potential barrier is expressed in the simple sinusoidal form $\frac{1}{2}V_3(1-\cos 3x)$ is discussed from analysis of the lines in the excited torsional states.

§ 2. Theory

According to the theory[1],[3] developed to interpret the spectra of CH_3OH-type molecules, the rotational energy can be separated into three terms:

$$W=W_{JK}+W_{K\mu n}+W^{(1)} \tag{1}$$

where W_{JK} is the rotational energy of a hypothetic rigid rotor, $W_{K\mu n}$ the energy of internal rotation and $W^{(1)}$ the perturbation energy due to asymmetry. The rotational energy W_{JK} is

$$W_{JK}=\frac{A+B}{2}\{J(J+1)-K^2\}+CK^2 \tag{2}$$

where

$$A=\frac{h^2}{8\pi^2 I_x}\,,\qquad B=\frac{h^2 I_y}{8\pi^2(I_y^2+D^2)}$$

and

$$C=\frac{h^2}{8\pi^2}\left(\frac{I_y+I_z}{I_yI_z-D^2}-\frac{I_y}{I_y^2+D^2}\right)$$

The definitions of the moments of inertia, I_x, I_y, I_z, and the product of inertia, D, were given in the previous papers[6] (also see Fig. 1).

The internal rotation energy, $W_{K\mu n}$, is given by the eigen-value of the wave equation which describes the internal rotation:

$$\frac{h^2}{8\pi^2}\left(\frac{I_z}{I_1 I_2}\right)^*\frac{d^2M}{dx^2}+[W_{K\mu n}-\tfrac{1}{2}V_3(1-\cos 3x)]M=0 \tag{3}$$

where

$$\left(\frac{I_z}{I_1 I_2}\right)^*=\frac{I_y I_z-D^2}{I_2(I_1 I_y-D^2)} .$$

The moment of inertia of the methyl group about its symmetry axis is I_2, and $I_1=I_z-I_2$.

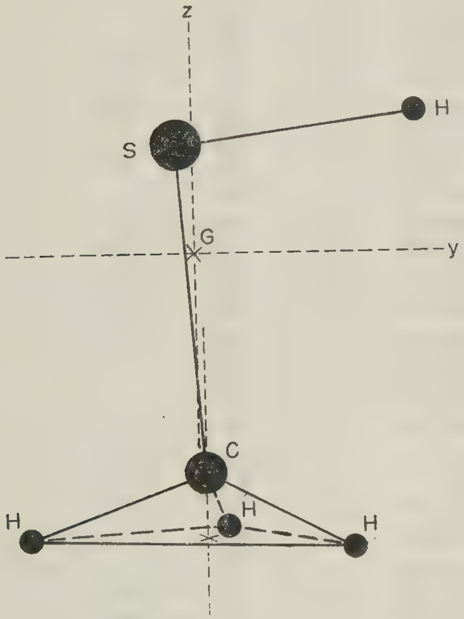

Fig. 1. Structure of methyl mercaptan.

The solution of (3) is expressed by

$$M(x)=\exp\left\{i\left(\frac{I_2}{I_z}\right)^*Kx\right\}\cdot Q(x) \tag{4}$$

where

$$\left(\frac{I_2}{I_z}\right)^*=\frac{I_2\sqrt{I_y^2+D^2}}{I_y I_z-D^2}$$

and $Q(x)$ is expanded in a Fourier series

$$Q(x)=\sum_{m=-\infty}^{\infty}a_m e^{imx} .$$

We have three types of solutions designated by $\mu=0$, 1 and -1:

$$\left.\begin{aligned} Q_{\mu=0}(x)&=\sum_{l=-\infty}^{\infty}a_{3l}e^{i3lx} ,\\ Q_{\mu=1}(x)&=\sum_{l=-\infty}^{\infty}a_{3l+1}e^{i(3l+1)x} ,\\ Q_{\mu=-1}(x)&=\sum_{l=-\infty}^{\infty}a_{3l-1}e^{i(3l-1)x} .\end{aligned}\right\} \tag{5}$$

The selection rule is $\Delta\mu=0$ in this expression.

The equations, (4) and (5), are expressed in a compressed form:

$$M(x)=\exp\left[i\left\{\left(\frac{I_2}{I_z}\right)^*K+\mu\right\}x\right]\cdot\sum_{l=-\infty}^{\infty}a_{3l+\mu}e^{i3lx} .$$

Then the internal rotation energy, $W_{K\mu n}$, is easily seen to be periodic in $(I_2/I_z)^*K+\mu$ with period 3.

When the barrier is relatively high, $W_{K\mu n}$ can be expressed in the first order approximation by[3),7)]

$$W_{K\mu n}=\alpha_n-\beta_n\cos\frac{2\pi}{3}\left\{\left(\frac{I_2}{I_z}\right)^*K+\mu\right\} \tag{6}$$

where α_n is the n-th torsional vibration energy in the high barrier limit.

The perturbation energy $W^{(1)}$ arises from the off-diagonal elements of the Hamiltonian, which were given in the previous papers[3),7)].

If a small sixfold term is allowed in the barrier such that

$$V=\frac{V_3}{2}(1-\cos 3x)+\frac{V_6}{2}(1-\cos 6x) , \tag{7}$$

then the rotational energy is expressed by

$$W=W_{JK}+W_{K\mu n}+W^{(1)}+W^{(6x)}_{K\mu n} , \tag{8}$$

where $W^{(6x)}_{K\mu n}$ is the perturbation term which arise from the sixfold term in the barrier and is given by the following equation:

$$\begin{aligned} Q^{(6x)}_{K\mu n}&=\int Q^*_{K\mu n}(x)\frac{V_6}{2}(1-\cos 6x)Q_{K\mu n}(x)dx\\ &=\frac{V_6}{2}\left(1-\sum_{m=-\infty}^{\infty}a_m a_{m+6}\right) . \end{aligned} \tag{9}$$

Since $W^{(6x)}_{K\mu n}$ is also periodic in $(I_2/I_z)^*K+\mu$ and can be expressed in the similar form as (6), it is impossible to determine the value of V_6 from the lines in only one torsional state.

§ 3. Experimental Results

The spectrometer used was the conventional Stark modulation type with both visual and recorder display. The observed lines within the range from 14 to 29 Gc/sec were previously reported[5)]. The observed lines in the range up to 37 Gc/sec are listed in Table I. The three series of lines, s, t, u, which show first-order Stark effects have been found in the range. The frequencies of lines of these series are plotted against the rotational quantum number J in Fig. 2, as well as those of the series, p, q, r, which were previously reported. The J values of the lines of the s-

(a) The Stark effects are designated by 1(o) for the first order Stark effect with the strongest outer components, 1(i) for the first-order Stark effect with the strongest inner components, 2(+) for the second-order Stark effect with positive Stark displacement and 2(−) for the second-order Stark effect with negative Stark displacement.

(b) The number in parenthesis shows the J value of the line.

(c) Many very weak lines from 31476 to 31575 Mc/sec are expected to be the series lines which arise from the isotopic molecule, $C^{12}H_3S^{34}H$.

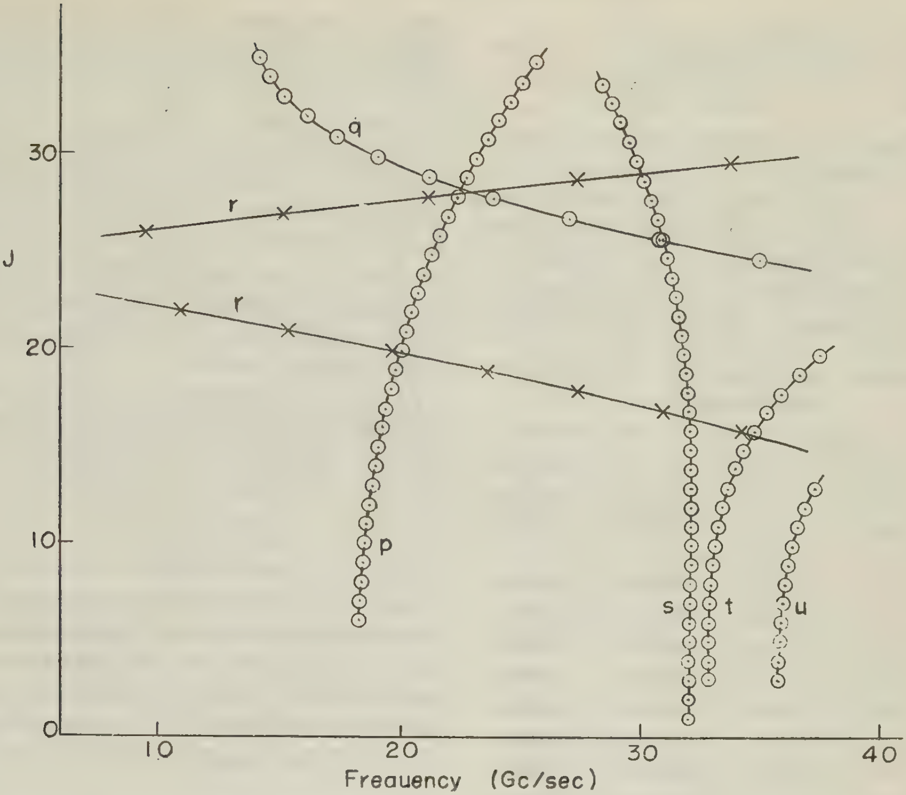

Fig. 2. ν−J diagram of the series lines.

Table II.

Series	ν_0	a	b	c	d	A	B
s	31986.96	1.319	−0.00321	-6.1×10^{-5}	9.1×10^{-7}	...	...
t	32824.40	0.809	0.03222	-5.89×10^{-5}	4.6×10^{-7}	0.646	0.0054

and t-series are determined from the Stark effects, while the J values of the lines of the other series are the estimated values.

The frequencies of the individual lines in the series can be expressed as a power series expansion in J^2+J as follows:

$$\nu=\nu_0+a(J^2+J)+b(J^2+J)^2 +c(J^2+J)^3+d(J^2+J)^4+\cdots$$

The values of these coefficients for s- and t-series were determined from the first five members of each series. They are listed in Table II.

The Stark effects of the lines of t-series were measured. The Stark displacement is expressed by $M\mathcal{E}[(A/J^2+J)+B]$, where $\mathcal{E}$ is the electric field and M the component of J along the field. The experimental values of A and B in (Mc/sec)/(V/cm) are listed in the last two columns of Table II.

§ 4. Analysis of the Ground Torsional State

(a) $\Delta J=\pm1$, $\Delta K=\mp1$ *lines*

Since the origins of the series corresponding to the transitions $\Delta J=0$, $\Delta K=\pm1$, $n=0\leftarrow0$ for methyl mercaptan are expected to lie far outside the observed range, the $\Delta J=\pm1$, $\Delta K=\mp1$ lines have been used in determining the potential barrier and the molecular structure as before[5].

The first six lines in Table III were identified from their Stark effects. The assignments of these lines were confirmed by the combination rule.

The frequencies of the lines corresponding to the transitions $(2_{1,2}\leftarrow3_{0,3}$, $\mu=0$, $n=0)$, $(2_1\leftarrow3_0$, $\mu=1$, $n=0)$ and $(1_1\leftarrow2_0$, $\mu=-1$, $n=0)$, are given by the following equations:

$$\left.\begin{aligned} 29091.9&=(W_{100}-W_{000})/h-3\nu_1+\varepsilon_1\,, \\ 23339.2&=(W_{110}-W_{010})/h-3\nu_1+\varepsilon_2\,, \\ 14764.5&=(W_{1-10}-W_{0-10})/h-2\nu_1+\varepsilon_3\,, \end{aligned}\right\}$$

where $W_{K\mu n}$ is the internal rotation energy and $\nu_1=25291$ Mc/sec is the frequency of the $J=1\leftarrow 0$, $K=0\leftarrow 0$ line. The perturbation terms, ε_1, ε_2, ε_3, are the contributions from the off-diagonal elements of the Hamiltonian, and are estimated to be -774.2, 20.2 and 0.4 Mc/sec, respectively. From these equations, the moments of inertia and the barrier height were determined by use of the D value obtained in § 5 (c). They are listed in Table IV.

Table III. $\Delta J=\pm 1$, $\Delta K=\mp 1$ lines in the $n=0$ state.

Assignment		Observed frequency in Mc/sec	Calculated frequency in Mc/sec
$J'_{K'}\leftarrow J_K$ or $J'_{K'_{-1}K'_{+1}}\leftarrow J_{K_{-1}K_{+1}}$	μ		
$2_{1,2}\leftarrow 3_{0,3}$	0	29091.9	(29092)
$5_{0,5}\leftarrow 4_{1,4}$	0	23256.9	23258
$2_1\leftarrow 3_0$	1	23339.2	(23339)
$5_0\leftarrow 4_1$	1	26994.2	26994
$1_1\leftarrow 2_0$	−1	14764.5	(14765)
$4_0\leftarrow 3_1$	−1	35857.4	35858
$9_{2,8}\leftarrow 10_{1,9}$	0	25659.7	25602
$10_{2,8}\leftarrow 11_{1,11}$	0	33077.9	32998
$12_{1,11}\leftarrow 11_{2,10}$	0	30741.8	30841
$14_{1,14}\leftarrow 13_{2,11}$	0	30508.6	30642
$8_2\leftarrow 9_1$	1	18039.5	18205
$11_1\leftarrow 10_2$	1	35913.5	35746
$9_2\leftarrow 10_1$	−1	21973.2	21938
$12_1\leftarrow 11_2$	−1	23801.8	23747

Table IV. Moments of inertia and the barrier height.

$$\left(\frac{I_2}{I_z}\right)^*=0.6522$$

$$\frac{A+B}{2}=25291\ \text{Mc/sec}$$

$$C=102733\ \text{Mc/sec}$$

$$I_1=1.7107\ \text{amuA}^2$$

$$I_2=3.2137\ \text{amuA}^2$$

$$I_z=4.9244\ \text{amuA}^2$$

$$D=-0.35\ \text{amuA}^2$$

$$V_3=443.9\pm 1.0\ \text{cm}^{-1}$$

From the moments of inertia and the barrier height determined above, the frequencies of other lines in the $n=0$ state were calculated. They agree with the observed values within the error of few hundred megacycles as shown in Table III.

(b) *Dipole moment*

The Stark energy for the $\mu=0$ transition is expressed by the sum of the second order perturbation terms which arise from the off-diagonal elements and the interaction terms between K-type doublet levels as in the case of slightly asymmetric rigid molecules, subject to modification of the energy values due to the internal rotation.

From the Stark effect of the $2_{1,2}\leftarrow 3_{0,3}$ line at 29091.9 Mc/sec, the components of the dipole moment parallel and perpendicular to the molecular axis were determined as

$$\mu_{\parallel}=1.33\pm 0.03\ \text{D}\,,$$

$$\mu_{\perp}=0.73\pm 0.03\ \text{D}\,.$$

The dipole moment of the molecule can be estimated from the bond dipole moments. By use of the values $\text{H}^+\rightarrow\text{S}^-=0.68$ D, $\text{C}^+\rightarrow\text{S}^-=1.00$ D and $\text{H}^+\rightarrow\text{C}^-=0.40$ D, one obtains $\mu_{\parallel}=1.30$ D and $\mu_{\perp}=0.71$ D, which agree well with the experimental values.

§ 5. Analysis of the Excited Torsional States

Since the frequency of the torsional vibration is about 200 cm^{-1}, some of the observed weak lines are ascribed to the molecules in the excited torsional states. In Table V the observed frequencies are compared with those

Table V. Lines in the excited torsional states.

(a) $\Delta J=\pm 1$, $\Delta K=\pm 1$ lines.

Assignment			Observed frequency in Mc/sec	Calculated frequency in Mc/sec
$J'_{K'}\leftarrow J_K$ or $J'_{K'_{-1}K'_{+1}}\leftarrow J_{K_{-1}K_{+1}}$	μ	n		
$3_{2,2}\leftarrow 2_{1,1}$	0	1	14320.2	12100
$3_{2,1}\leftarrow 2_{1,2}$	0	1	15339.0	13120
$2_1\leftarrow 1_0$	1	1	18417.6	17690

(b) Series lines ($\Delta J=0$).

Series	Assignment			Frequency of origin in Mc/sec	
	$K'-K$	μ	n	Observed	Calculated
r	$1\leftarrow 2$	0	1	(60800)	63020
s	$0\leftarrow 1$	1	1	31987	32730
t	$3\leftarrow 2$	−1	1	32824	28980
p	$5\leftarrow 6$	−1	2	18300	21780

calculated by using the molecular contants which have been determined in the previous section.

The difference between the internal rotation energies of the two levels with which the transition concerns, $W_{K'\mu n}-W_{K\mu n}$, is sometimes larger than several cm^{-1} in the excited torsional states. Therefore, the spectrum for the excited torsional states is quite different from the spectrum for the ground torsional state as shown in the following subsections.

(a) *Pair lines.*

The lines at 14320.2 Mc/sec and 15339.0 Mc/sec which show the second-order Stark effect are assigned as the transition $J=3\leftarrow2$, $K=2\leftarrow1$, $\mu=0\leftarrow0$, $n=1\leftarrow1$. The Stark components of the lower frequency line move towards higher frequencies and those of the higher frequency move towards lower, so that the lines appear to be mirror images. The directions of the Stark displacements, however, are reversed to those of the "mirror lines" observed in the spectrum of methyl alcohol by Hughes, Good and Coles[8].

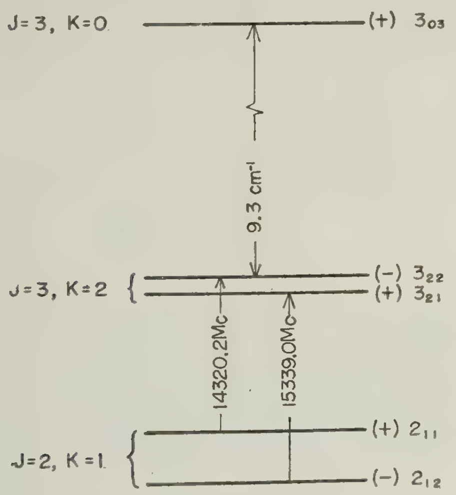

Fig. 3. Pair lines in the $n=1$ state.

Each energy level of $\mu=0$ ($K\neq0$) splits into doublet due to asymmetry (K-type doubling). The wave function for a K-type doublet level of $J=3$, $K=2$ has one of the two following forms:

$$\Psi^{(+)}_{K=2}=a_0\psi_0+a_2(\psi_{-2}+\psi_2) \qquad a_0<a_2 \tag{10a}$$

and

$$\Psi^{(-)}_{K=2}=b_2(\psi_{-2}-\psi_2) \tag{10b}$$

where the ψ_K are the symmetric hindered rotor wave functions. The shift from the symmetric hindered rotor energy*, $W^{(0)}_{J=3,K=2}$ is

$$\Delta^{J=3}_{K=2}=2\frac{\left(\int\psi_2{}^*H^{J=3,K=2}_{J=3,K=0}\psi_0dv\right)^2}{W^{(0)}_{J=3,K=2}-W^{(0)}_{J=3,K=0}} \tag{11}$$

for the $\Psi^{(+)}_{K=2}$ level, while the $\Psi^{(-)}_{K=2}$ level remains unperturbed. As shown in the energy level diagram for the $n=1$ state (Fig. 3), $W^{(0)}_{J=3,K=0}$ is higher than $W^{(0)}_{J=3,K=2}$ by 9.3 cm^{-1} because of the large internal rotation energy of the $J=3$, $K=0$ level. Thus the $\Psi^{(+)}_{K=2}$ level is shifted down by $\Delta^{J=3}_{K=2}$, so that the K-type doublet levels of $J=3$, $K=2$, $\mu=0$, $n=1$ are inverted to those of a rigid asymmetric rotor. In Fig. 3 the notation of energy level, $J_{K_{-1}K_{+1}}$, defined for asymmetric rigid rotor is also used for convenience.

Since the Stark effects of the pair lines are mainly due to the interaction between the near-by levels $3_{2,2}$ and $3_{2,1}$, the Stark components of the $3_{2,2}\leftarrow2_{1,1}$ line at 14320.2 Mc/sec move towards higher frequencies while those of the $3_{2,1}\leftarrow2_{1,2}$ line at 15339.0 Mc/sec towards lower.

Since the splitting of the $J=3$, $K=2$ level is calculated to be 9.3 Mc/sec from (11), the K-type splitting of $J=2$, $K=1$ level, $\Delta^{J=2}_{K=1}$ is obtained as 1028.6 Mc/sec. $\Delta^{J}_{K=1}$ is given by

$$\Delta^{J}_{K=1,n=1}=\frac{A-B}{2}I^{-101}_{101}J(J+1) \tag{12}$$

where

$$I^{-101}_{101}=\int Q^*_{101}Q_{-101}dx \tag{13}$$

The value of I^{-101}_{101} is calculated to be 0.640 by using the moments of inertia and the potential barrier given above. Then $(A-B)/2$ $=267.8$ Mc/sec is obtained. This value can be compared with the value 276.6 Mc/sec which is determined from the lines of K-type transition in the ground state.

(b) *Stark effect of the $J=1\leftarrow0$, $K=0\leftarrow0$ lines.*

The Stark effects of the $J=1\leftarrow0$, $K=0\leftarrow0$ lines are listed in Table VI. It is noticeable that the $\mu=\pm1$, $n=1$ line has small Stark coefficient in comparison with others. The Stark displacement of these lines is theoretically expressed by $\Delta\nu=(A\mu_{\|}{}^2+B\mu_{\perp}{}^2)\mathcal{E}^2$ where $A\mu_{\|}{}^2\mathcal{E}^2$ is the same as in the case of sym-

---

* The symmetric hindered rotor energy, $W^{(0)}_{JK}$ is $(W_{JK}+W_{K\mu n})$ in Eq. (1).

Table VI. Stark displacement of the $J=1\leftarrow 0$, $K=0\leftarrow 0$ lines: $\Delta\nu = C\varepsilon^2$.

Assignment		Frequency in Mc/sec	C in (Mc/sec)/(V²/cm²)
n	μ		
0	0	25290.9	0.994×10^{-5}
0	±1	25291.9	0.994
1	0	25219.5	0.998
1	±1	25206.9	0.576
2	0	25143.6	1.026
2	+1	25154.9	1.011

metric rotor and $B\mu_{\perp}{}^2\mathcal{E}^2$ in the contribution from the $H_{J,K}^{J-1,K-1}$ element of the Hamiltonian. Since the energy differences between the J, K and $J-1$, $K-1$ levels are estimated from the observed lines in the $n=1$ state, the dipole moment can be determined from the coefficients of the $n=1$ lines. The values obtained are

$$\mu_{\parallel}=1.36\ \mathrm{D}$$

and

$$\mu_{\perp}=0.76\ \mathrm{D}\ .$$

They coincide with the values obtained from the $2_{1,2}\leftarrow 3_{0,3}$ line in the $n=0$ state within the estimated accuracy.

(c) *Analysis of the series lines* ($\Delta J=0$)

The Stark effect for the series lines of $\mu=\pm1$ is predominantly of first-order with a small admixture of second-order. The Stark displacement for the t-series lines is given in the first-order expression by

$$\Delta\nu=0.5032\left\{-\frac{\mu_{\parallel}+21.57\mu_{\perp}G}{J^2+J}+3.722\mu_{\perp}G\right\}\mathcal{E}M \tag{14}$$

where $G=(h/8\pi^2)(D/I_y{}^2)$ is in cm^{-1}, ν in Mc/sec, μ in Debye unit and $\mathcal{E}$ in V/cm. By use of the experimental values listed in Table II, the value of D can be determined as -0.35 amuA².

The quantities a and b appearing in Table II are the coefficients of the J^2+J and $(J^2+J)^2$ terms, respectively, in the expansion form of the frequencies for the s- and t-series. The coefficient b is due principally to the off-diagonal elements, $H_{J,K}^{J,K+2}$. The calculated values of b for these series are in good agreement with the experimental values as shown in Table VII. The coefficient a is due to not only the off-diagonal elements $H_{J,K}^{J,K+1}$ and $H_{J,K}^{J,K+2}$, but also the centrifugal stretching of the molecule. The contributions from the off-diagonal elements can easily be calculated, but it is difficult to evaluate the centrifugal effect with any exactness. By modifying the theory which was developed by Kivelson⁹⁾ to interpret the fine structure of the $J=1\leftarrow 0$, $K=0\leftarrow 0$ line of methyl silane and was also successfully applied to methyl alcohol¹⁰⁾ and methyl mercaptan⁵⁾, the displacement of each line of the series from its origin due to the centrifugal effect can be expressed in a rough approximation by

Table VII. Coefficients of the s- and t-series in the expansion form.

Series	b_{cal}	b_{exp}	$a_{\mathrm{centrifugal}}$	$a_{K+1\leftrightarrow K}$	$a_{K+2\leftrightarrow K}$	a_{cal}	a_{exp}
s	−0.0039	−0.00321	1.00	0.236	0.007	1.24	1.319
t	0.03223	0.03222	−4.66	4.06	−0.393	−0.99	−0.809

$$\Delta\nu=(J^2+J)\Big[F_v\{\langle K'|1-\cos 3x|K'\rangle-\langle K|1-\cos 3x|K\rangle\}+\frac{4\pi^2}{h^2}G_v\{\langle K'|p_x{}^2|K'\rangle-\langle K|p_x{}^2|K\rangle\}\Big] \tag{15}$$

where $p_x=(h/2\pi i)(\partial/\partial x)$ and K represents the initial state and K' the final state. Since the coefficients F_v and G_v have been obtained in the previous paper the centrifugal effect can be estimated. The resulting value of a is compared with the experimental value as shown in the last two columns of Table VII.

The r-series has its origin outside the observed range and extends towards lower frequencies. It goes to zero frequency and come again towards higher frequencies. The position of each line of the series is mainly due to the K-type doubling of the levels with which the transition concerns. When the K-type doubling becomes large with high J, the involved levels are reversed. Since the Stark energy for the high J lines of the series is mainly due to the J, $K\leftrightarrow J$, $K-1$ interaction, the Stark components of the observed lines (containing the lines which arise from the transition between the reversed levels) move towards higher frequencies with increasing field. The frequency of the origin of the r-series is estimated to be 60800 Mc/sec by using the frequencies of the pair lines mentioned above which arise from the same transition of internal rotation.

The p-series has its origin at about 18300 Mc/sec and extends towards higher frequencies. Though the J values of the individual lines of the series can not be definitely determined, the dependence of the frequencies on the estimated J values is not inconsistent with the consideration of the centrifugal effect.

The u-series is considered to arise from the isotopic molecule $C^{12}H_3S^{34}$ from its intensity.

§ 6. Discussion of Potential Barrier

In Table V the observed frequencies of the $n=1$ lines are compared with those which are calculated from the moments of inertia determined by the analysis of the ground torsional state. The differences between the observed and calculated frequencies are considered as due to the effects of the deformation of the potential barrier from the sinusoidal form and the nonrigidity of the molecule. The value of V_6 in Eq. (7) is determined as $V_6=-2.0\,\mathrm{cm}^{-1}$ in order to make the best fit between the observed and calculated frequencies of both the $n=0$ lines and the $n=1$ lines. Though this value of V_6 is not significant because of the assumption of the rigid rotor, it may be concluded that the potential barrier of methyl mercaptan is sinusoidal in form with an accuracy of better than one percent. Recently, Burkhard and Dennison[11] obtained a similar result in the case of methyl alcohol.

§ 7. Molecular Structure

The method used to determine the molecular structure is the same as used before[5]. In addition to the values of I_1, I_2 and D obtained in the previous sections, we have the following equation for each of the isotopic molecules:

$$\frac{h}{16\pi^2}\left(\frac{1}{I_x}+\frac{I_y}{I_y^2+D^2}\right)=2B_v \qquad (16)$$

In above equation B_v is the rotational constant corresponding to the equilibrium position of the SH-bond, which is defined by

$$\nu=2B_v+2G_v\frac{4\pi^2}{h^2}\langle 0\mu n|p_x^2|0\mu n\rangle + 2F_v\langle 0\mu n|1-\cos 3x|0\mu n\rangle+\varepsilon \qquad (17)$$

where ν is the frequency of the $J=1\leftarrow0$, $K=0\leftarrow0$, line and ε the contribution from the off-diagonal elements of the Hamiltonian due to asymmetry. By using the values of B_v for CH_3SH, CH_3SD and CD_3SH which were obtained before[5], the molecular dimensions are determined as shown in Table VIII.

Table VIII. Molecular structure of methyl mercaptan.

$d_{SH}=1.335\pm0.010$ A	
$d_{CS}=1.819\pm0.005$ A	$\angle$CSH$=96°30'\pm30'$
$d_{CH}=1.092\pm0.010$ A	$\angle$HCH$=109°45'\pm30'$

The angle between the CS-bond and the symmetry axis of the methyl group is 2°10′±30′.

The author expresses his hearty thanks to Professor Koichi Shimoda for his encouragement and advice throughout this work. Thanks are also due to Dr. Tetsuji Nishikawa for his valuable discussions.

Heating of a Plasma by Acoustic Waves

By Tarô Dodo

Hitachi Central Research Laboratory, Kokubunji, Tokyo

(Received March 16, 1960)

Generation of an acoustic wave and transformation of its energy into thermal energy are considered. We generate an acoustic wave, imposing an oscillating magnetic field to a cylindrical plasma in a static magnetic field. When the suitable frequency of oscillating field is chosen, an acoustic wave is excited at an intermediate state between adiabatic and isothermal states. In this situation acoustic energies are transformed into thermal energies through the irreversible flow of heat due to stress relaxation.

In this method, the efficiency of heating is very high. The calculation shows that this method should be suitable to heat a plasma of moderate temperature ($10^5 \sim 10^6$ °K) and of high density ($10^{14} \sim 10^{16}$ particles/cm^3).

§ 1. Introduction

For the creation of a thermonuclear plasma, the heating of plasma through an application of oscillating electromagnetic field[1),2)] is a very important means. When an oscillating field is applied to a plasma, an organized motion will be generated. However, unless the energy of organized motion is transformed rapidly to the random energy, the motion of large amplitude may cause an instability and this method will be inadequate for heating plasma.

Here, it is proposed to heat a plasma through a generation of acoustic wave. As for the thermalization of acoustic energy, we call attention to that a plasma is a dispersive medium with respect to acoustic waves. In ordinary gases and solids, only above ultra high frequencies, 10^9 cycles/sec or more, acoustic waves are generated at isothermal state. But in a high temperature plasma, the thermal conductivity is very high. So acoustic waves are mostly generated at isothermal state. Of course, there is no dissipation of acoustic energy in either the isothermal or the adiabatic state. If the time τ, in which the heat flows from the compressed portion to the dilated portion of acoustic wave, is the same order of magnitude as the period of sound, the heat flows irreversibly. Then the acoustic energy is transformed to the thermal energy. This dispersive absorption is similar to the absorption of the electromagnetic wave in dielectric media or the elastic wave in visco-elastic high polymers.

§ 2. Generation of an Acoustic Wave

We shall consider the generation of acoustic wave in an infinitely long cylindrical plasma confined by static magnetic field $\boldsymbol{B}_0$ directed to z-axis. The radius of the plasma is r_0. When an oscillating field $\boldsymbol{B}_1=\varepsilon\boldsymbol{B}_0\sin kz\exp(i\omega t)$ is superposed to this static field, the radius of plasma cylinder oscillates according to

$$r=r_0[1-(1/2)\varepsilon\sin kz\exp(i\omega t)]\,, \tag{1}$$

because of the relation $r^2B=$constant. If the mean free path of particles is sufficiently shorter than r_0 and $2\pi/k$, an acoustic wave will be generated as shown in the following*.

Let ξ be the axial displacement of the centre of masses, ρ be the mass density and p be the pressure. The equations of motion and of conservation of mass are

$$\rho\frac{\partial^2\xi}{\partial t^2}=-\frac{\partial p}{\partial z}=-\frac{\partial p}{\partial\rho}\frac{\partial\rho}{\partial z}\,, \tag{2}$$

$$\rho_0 r_0^2=\rho r^2\left(1+\frac{\partial\xi}{\partial z}\right). \tag{3}$$

With these equations and Eq. (1), we obtain an equation of forced oscillation

$$\frac{\partial^2\xi}{\partial t^2}=c^2\left(\frac{\partial^2\xi}{\partial z^2}-\varepsilon k\cos kz e^{i\omega t}\right), \tag{4}$$

$$c^2=\frac{dp}{d\rho}\,. \tag{5}$$

Eq. (4) shows that a longitudinal oscillation is generated as a result of the radial oscillation given in Eq. (1).

§ 3. Thermalization of Acoustic Energy

The thermal conduction being taken into

---

* The compatibility of the condition $r^2B=$const. and the condition of excitation of acoustic wave is not discussed here.

account, the sound velocity $c^2=dp/d\rho$ is determined by the equations of state[3]

$$\Delta\rho=(c_T^2)^{-1}\Delta p-\mu\Delta T\,, \tag{6}$$

$$C\frac{\partial}{\partial t}(\Delta T)=K\nabla^2(\Delta T)+\alpha\frac{\partial}{\partial t}(\Delta\rho)\,, \tag{7}$$

where

$$c_T=(\partial p/\partial\rho)_{T=\mathrm{const.}}^{1/2}=(p_0/\rho_0)^{1/2}\,,$$
$$\mu=-(\partial\rho/\partial T)_{p=\mathrm{const.}}=\rho_0/T_0\,,$$
$$\alpha=C(\partial T/\partial\rho)_{\mathrm{adiabatic}}\,,$$

K is the thermal conductivity, C=heat capacity per unit volume, $\Delta\rho$, Δp and ΔT are the deviations from the equilibrium values ρ_0, p_0 and T_0, respectively. Eliminating ΔT from Eqs. (6) and (7), we obtain

$$c_T^2[\tau_A(\Delta\dot{\rho})+\Delta\rho]=\tau_T(\Delta\dot{p})+\Delta p\,, \tag{8}$$

where

$$\tau_A=(c_A^2/c_T^2)\tau_T\,,\quad c_A^2=(1+\mu\alpha/C)c_T^2\,,$$

and τ_T is determined by the equation of heat conduction

$$(K/C)\nabla^2(\Delta T)+\tau_T^{-1}(\Delta T)=0\,.$$

τ_T is the stress relaxation time in which heat flows from the compressed portion to the dilated portion. From the above equation, we get

$$\tau_T^{-1}=(K/C)(2\pi/\lambda)^2\,, \tag{9}$$

where λ is the wave length of sound.

Now we obtain the expression of sound velocity from the equation of state (8). If $\Delta\rho$ and Δp vary as

$$\Delta\rho,\ \Delta p\propto\exp(i\omega t)\,,$$

we obtain the sound velocity

$$\frac{dp}{d\rho}=c^2=\frac{i\omega\tau_A+1}{i\omega\tau_T+1}c_T^2$$
$$=\frac{\omega^2(\tau_A\tau_T)+1+i\omega(\tau_A-\tau_T)}{(\omega\tau_T)^2+1}c_T^2\,. \tag{10}$$

In limiting cases, this expression becomes the adiabatic or the isothermal sound velocity:

$$\frac{dp}{d\rho}=\frac{\tau_A}{\tau_T}c_T^2=c_A^2\quad\text{for}\quad\omega\tau_T\gg1\,,$$

$$\frac{dp}{d\rho}=c_T^2\qquad\text{for}\quad\omega\tau_T\ll1\,.$$

The dispersion relation (10) is well-known for the case of the absorption of electromagnetic wave in dielectric media*.

The phase angle δ between $\Delta\rho$ and Δp is given by

$$\tan\delta=\frac{\text{imaginary part of }c^2}{\text{real part of }c^2}$$
$$=\frac{\omega(\tau_A-\tau_T)}{1+(\omega\tau)^2}=\frac{c_A^2-c_T^2}{\bar{c}^2}\frac{\omega\bar{\tau}}{1+(\omega\bar{\tau})^2}\,, \tag{11}$$

where

$$\bar{\tau}^2=\tau_A\tau_T\quad\text{and}\quad\bar{c}^2=c_Ac_T\,. \tag{12}$$

When δ is not so large, the relation between δ and the fractional decrease of sound energy per cycle $\Delta W/W$ is as follows:

$$2\pi\tan\delta=\Delta W/W\,. \tag{13}$$

The relaxation strength $(c_A^2-c_T^2)/\bar{c}^2$ in this case is very large. So a large fraction of the energy of organized motion is transformed to the thermal energy.

§ 4. Examples

Two cases are considered for the acoustic heating, one is the heating by standing wave and the other is by travelling wave.

We shall first discuss the heating by standing wave. The solution of Eq. (4) is

$$\xi=\xi_0\cos kz\exp(i\omega t)\,,\qquad \xi_0=\frac{\mathcal{E}kc^2}{\omega^2-c^2k^2}\gtrsim\frac{\mathcal{E}}{k}\,. \tag{14}$$

If the frequency of external field is not equal to the natural frequency of plasma, ξ_0 is the order of $\mathcal{E}/k$. The acoustic energy is $(1/2)\rho\cdot(\omega\xi_0)^2\simeq(1/2)\rho c^2\mathcal{E}^2\simeq(1/2)p\mathcal{E}^2$. In usual cases, $p\simeq(1\sim10^{-1})\times$(magnetic energy for confinement), so the acoustic energy is $(1\sim10^{-1})\times$(energy of osillating magnetic field). Therefore, the thermal energy supplied to the plasma through acoustic energy is $(10^{-1}\sim10^{-2})\times$(magnetic energy of oscillating magnetic field), because $\tan\delta\simeq10^{-1}$.

On the other hand, the Q-value of coil system, the ratio of the energy of oscillating magnetic field multiplied by the angular frequency to the ohmic power loss in the coil, is order of 10^2. Therefore, the thermal energy supplied to the plasma is $(10\sim1)\times$(energy dissipated in the coil). Thus we get the efficiency of suppling energy to plasma through standing wave of suitable frequency as 50% or more.

For the particular case of deuterium plasma, the sound velocities and the thermal diffusion coefficient are

---

* ρ, p and c^2 correspond to the electric field $\boldsymbol{E}$, displacement $\boldsymbol{D}$ and dielectric constant ε, respectively.

$$\left.\begin{aligned} c_A&=\sqrt{\gamma p/\rho}=\sqrt{\gamma(Z+1)n_i\kappa T/n_i m_i}\\ &=1.17\times10^4 T^{1/2} \quad \text{cm/sec deg}^{1/2}\,,\\ c_T&=\sqrt{p/\rho}=9.1\times10^3 T^{1/2} \quad \text{cm/sec deg}^{1/2}\,,\\ \bar{c}&=\gamma^{1/4}(p/\rho)^{1/2}=1.03\times10^4 T^{1/2} \quad \text{cm/sec deg}^{1/2}\,, \end{aligned}\right\} \tag{15}$$

$$\left.\begin{aligned} K/C=D&=\alpha(\kappa T)^{5/2}/m_e^{1/2}e^4 Z n_i=5.7\\ &\times10^9 T^{5/2} n_i^{-1} \quad \text{cm}^{-1}\,\text{sec}^{-1}\,\text{deg}^{-5/2}\,, \end{aligned}\right\} \tag{16}$$

where γ is the ratio of specific heats, C_p/C_v, κ is the Boltzman constant and α has the magnitude[4] around 10. For a cylindrical deuterium plasma of radius 5 cm, density 10^{15} ions/cm³ and 10^5 °K, numerical values of the above expressions are

$$\left.\begin{aligned} c_A&=3.7\times10^6\ \text{cm/sec}\,, \quad c_T=2.88\times10^6\ \text{cm/sec}\,,\\ \bar{c}&=3.25\times10^6\ \text{cm/sec}\,, \quad D=1.8\times10^7\ \text{cm}^2/\text{sec}\,, \end{aligned}\right\} \tag{17}$$

and a suitable wave length λ to generate an acoustic wave will be

$$\lambda\simeq20\ \text{cm}\,. \tag{18}$$

For the most efficient frequency $f=(2\pi\bar{\tau})^{-1}$, we get from Eqs. (9), (12), (17) and (18)

$$\begin{aligned} f&=(2\pi\bar{\tau})^{-1}=D(2\pi/\lambda^2)/2\pi(\gamma)^{1/2}\\ &=2.2\times10^5\ \text{cycles/sec}\,. \end{aligned} \tag{19}$$

In this case, using the above numerical values, we get the acoustic energy $(1/2)\rho(\omega\xi_0)^2$ as

$$(1/2)\rho(\omega\xi_0)^2\simeq(3/2)p\mathcal{E}^2\,. \tag{20}$$

When $\tan\delta$ is not so small, $\varDelta W/W$ should be given by, instead of Eq. (14),

$$\varDelta W/W=[1-\exp\{-4\pi\tan(\delta/2)\}]\,. \tag{21}$$

In our case, from Eq. (11)

$$\tan\delta=\frac{\gamma-1}{\gamma^{1/2}}\frac{1}{2}=\frac{1}{\sqrt{15}}\,, \tag{22}$$

and we get

$$\varDelta W/W\simeq0.8\,.$$

If the gas pressure p is one tenth of the magnetic energy for confinement, the thermal energy supplied by the oscillating magnetic field is

$$\varDelta W\simeq(0.8)\times(3/2)\times(1/10)\times(\text{energy of oscillating magnetic field})\,.$$

When the Q-value of coil system is 100, the effeciency η is in this example

$$\begin{aligned} \eta&=\frac{\varDelta W}{\varDelta W+\text{ohmic loss}}=\frac{10^{-1}}{[10^{-1}+2\pi(100)^{-1}]}\\ &\simeq60\%\,. \end{aligned} \tag{23}$$

We shall next discuss the heating by travelling wave. If we generate a travelling acoustic wave by imposing an oscillating magnetic field on a small longitudinal section (heating section) of a cylindrical plasma, the wave length λ is determined automatically by the frequency of oscillating field and the temperature of plasma. In this case, the most suitable frequency is determined by the following simultaneous equations:

$$\left.\begin{aligned} f&=(2\pi\bar{\tau})^{-1}=D(2\pi/\lambda)^2/2\pi(\gamma)^{1/2}\,,\\ f&\simeq\bar{c}/\lambda\,. \end{aligned}\right\} \tag{24}$$

For the deuterium plasma employed in the above example, $n_i=10^{15}$ and $T_i=T_e=10^5$ °K, the frequency and the wave length determined by the above equations are

$$f=1.2\times10^5\ \text{cycles/sec} \quad \text{and} \quad \lambda=27\ \text{cm}\,. \tag{25}$$

The logarithmic decrement of the wave amplitude is

$$\text{log. dec.}=2\pi\tan(\delta/2)\simeq\pi\tan\delta=0.8\,,$$

using the numerical value in Eq. (22). The eighty per cents of acoustic energy are transformed to the thermal energy after travelling one wave length (=27 cm).

Appendix.

The Physical Meaning of τ_T and τ_A

If we decrease rapidly the volume of the container of gases, the gas pressure increases by the amount $\varDelta p=c_A^2\varDelta\rho$. As the time elaspses, heat flows from the gases to the surrounding walls and the increment $\varDelta p$ approaches to $\varDelta p=c_T^2\varDelta\rho$. The decay constant τ_T of $\varDelta p$ is called the stress relaxation time. (See Fig. 1 (a))

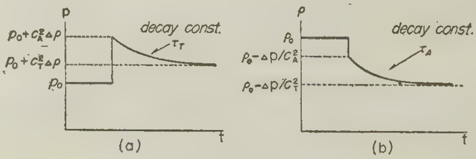

Fig. 1. (a) The stress $c_A^2\varDelta\rho$ relaxes with the time constant τ_T. (b) The strain $\varDelta p/c_A^2$ relaxes with the time constant τ_A.

In the similar way, when we increase the pressure applied to the container of gases, decrement $\varDelta\rho$ approaches to $\varDelta\rho=\varDelta p/c_T^2$ with the decay time τ_A. (See Fig. 1 (b))

Exciton-Induced Luminescence in KI/Tl.*

Masao TOMURA and Yozo KAIFU
Department of Applied Physics, Osaka City University, Osaka

(Received on February 17, 1960)

In a single crystal of KI/Tl, emissions from Tl^+ ion and a certain impurity were observed under excitation of light in the first characteristic absorption band of KI. These exciton-induced luminescences were measured at various temperatures for specimens of several concentrations of Tl^+ ion. The intensities of the exciton-induced luminescences attained saturated values at about liquid oxygen temperature. In consideration of the amount of energy transferred to the impurity, the saturated intensities of the exciton-induced luminescence from Tl^+ ion are almost independent of the concentration of Tl^+ ion in the range of $10^{15} \sim 10^{19}/cm^3$ and showed a quantum efficiency as high as 30%. Therefore the migration of an exciton through the crystal was confirmed.

§ 1. Introduction

A possibility of migration of an exciton in alkali halide crystals has been discussed theoretically[1], and an explanation[2] for no appearance of the edge luminescence of alkali halides was based on the nature of migration of an exciton through the crystals.

Apker and Taft[3] have observed that the excitons in alkali halides interacted with F centers and transferred their energy to the latter, ejecting electrons out of these centers. They adopted the external photoelectric effect as the detecting method and obtained the value of quantum yield as small as 1×10^{-3} for the exciton-induced photoelectric effect. Although the real quantum yield for ejecting an electron out of the F center was not determined, they estimated the yield of 10^{-2} in the order of magnitude by considering the lost part of ejected electrons in the erystal. Because of the very small quantum yield, they could not deny a possibility of energy-transfer from the exciton to the F center through the so-called dipole-dipole interaction proposed by Dexter[4]. On the other hand Dexter and Heller[5] have calculated the interaction between the exciton and the F center, obtaining 10^{12} sec^{-1} as the probability of ionization of the F center. Then in the case of Apker and Taft's experiment where the concentration of the F center was estimated as high as $10^{18}\sim10^{19}/cm^3$, the exciton-induced yield of the ionization should be unity in the order of magnitude on the stand point of the migration of the exciton.

In the next place, Inchauspé[6] has carried out a similar experiment as that by Apker and Taft, using a method of detecting photoconductivity. His results showed that the exciton-induced photocurrent was independent of the F center concentration, and seemed to show the migration of the exciton. The exciton-induced photocurrent, however, could be observed only in the region of the long wavelength tail of the exciton absorption band, and then it is ambiguous that the photoelectron he caught came from the F center alone. In his experiment, a value of about twenty can be obtained as the real quantum yield of the exciton-induced photoconductivity, if we assume that the same process takes place as in the case of ionization of the F center under irradiation of F band light. Furthermore, his results were obtained through D. C. method, so the real magnitude of photocurrent might be hardly obtained in these insulators because of the space charge formation. It is necessary to clarify the process of interaction between the exciton and the F center in order to interpretate his results.

---

* Reported at the meetings of the Physical Society of Japan. Oct. (1958) & Apr. (1959).

Ueta and co-workers7) have also studied on the interaction between the exciton and the F center through detecting F center bleaching. In their experiments only light in the tail of the characteristic absorption band was used. The quantum yield of the bleaching effect by excitons was about 15, and they proposed a model that the thermal spike due to excitons took place and eventually F centers were thermally bleached, being converted to metallic colloids. In their experiments, however, the problem of exciton-migration was not touched.

Although the interaction of the exciton with the F center in alkali halide crystals was confirmed as mentioned above, the nature of exciton-migration has not been clarified. In the present work, measurements were carried out to make ascertain the existence of the moving exciton in KI by detecting the exciton-induced luminescence which is the most suitable for the present purpose.

§ 2. Luminescence of KI/Tl

It is well known about natures of luminescence of alkali halides containing Tl$^+$ ion as an activator8). A few characteristic properties of the luminescent material are as follows. Tl$^+$ ion occupies substitutionally some of the sites of alkali metal ion, distributing randomly in the crystal. The quantum yield of luminescence is nearly unity. The luminescence has no nature of thermal quenching below room temperature and also concentration quenching even in the case of rather high concentration of the activator. Then the luminescent material is very useful for studying the interaction between excitons and Tl$^+$ ion. For instance, in measuring of temperature-and concentration-dependence of the interaction, the above mentioned properties of the direct luminescence from Tl$^+$ ion itself will not confuse results.

KI/Tl single crystals were prepared by the Kylopoulos method. The concentration of Tl$^+$ ion was determined by measuring the optical density of the absorption band peaked at 283 mμ at room temperature. As the oscillator strength of the absorption band, the data given by Yuster and Delbecq9) were adopted. The oscillator strength at room temperature was assumed to be equal to the one at liquid nitrogen temperature which was obtained by the above authors. In case of very high concentration of Tl$^+$ ion, the amount of Tl$^+$ ion was obtained by the chemical analysis.

All the intensities of emissions observed varied proportionally with the intensity of incident light, therefore measurements of luminescence were carried out as reported before10). Absolute values of quantum yield of luminescence were not determined, however, yields were obtained through refering to the intensity of the direct emission due to Tl$^+$ ion itself in the case of high concentration of Tl$^+$ ion such as 10^{18}/cm^3 where the almost all of the incident light was absorbed in the specimen. The quantum yield of the direct emission from Tl$^+$ ion is about 80%.

The optical absorption curve of KI/Tl at liquid nitrogen temperature9) is shown in Fig. 1. The dominant absorption bands appear at 224, 233, 244 and 282 mμ. The first band is

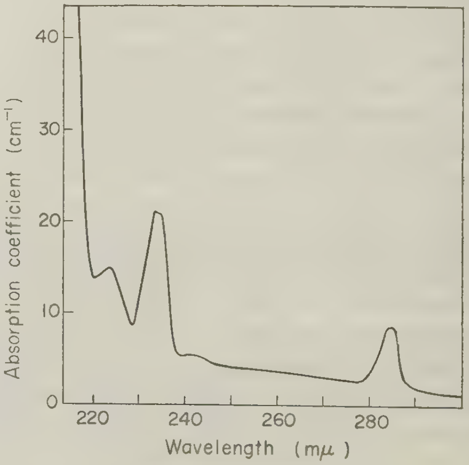

Fig. 1. The absorption curve of KI/Tl at liquid nitrogen temperature. Tl$^+$ ion concentration is 1.2×10^{-6} mol. (after Yuster and Delbecq).

known as the Greek band due to Tl^+ ion, that is the adsorption band of the localized exciton around Tl^+ ion. In cases of very high concentration of Tl^+ ion, absorption bands at 250 and 290 mμ appear. They are due to double Tl^+ ions center.

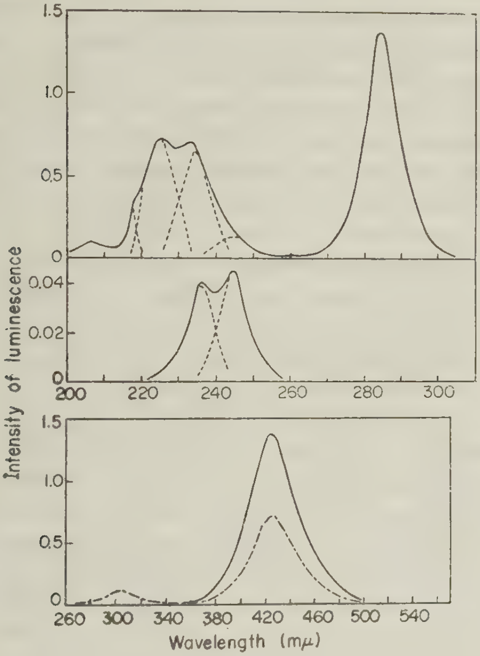

Fig. 2. The emission and excitation spectra for KI/Tl at liquid oxygen temperature. Tl^+ ion concentration is $3\times10^{17}/cm^3$.
Upper: The excitation spectra for the emission at 440 mμ.
Middle: The excitation spectra for the emission at 305 mμ.
Lower: The emission bands under excitation of 283 mμ (solid line) and 250 mμ (chained line) lights.

There are little data on the luminescence of KI/Tl, so we have attempted to study detailed properties of the above luminescence. In Fig. 2* one example of the luminescence of KI/Tl at liquid oxygen temperature is shown. As in the following, intensities of emission are shown for constnt energy of incident light through out all of the wavelength region. At liquid oxygen temperature, an emission band lying at 425 mμ is observed under excitation of 224, 233 and 282 mμ lights and an emission at 305 mμ appears under excitaion of only 233 and 244 mμ lights. The latter emission quenches thermally at room temperature against the former. In cases of very high concentration of Tl^+ ion, a new emission at 320 mμ appears under excitation of 250 and 290 mμ lights. It may be attributed to the double Tl^+ ion center.

§3. Exciton-induced Luminescence of KI/Tl

At liquid oxygen temperature, under excitation by exciton light, two kinds of emission are observed. As Fig. 3 shows, one lies at 425 mμ and the other at 360∼380 mμ.** The former is coincident with the direct emission from Tl^+ ion itself and the latter is the same

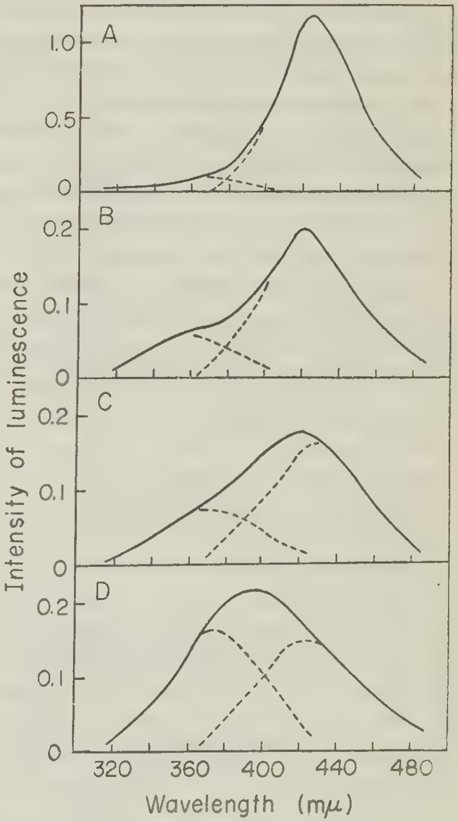

Fig. 3. The emission spectra under excitation of the exciton energy (216 mμ) at liquid oxygen temperature. Tl^+ ion concentrations are; A: $6\times10^{18}/cm^3$, B: $3\times10^{17}/cm^3$, C: $1\times10^{17}/cm^3$ and D: $5\times10^{15}/cm^3$.

---

* The intensity scale of luminescences shown in Fig. 2 and 3 is different from that shown in the following figures. The band pass of the incident light was 4 mμ at 220 mμ through out the present measurements.

** The crystal used in this measurement is obtained from another reagent than that used for the crystals in the following measurements.

one as that appeared in pure KI crystal[10)11)]. The emission at 305 mμ from Tl^+ ion mentioned before cannot be found in this case. Therefore we have confirmed actually the exciton-induced luminescences from Tl^+ ion and a certain impurity involvod in the host crystal. In the other words, the exciton transfers its energy to Tl^+ ion and the unknown impurity, whose excitations lead eventually to emit their own luminescences. The figure shows that the higher is the concentration of Tl^+ ion, the more intense is the emission lying at 425 mμ against the emission band at 360∼380 mμ.

In the next place, temperature-dependences of the exciton-induced luminescences were measured for specimens of various concentrations of Tl^+ ion. In these measurements, two sets of glass filters (Toshiba Electric co.) were adopted to separate the above two kinds of emission in place of the monochromator used for measurement of the emission spectrum. A set of V-Y3C and V-CIA filters was used for the emission from Tl^+ ion, and a set of UV-DI and UV-DII filters for the emission at 360∼380 mμ which came from the unknown impurity. (In the following, we call this impurity D impurity.) The transmission curves of these filters are shown in Fig. 4. As both emissions hardly alter their positions over all the temperature region in the present measurement, these filters are sufficient for separation of the two emissions.

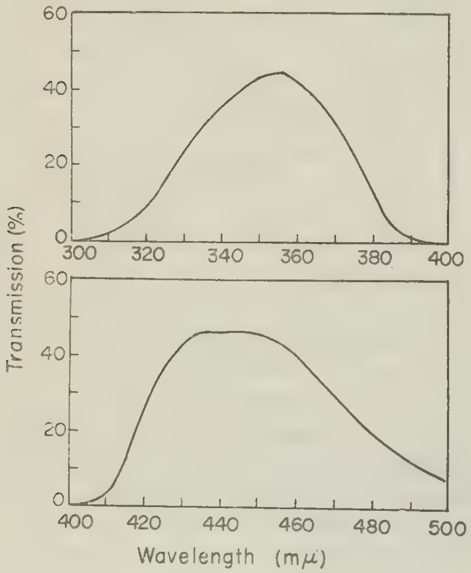

Fig. 4. Transmission curves of optical filters. Upper: UV–DI+UV–DII. Lower: V–Y3C+V–CIA.

Fig. 5 shows one example of excitation spectra of the exciton-induced luminescences from Tl^+ ion and D impurity at various temperatures. The excitation bands due to the direct absorption by Tl^+ ion in the longer wavelength region than the exciton absorption band are omitted for the moment in the figure. The excitation curve for the exciton-induced luminescence from Tl^+ ion overlaps with the excitation curve due to Tl^+ ion itself, so they are designated roughly separately with dotted curves in the figure.

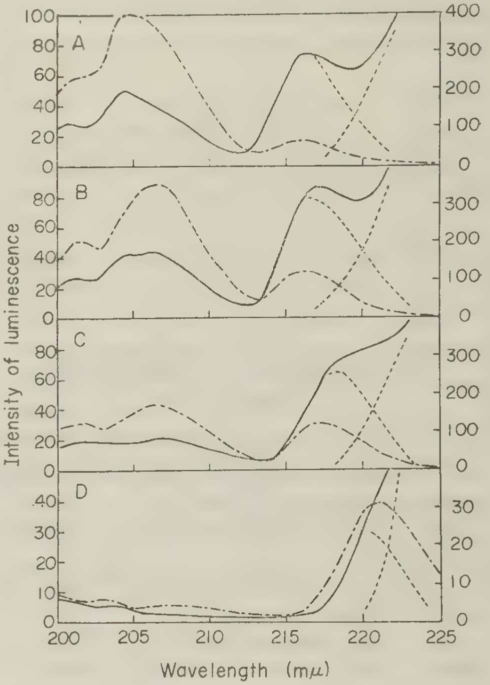

Fig. 5. The excitation spectra for the exciton-induced luminescences from Tl^+ ion (solid line) and D impurity (chained line) at several temperatures. Tl^+ ion concentration is $4.2\times10^{16}/cm^3$. A: −211°C, B: −202.5°C, C: −174°C and D: −138.5°C. The left and right ordinate scales correspond to the solid and chained lines respectively.

The peak of the exciton absorption band of KI lies at 214 mμ at liquid nitrogen temperature and 220 mμ at room temperature. As the figure shows, the exciton-induced responses are found in these wavelength region. At low temperatures the shape of excitation spectrum for the exciton-induced luminescence is similar to that for the exciton-induced photoelectric effect observed by Apker and Taft[3]. At higher temperatures, however, the exciton-induced luminescence decreases and the shape of the excitation spectrum becomes flat as in the case of the above authors.

The yield of the exciton-induced luminescence at lower temperatures shows a minimum just at the peak of exciton absorption band. Because of very high absorption coefficient at this peak the exciton may decomposes near the surface of the crystal and the yield may diminish markedly. Thus the shape of excitation spectrum is not so simple to define the intensity of the exciton-induced luminescence. We shall tentatively take the maximum height of the excitation spectrum which lies at above 216 mμ in the case of lowest temperature as the intensity of the exciton-induced luminescence from Tl^+ ion. As will be discussed in the following paper, at the wavelengh region of this maximum the absorption coefficient seems to be so small that excitons are created deep in the interior of the crystal under irradiation of light at this wavelength. Therefore this induced luminescence will not suffer from the influence of the surface of the crystal. It can be seen in Fig. 1 that the absorption coefficient of a single crystal at 216 mμ is so small as $10^2\,cm^{-1}$ in contrast with the one of evaporated polycrystalline film which is about $10^5\,cm^{-1}$.

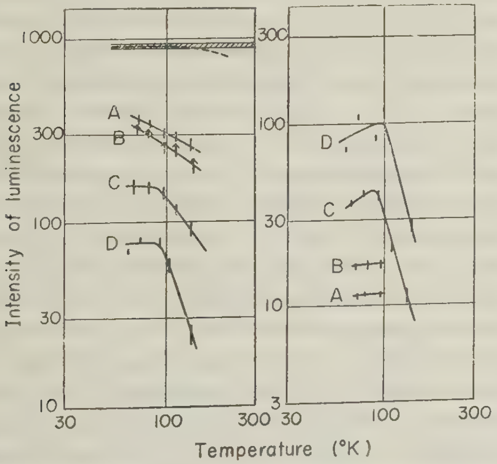

Fig. 6. The temperature-dependence of the exciton-induced luminescences from Tl^+ ion and D impurity for specimens of several concentrations. Tl^+ ion concentrations are A: $2.7\times10^{19}/cm^3$, B: $5.7\times10^{18}/cm^3$, C: $7\times10^{17}/cm^3$ and D: $4.4\times10^{16}/cm^3$. Left is for Tl^+ ion and right for D impurity. In the left figure the hatched line shows the maximum intensity of the direct emission from Tl^+ ion and the broken line shows the maximum intensity of emission in the Greek band due to Tl^+ ion.

Since the excitation spectrum of the exciton-induced luminescence overlaps with that of the direct emission in the Greek band of Tl^+ ion, rather large errors come into the procedure of separation of both excitation spectra, especially at higher temperatures and for specimens of higher concentration of Tl^+ ion. As for the exciton-induced luminescence from the D impurity, its intensity at the wavelength where the excitation spectrum for Tl^+ ion emission shows maximum was taken instead of the maximum value of the excitation spectrum for the D emission. Thus we obtained the intensities of the exciton-induced luminescence at various temperatures for specimens of several concentrations of Tl^+ ion. The results are shown in Fig. 6.

The yield of the exciton-induced luminescence increases with decrease of temperature and attains a saturated value at about liquid oxygen temperature.

§ 4. Migration of Exciton

We have obtained already an evidence that the exciton transfers its energy to both Tl^+ ion and D impurity. Therefore, if we want to discuss the real yield of the exciton-induced luminescence from Tl^+ ion only, we must correct the obtained intensity by the amount of the energy transferred to D impurity other than Tl^+ ion. If the host crystal contained no D impurity, the energy transferred to D impurity should be also transferred to Tl^+ ion.

The exciton will loses its energy also through creating and ionizing F centers. At present we have no quantitative knowledge of these effects, however, the amount of dissipating energy might not overcome the one transferred to D impurity. Furthermore, there may be many defects such as dislocation and vacancy in the crystal, and the exciton may decompose at these imperfections. In order to detect such effects, the surface of the annealed crystals were polished and the influence of polishing was observed. By polishing the exciton-induced yield decreases at the wavelength regions of maxima of the excitation spectra as shown in Fig. 7. In viewing of these results, it is known that some defects which are perhaps dislocations hinder the energy-transfer of the exciton to Tl⁺ ion and D impurity.

Then if we correct the intensity of the exciton-induced luminescence from Tl⁺ ion by the amount of the exciton energy lost to the D impurity and imperfections, it seems to become nearly independent of the concentration of Tl⁺ ion in the range of $10^{15}\sim10^{19}/\text{cm}^3$. The curve A in Fig. 8 shows the concentration-dependence of the exciton-induced luminescence at liquid oxygen temperature at which the yields have the saturated values. The dependence seems rather weak. Correcting it by the lost part of exciton energy to D impurity which is shown with the curve B, the curve C is obtained.

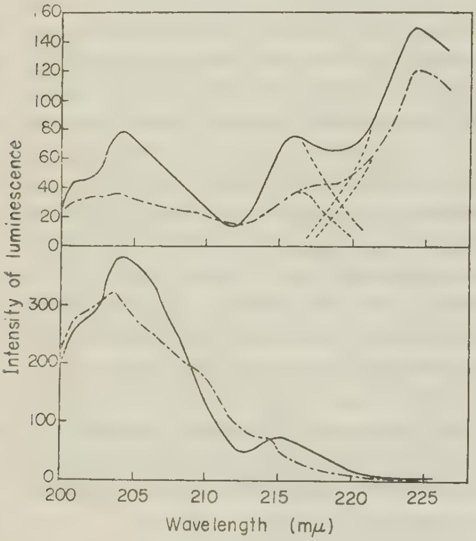

Fig. 7. The influence of polishing on the exciton-induced luminescences. Tl⁺ ion concentration is $4.2\times10^{16}/\text{cm}^3$. Upper: excitation spectra for Tl⁺ emission. Lower: excitation spectra for D emission. The solid and chained lines correspond to the annealed crystal (−207°C) and polished crystal (−209°C) respectively.

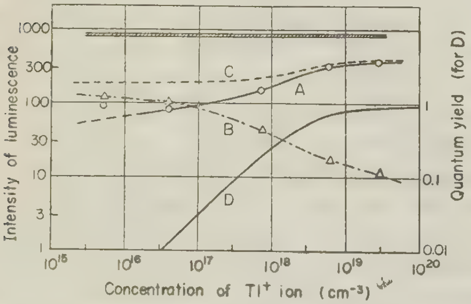

Fig. 8. The relations between the saturated intensities of the exciton-induced luminescences and the concentrations of Tl⁺ ion. A: for Tl⁺ ion emission and B: for D emission. C: the sum of the intensities of emissions from Tl⁺ ion and D impurity. D: the quantum yield calculated by Dexter for the case of energy transfer through dipole-dipole interaction. The hatched line shows the maximum intensity of the direct emission from Tl⁺ ion.

As for the absolute quantum efficiency of the exciton-induced luminescence, the curve C should be compared to the hatched line in the figure. The latter shows the maximum intensity of the luminescence due to the absorption by Tl⁺ ion itself as mentioned in § 2. The efficiency attains about 40% of the above reference intensity.

In the process of energy-transfer, there are two mechanisms to be considered. One is the so-called dipole-dipole interaction proposed by Dexter[4] and the other is the migration of the exciton through the crystal[1]. According to the former theory, the exciton transfers its energy to Tl⁺ ion over some distances and the probability of transfer-process decreases rapidly at lower concentrations of Tl⁺ ion. The curve D in Fig. 8 shows the concentration-dependence of energy-transfer calculated for NaCl at an appropriate condition by Dexter[4]. Since the present experiment shows already the intensity of the exciton-induced luminecence from Tl⁺ ion nearly independent of Tl⁺ ion concentration in the range of $10^{15}\sim10^{19}/\text{cm}^3$, the migration mechanism of exciton through the crystal is found to play a dominant role. The exciton collides with a Tl⁺ ion after wandering to a more or less distance through the crystal, transferring its energy to Tl⁺ ion, of which excitation leads eventually to its own luminescence. The high quantum efficiency of the exciton-induced luminescence such as 40% of the efficiency of direct emission from Tl⁺ ion itself also seems to support the above process.

The emission band at 305 mμ from Tl⁺ ion can be observed only under excitation of lights in 233 and 244 mμ absorption bands at low temperatures, and does not appear under excitation of lights in the exciton absorption band as well as the Greek band 224 mμ due to Tl⁺ ion. In view of the fact that irradiation of light in the exciton absorption band which has higher energy than lights in the absorption bands 233 and 244 mμ cannot give rise to the emission at 305 mμ in contrast to the latter lights, the following model will be proposed. After an exciton meets a Tl$^+$ ion, it may be trapped around the ion with dissipating a small part of its energy to the lattice and then only the emission at 425 mμ takes place in a similar way as in the Greek band due to Tl$^+$ ion around which an exciton localizes.

As mentioned before, the direct emission of Tl$^+$ ion below room temperature is found to be nearly temperature-independent. On the other hand, the emission in the Greek band seems to show a weak temperature-dependence in the case of high Tl$^+$ ion concentration as shown in Fig. 6. This phenomenon may be caused by broadening effect of the tail of exciton absorption band with increase of temperature, that is by resulting decrease of the amount of absorption in the Greek band itself. As the intensity of the emission in the Greek band increases with annealing of the specimen (See Fig. 7), it seems that the absorption coefficient at the tail of the exciton absorption band decreases with annealing and eventually the amount of absorption in the Greek band increases, resulting the increases of the emission in the Greek band. Accordingly, it is natural to consider that the above emission in the Greek band is temperature-independent below room temperature.

On the other hand, the exciton-induced luminescence shows clearly temperature-dependence as seen in Fig. 6. Also in Apker and Taft's experiment, the yield of the exciton-induced photoelectric effect at room temperature is so small as few tenths of that at liquid nitrogen temperature. As the emission due to direct absorpton by Tl$^+$ ion shows no temperature-dependence, the cause of temperature-dependence of the exciton induced luminescence may be attributed to the process of interaction between the exciton and Tl$^+$ ion or the nature of the exciton itself.

§5. Exciton-induced Luminescence from D Impurity.

Under irradiation of light in the first characteristic absorption band the emission at 360~380 mμ as well as the emission from Tl$^+$ ion was found as mentioned in §3. The peak of the former emission changes its position a little from specimen to specimen even in pure KI crystal. Because the original reagent of KI involves a little amount of Tl$^+$ ion, the exciton-induced emission from Tl$^+$ ion deforms the shape of D emission at the longer wavelength side a little. As shown in Fig. 5 the excitation spectrum for D emission has a different shape from that for Tl$^+$ ion emission. At lower temperatures the height of maximum at the shorter wavelength (about 206 mμ) is higher than that at the longer wavelength (about 216 mμ) in contrast with the case for Tl$^+$ ion emission. The height of the latter maximum depends on Tl$^+$ ion concentration, and in the case of very high concentration the maximum disappears, being converted to a step.

Considering these results, the distribution of D impurity may be different from that of Tl$^+$ ion which should be uniform in the crystal. The difference between relative intensities of D emission to Tl$^+$ ion emission in the wavelength regions of larger and smaller absorption coefficients may mean that D impurity localizes especially in the vicinity of of the surface of the crystal. The intensity of D emission shown in Fig. 3 indicates that the effective concentration of this impurity in the deep interior of the crystal is $10^{16}/\mathrm{cm}^3$ in the order of magnitude with reference to the intensity of the exciton-induced emission from Tl$^+$ ion. Therefore, we can hardly suppose the emission in question to be the emission of intrinsic type from the host KI crystal against the opinion by Teegarden[11]. Furthermore, it is difficult in the usual theory of exciton to assume that the exciton gives rise to the emission suffered with such a large Stokes shift.

The exciton-induced luminescence from D impurity is thermally quenched thoroughly at room temperature against that from Tl$^+$ ion and the activation energy in this process is about 0.08 eV. Thus the temperature-dependence of exciton-induced luminescence from D impurity is stronger than that from Tl$^+$ ion.

§6. Conclusion.

In order to confirm the nature of migration of exciton in a KI single crystal, details of luminescences from KI/Tl under excitation of light in the first characteristic absorption band were measured. The exciton-induced luminescences from Tl^+ ion and a certain impurity localized in the vicinity of the surface of the crystal were found. At liquid oxygen temperature, the intensity of the exciton-induced luminescence from Tl^+ ion was found to be independent of the concentration of Tl^+ ion in the range of $10^{15}\sim10^{19}/cm^3$. Accordingly, the migration of the exciton through the crystal was conculuded. The exciton-induced effect, however, was found to decrease at higher temperatures.

Details of the interpretation on the exciton-induced luminescence will be reported in the following paper[12].

We wish to thank Messrs. H. Hosaka and M. Yamakawa for their active supports in the measurement.

Dichroism of Z Bands

By Masakazu ISHIGURO, Etsu SUGIOKA and Nozomu TAKEUCHI

Institute of Scientific and Industrial Research,
Osaka University, Kitahanada, Sakai

Received March 14, 1960)

The dichroic properties of Z bands and their correlation to that of the F band have been studied on NaCl:Sr and KCl:Sr single crystals.

From the experiment on the anisotropic bleaching, the Z_1 center was found to be a center of high symmetry in agreement with the result of paramagnetic resonance experiment. The Z_2 band showed dichroism when irradiated with [010] polarized light in the Z_2 or F band at room temperature, accompanying the dichroism of opposite sign in the F band. This is another example of the correlation in dichroism between two absorption bands as shown in the F-M system which has been found by Van Doorn and Haven. It is, however, questionable to simply decide the symmetry of the Z_2 center from the dichroism mentioned above, because in the case of KCl:Sr its peak position is shifted to shorter wavelength than the normal Z_2 band.

§1. Introduction

Z bands in KCl and NaCl crystals containing divalent cation impurities have been studied by many authors. Pick[1] and Seitz[2] proposed different models for the centers responsible for the Z_1, Z_2 and Z_3, and Cole and Friauf[3] for the Z_4 band (Fig. 1). The work of Kawamura[4] et al on the electron spin resonance of the Z_1 center suggested the high symmetry of this center and provided a powerful support for the Seitz's model which is an electron trapped at a divalent cation at a normal cation site. On the other hand, Pick's models of the Z_1 center should give some dichroism in [011] direction, for it is an electron trapped at a divalent cation with a positive ion vacancy in the nearest cation site. West and Compton[5] have measured the degree of polarization of the emission induced by the polarized Z_2 light excitation at 77°K in KCl : Sr crystal and concluded that the Z_2 center is of high symmetry. Thus, they supported the high symmetry model of Z_2 center proposed by Pick which is an electron trapped at a divalent cation. G. Chiarotti et al[6] tried the anisotropic bleaching with [010] polarized Z_2 light irradiation at dry ice temperature, but failed to find any dichroism after 25% bleaching of Z_2 band. Recently, however, Remaut et al[7] found small dichroism in the initial stage of the bleaching with [010] polarized Z_2 light in NaCl : Sr. Thus, the experimental results for the Z_2 band are very much complicated, moreover, Seitz's model which is an electron trapped at a divalent cation next to a paired vacancy gives an ambiguity for its symmetry.

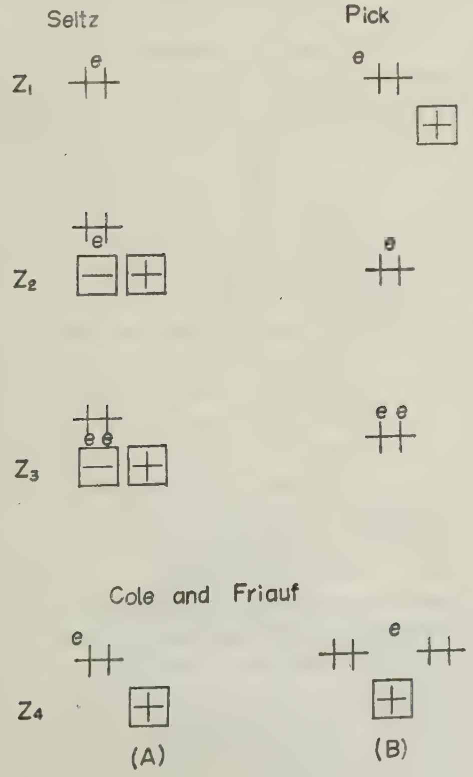

Fig. 1. Models for Z centers.

The present authors tried some experiments on the dichroic properties of the Z_1 and Z_2 bands in more involving way to obtain a little more clear knowledge to the model of these centers and also to see whether or not any correlation in dichroism presents between these bands and the F band.

§2. Experimental Procedure

Single crystals of KCl : Sr were grown by the Kyropoulos method from the melt of KCl containing 0.1 mole% $SrCl_2$. The rate of withdrawal from the melt was about 1 cm per hour, so the crystals are supposed to contain about 0.01 mole% $SrCl_2$. The additive coloration was achieved by heating in potassium vapour at about 500°C for 3 hours in a Pylex envelope and cooling slowly to room temperature. Immediately prior to an experiment a sample of about 0.1 cm thick cleaved from a colored block was wrapped in aluminium foil to prevent optical bleaching and heated at 400°C for 3 minutes, with subsequent quenching to room temperature. The crystal thus prepared showed the F band only. The Z_1 band was formed by irradiating it with the light in the F band at room temperature. Besides, there appeared another band called Z_4 after prolonged F light irradiation. When the crystal containing F and Z_1 bands was heated to 110°C and then cooled slowly to room temperature, comparable amount of F and Z_2 bands were formed. The Z_2 band can also be formed by slow cooling from the temperature of additive coloration. We used here the Z_2 band formed in either way and got the same results.

NaCl : Sr crystal was also grown from the melt of NaCl containing $SrCl_2$ of 0.1~0.03 mole% to give the various concentrations of Z_2 center. When such crystals were heated in sodium vapour at 600°C for 2 hours and quenched to room temperature in the dark, Z_2 and F bands appeared. The ratio of these bands can be controlled from the major F to the major Z_2 by the concentration of strontium in the virgin crystal.

The optical absorption was measured as a function of wavelength with a recording spectrometer modified for the measurements at low temperature. In the irradiation of the crystal, light from a tungsten lamp or a super high pressure mercury lamp through glass filters or a monochromator were used. In the experiment with polarized light, a polarized film and a nicol prism were used, and all the anisotropic optical bleaching was made at room temperrture unless otherwise stated.

§ 3. Results

F and Z_1 bands in KCl : Sr crystal convert to each other by the irradiation in the F or Z_1 band. The anisotropic bleaching with [010] or [011] polarized Z_1 band light in KCl : Sr crystal containing both F and Z_1 bands gives no dichroism at all in any band regions, and similar result is given in the bleaching with F band light, indicating either of F and Z_1 centers cannot be an origin of dichroism (see Fig. 2). On the other hand, in the crystal containing the F and Z_2 bands, the situation is striking; when such crystals are exposed to the irradiation of [010] polarized Z_2 light, the Z_2 and F bands show dichroism whose signs at the peak positions are opposite with each other (Fig. 3A). This time, the Z_2 band increases at the expense of the F band even under Z_2 light irradiation; in the irradiation with [010] polarized Z_2 light, the increase of Z_2 and the decrease of F in the absorption measured with the light polarized parallel to the irradiation light are less than those measured with the light perpendicular to the irradiation light. A Similar experiment with [010] polarized F light shows the dichroism in the F band and that of opposite sign in the Z_2 band, as shown in Fig. 3B. In Fig's 3A and 3B, the upper curves, which are termed the dichoroic spectrum, are the differences between absorptions measured with the polarized light parallel and perpendicular to the irradiation light. There is some discrepancies between the peak positions of the dichroic spectra and those of the absorption bands; the peak position of the F band region in the dichroic spectra is nearly equal to that of the F band, but the peak of the Z_2 band region seems to be considerably shorter than that of the Z_2 absorption band rather close to the Z_1 band.

After prolonged irradiation of [010] polarized Z_2 light, the Z_2 band reaches its saturation value, and the dichroism in the F and Z_2

band regions disappears. When [011] polarized light is used in place of [010] light as the bleaching light, to confirm the symmetry of the centers, there is no dichroism found in either of the Z_2 or F band.

Our present results in KCl : Sr crystal seems to contradict with the experimental data concerning its symmetry reported up to the present, but these investigators carried out the bleaching and excitation of the samples at low temperatures. Thus the temperature effect on the dichroic properties has been confirmed. In the bleaching with Z_2 light at −150°C, the Z_2 band is bleached at first as well as the F band, accompanying formation of the F′ and Z_3 bands, then it shows very rapid recovery to the initial curve even under continuous Z_2 light irradiation, thus the observation of dichroism becomes impossible. At dry ice temperature, though it is also difficult to measure because of its rapid recovery to the initial sbsorption curve. there is the same dichroism observed as at room temperature.

NaCl : Sr crystal containing Z_2 and F bands shows the similar dichroic behaviour to that in KCl : Sr crystal for the irradiation with [010] polarized Z_2 light as shown in Fig. 4A. This time, both F and Z_2 bands bleach in the initial stage, then the F band appears to rise while the Z_2 band continues to decrease slowly. As the position of the Z_2 band is very close to the Z_1 band which is supposed to be formed after intense irradiation with Z_2 light, it is difficult to analyse the resultant absorption curve into these two bands even in the low temperature measurement. Prolonged irradiation with this light removes the dichroism, producing new bands at the longer wavelength side of the Z_2 band and at the shorter wavelength side of the F band. The dichroism mentioned above is lost whithin several hours in the dark at room temperature. A Similar experiment with [010] polarized F light also shows the dichroism in the F band and that of opposite sign in the Z_2 band as shown in Fig. 4B. This case, however, the F band bleaches rapidly while the Z_2 band seems to bleach a little and the newly formed bands are the same as in the

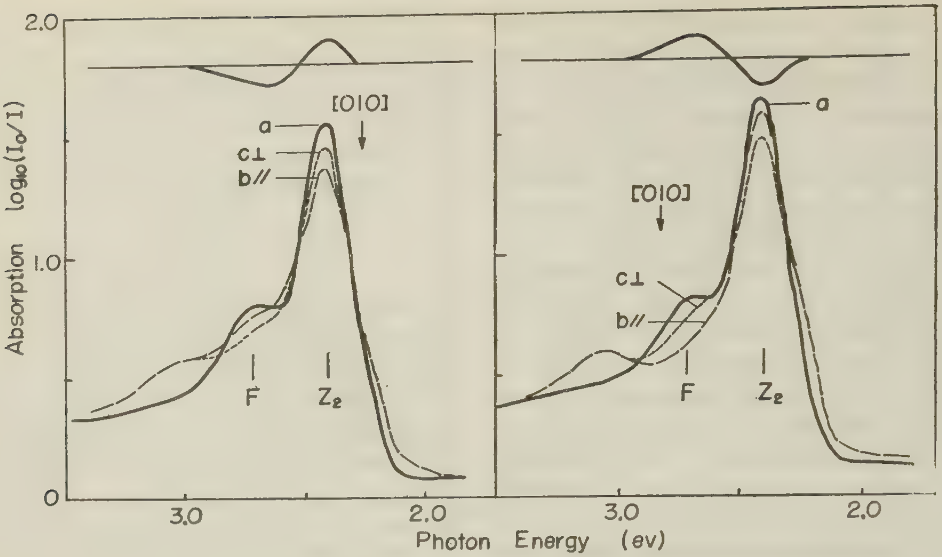

Fig. 4A) Anisotropic irradiation of the Z_2 band in NaCl:Sr crystal containing Z_2 and F. Curve a—before irradiation, measured with [010] and [001] polarized light. case of the bleaching with Z_2 light. The peak positions of the dichroic spectrum in either case are not definitely determined because of their small amount and overlapping due to the proximity of their wavelength, but the peak in the F band region lies at about the same wavelength as the F absorption band and the peak in the Z_2 band region is nearly equal to that of the Z_2 absorption band.

In this system [011] polarized light in the Z_2 or F band dose not produce any dichroism in either band. Thus, these dichroic behaviours are very much alike to those in KCl : Sr system described above.

The correlation in dichroism between the F and Z_2 bands is similar to that between the F and M bands which has been reported by Van Doorn[8]. Thus, we tried some experiments to examine the present phenomena from the view point of " overlapping " proposed by Van Doorn; if this hypothesis " overlapping " is realized, the ratio of the amount of dichroism in the F and Z_2 band regions should be constant irrespective of the amount, and even of the methods of induc-

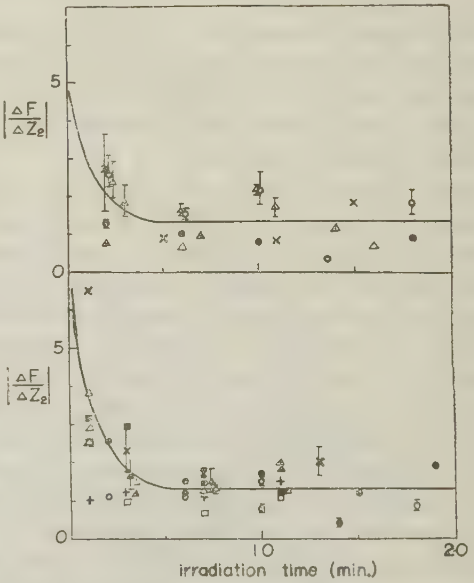

Fig. 5A) The ratio of the amount of dichroism in the F band to that in the Z_2 band in NaCl:Sr crystal as a function of the [010] polarized Z_2 light irradiation time.

Fig. 5B) The ratio of the amount of dichroism in the F band to that in the Z_2 band in NaCl:Sr crystal as a function of the [010] polarized F light irradiation time.

ing dichroism in the center whose symmetry axis is along the [010] direction. Fig. 5 shows this situation; at the initial part of bleaching, the ratio is larger than unity, but as the bleaching proceeds, it approaches to unity for the polarized F or Z_2 light irradiation.

§ 4. Discussion

That no dichroism was found in the crystal containing Z_1 and F bands, seems to be a nice agreement with the result obtained by the paramagnetic resonance experiment, supporting the high symmetry of Seitz's model for this center. On the other hand, Pick's model of Z_1 center should show some dichroism in the bleaching with [011] and also [010] polarized light, but the absence of it decreases the reliability of this model*.

The model of the Z_2 center will be supposed to be the one whose symetry axis is along ⟨100⟩ direction from the dichroism of this band described in the previous section, but the details of the dichroism obtained in the present experiment seem to be so complicated in KCl : Sr crystal that the symmetry of this center cannot be simply decided from it: (1) Z_2 light irradiation on the sample containing Z_2 band shows an increase in the Z_2 band and a decrease of the F band, with a shift of both peaks to shorter wavelength side. (2) The peak of the dichroic spectrum in the Z_2 band region shifts to shorter wavelength than the normal Z_2 band peak or rather to the Z_1 band peak. (3) The F light irradiation on the same sample also shows an increase in the Z_2 band with the same shifts of the peak as in the above case. The peak of the dichroism in the Z_2 band region induced by polarized F light irradiation also lies at the shorter wavelength side as shown in Fig. 3B. (4) The prolonged irradiation with polarized Z_2 or F light causes decrease of the dichroism in the Z_2 and F band regions and finally disappearance in the both regions, still leaving considerable amount of absorption. From the fact described above, it appears that the dichroism in the Z_2 band region is not due to the symmetry of the Z_2 center itself, but may be caused by some center which appears in the optical process under the irradiation of Z_2 or F light.

In connection with the above speculation, it is interesting to note that there are several configurations similar to the Seitz's model of the Z_2 center, one of which has optical dipole or dipoles oriented along the cubic axis.

Thus in the present stages, we cannot conclude any decisive model for the Z_2 center, but the Seitz's model of this center seems to be the one which should be preserved for the present.

It is serious that there is the same correlation in dichroism between the F and Z_2 band regions as that between the F and M bands. Though, it is difficult to proceed analysis quantitatively about this phenomena because of the very close position of the Z_2 band to the F band, we tried some experiments along the Van Doorn's hypothesis "overlapping" as mentioned in the previous section. The fact that, as the anisotropic irradiation proceeds, the ratio of the dichroism in F and Z_2 band regions approaches to unity irrespective of the amounts or the methods of inducing dichroism gives a support to the "overlapping" hypothesis, but the anomalous large values at the initial stages of the irradiation leave room for considerable doubt to it.

Thermal Bleaching of Color Centers in KCl Crystals Containing *U* Centers

By Masamitsu HIRAI

Department of Physics, The Faculty of Science,
University of Tohoku, Sendai

(Received April 6, 1960)

From the study of thermal bleaching of the *F*, *M* and R_2 bands in KCl crystals containing *U* centers, the behavior of the hydrogen molecules produced from *U* centers was examined. The hydrogen molecules do not react with *F* centers but with *M* centers by bimolecular reaction and make *M* centers convert to *U* centers.

Furthermore, thermal bleaching of the Z_1 and Z_2 bands in KCl crystals containing divalent cations was also investigated. The Z_1 and Z_2 bands are thermally unstable at temperature above 80°C, while they are stable up to 110°C and 250°C, respectively, in the crystal containing no *U* centers. From these results, in KCl:Sr crystals it is supposed that Z_1 centers do not return to *U* centers but form unknown centers by combining with the hydrogen molecules.

§ 1. Introduction

The alkali halide crystals are colored with the introduction of the *F* band by the addition of a stoichiometric excess of alkali metal, and the following phenomena have been well known. When KCl crystals containing *F* centers are illuminated at room temperature, with light absorbed in the *F* band (*F* light), the *F* band bleaches partially, while the *M*, R_1, R_2 and *N* bands appear on the longer wavelength side of the *F* band. These bands are stable in dark at room temperature.

The model of the *F* center given by de Boer[1] as shown in Fig. 1 has been confirmed by many optical and paramagnetic resonance experiments[2]. While, investigations on the dichroic property[3] of the *M* band suggest that it has a structure of non-cubic symmetry as shown in Fig. 1[4]. Furthermore, it is inferred that if the *M* band grows, its second absorption band becomes to overlap the *F* band[5]. Models of the other centers were given by Seitz as shown in Fig. 1, but they have not yet been confirmed exactly[4].

On the other hand, it was previously found[6] that the *F* band converted from the *U* band is thermally stable at room temperature and it bleaches by the *F* light illumination, and the *M*, R_1, R_2 and *N* bands appear as in the case of the additively colored pure crystal. However, the *M* band thus produced is thermally unstable at room temperature and bleaches completely. The *F* band bleaches partially too and its decrement in the optical density is nearly equal with that of the *M* band.

The so-called *U* band appears in the ultraviolet region when the additively colored crystal is heated in the atomosphere of the hydrogen gas. Its absorption maximum lies at λ 216 mμ in KCl crystals at room temperature. The model of the *U* center is tentatively considered by Hilsch and Pohl[7] to be an H^- ion occupying substitutionally the negative ion site. When the crystals containing *U* centers (KCl+*U* crystals) are illuminated with light in the *U* band (*U* light) at room temperature, the *U* band bleaches partially and only the F band appears again photochemically. The other bands such as *M*, R_1, R_2 and *N* bands do not appear in the process of $U \rightarrow F$ conversion. The conversion mechanism was explained by Mott and Gurney[8] as follows. The excited state of the *U* center is metastable as a result of crossing of the crystalline Franck-Condon levels, and a hydrogen atom may escape from the center in the metastable state, leaving an *F* center. The hydrogen atoms migrate through the crystal and combine immediately with each other to form the molecules, as indicated by the disappearance of the paramagnetic absorption[9]. However, there is no information concerning the migration of the hydrogen molecules through the crystal.

In the present paper, from the observation on thermal bleaching of the M band in KCl+U crystals and its dependence on the concentration of the hydrogen molecules, it will be discussed how the hydrogen molecules behave in the crystal and how they interact with M centers.

Furthermore, thermal bleaching of the Z_1 and Z_2 bands in KCl crystals containing divalent ions was also investigated. These bands lying on the longer wavelength side of the F band were discovered by Pick[10] in the additively colored crystals containing divalent ions. Models of the centers corresponding to these bands were proposed independently by Seitz and Pick as shown in Fig. 1. From the fact that the behavior of the Z_1 and Z_2 bands in the crystals containing U centers differ from that in the crystals containing no U centers, it will also be discussed how the hydrogen molecules react with Z_1 centers.

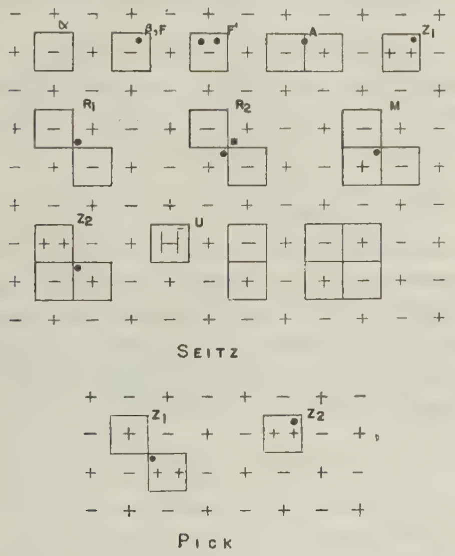

Fig. 1. The model of various color centers and vacancy clusters.

§ 2. Experimental Procedures.

KCl crystals obtained from Harshaw Chemical Co. were additively colored with F centers by the conventional method. The concentration of F centers was about 3×10^{18}/c. c., which was determined optically by using well known Smakula's equation,

$$n_F\cdot f_F=1.31\times10^{17}\times\frac{n'}{(n'^2+2)^2}\times\alpha_M\times H_F. \quad (1)$$

Putting $f_F=0.81$, $n'=1.49$ and $H_F=0.35$ ev. for KCl crystals, Eq. (1) is simplified as follows:

$$n_F=1.09\times10^{16}\times(\log I_0/I)_F/d, \quad (2)$$

where $(\log I_0/I)_F$ is the optical density at the F band peak, and d is the thickness of the crystal in centimeter.

The crystals colored with F centers were heated again at 500°C for 3 hours in a hydrogen atmosphere of about 90 atmospheric pressure in a stainless steel tube of 1 cm in thickness. F centers in the crystals disappeared completely by this treatment and were converted to U centers. The number of U centers was calculated by the equation

$$n_U=1.27\times10^{16}\times(\log I_0/I)_U/d, \quad (3)$$

which was determined from the present work as described in the later section. $(\log I_0/I)_U$ is the optical density at the U band peak.

The hydrogen discharge tube, of which operation voltage and current were A.C. 2000 volt and 1.6 ampere, respectively, was used for the illumination to generate F centers from U centers. The crystals were illuminated through the crystalline quartz window and through the air layer of about 1 cm in thickness, so that the wavelengths of light actually incident on the crystal were longer than 185 mμ. "The full light" used hereinafter means light in this spectral region. Spectral absorption measurements between λ 200 mμ and λ 1200 mμ were made with a Hitachi-spectrophotometer (Model EPU-2). The F light illuminations were made with the full light in the spectral region from 540 mμ to 580 mμ.

§ 3. Experimental Results.

3–1. *Absorption spectra.*

Fig. 2 shows a sequence of absorption measurements performed on a specimen of KCl+U crystals at room temperature. Curve (A) shows the initial state of the crystal showing only the U band. Curve (B) shows the state after about 30 minutes' illumination with "the full light". In this process only the F band appeared and it was thermally stable at room temperature. The crystal showing such absorption spectra is hereinafter referred to as "the crystal showing the U, F bands". U centers were not completely converted to F centers by the further illumination. This may be due to the fact that F centers return to U centers by the back reaction caused by the illumination with the visible light of the hydrogen discharge tube or by the destructive action of *F* centers due to the exciton[11] created by light near λ 185 mμ. By the *F* light illumination on "the crystal showing the *U*, *F* bands" the *F* band bleached partially and the *M* band appeared as shown by curve (C). ("The crystal showing the *U*, *F*, *M* bands"). By a prolong illumination the *F* band bleached further, and the *M* band did also after reaching its maximum value and the R_1 and R_2 bands appeared as shown by curve (D). ("The crystal showing the *U*, *F*, *M*, *R* bands"). These bands in the visible region were thermally unstable at room temperature and bleached completely for a long period of the *F* light illumination and returned to the *U* band.

Curve (A) The initial state showing only the *U* band.

Curve (B) The state after 30 minutes' illumination with "the full light". In this process only the *F* band appeared.

Curve (C) and (D) Successive states of the illumination with *F* light at room temperature. The *M*, R_1 and R_2 bands appeared and they bleached completely with a prolong illumination.

3-2. *The Oscillator strength of the U center in KCl crystals.*

The oscillator strength of the *U* center in KCl crystals was determined as follows. As mentioned in section 3 1, during the process of *U*→*F* conversion at room temperature, only the *F* band appears. Assuming, therefore, that an *F* center is created from a *U* center we can put as follows,

$$-\Delta n_U = \Delta n_F, \tag{4}$$

where $-\Delta n_U$ and Δn_F are the number of destroyed *U* centers and that of created *F* centers, respectively. If we use Smakula's equation for the calculation of the number of *U* centers, it may be expressed by Eq. (1), with putting $n'=1.66$ and $H_U=0.54$ eV. in KCl crystals at room temperature. Namely,

$$n_U f_U = 1.19\times 10^{16}\times(\log I_0/I)_U/d, \tag{5}$$

where f_U is the osillator strength of the *U* center. By using Eqs. (2), (4) and (5), f_U can be determined by the equation:

$$f_U = 1.19\times\frac{\Delta(\log I_0/I)_U}{\Delta(\log I_0/I)_F}, \tag{6}$$

where Δ (log $I_0/I)_U$ and Δ (log $I_0/I)_F$ are the quantities of the changes of the optical density at the *U* and *F* band peaks, respectively. Fig. 3 shows the relation between the increment of the *F* and the decrement of the *U* band peaks in the processes of *U*→*F* con-

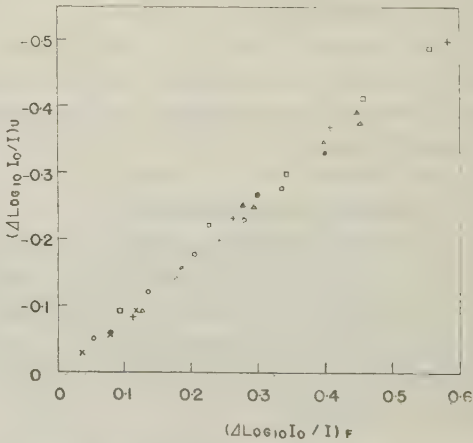

Fig. 3. The increment of the *F* and the decrement of the *U* band peaks in the process of *U*→*F* conversion by the illumination with "the full light" at room temperature.

version in several crystals containing different concentrations of U centers. Using this relation f_U was determined as 0.94 ± 0.01. Terefore, the formula to determine the number of U centers can be written as Eq. (3).

3-3. *Optical bleaching of the F band in KCl+U crystals at −70°C.*

In order to examine wherther or not free electrons released from F centers react with the hydrogen molecules, the following experiment was carried out. When "the crystal showing the U, F bands" (curve A in Fig. 4) was cooled to −70°C and illuminated with F light, the F band bleached rapidly and the F' band was formed. (Curve C). This fact is analogous to the case of the crystal containing no U centers[12]. However, the height of the U band did not increase. Furthermore, when the crystal was warmed to room temparature after the attainment of this state, its absorption spectra (curve D) coincided with that (curve A) at the initial state. This fact shows that the change of the number of U and F centers in the crystal was not caused by the F light illumination at −70°C.

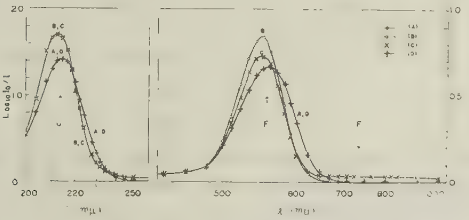

Fig. 4. Optical bleaching of the F band (at −70°C) converted from the U band in KCl crystals.

Curve (A) The initial state after $U\rightarrow F$ conversion by the illumination with "the full light" measured at room temperature.

Curve (B) The state after cooling the crystal of curve (A) to -70°C.

Curve (C) The state after the illumination with F light at -70°C. Measurements were made at the same temperature.

Curve (D) The state after warming the crystal of curve (C) to room temperature. Measurements were made at room temperature.

3-4. *Thermal bleaching of the F, M and R_2 bands.*

As mentioned before, when "the crystal showing the U, F, M bands" was kept in dark at room temperature, the F and M bands bleached thermally by nearly equal amount in the optical density. Curves (F) and (M) in Fig. 5 show the decrement of the optical density at the F and M band peaks of the crystal kept in dark at room temperature, and curve (U) shows the increment of the U band as a function of time. From the fact that the optical density changes are nearly equal in all bands, it may be considered that the hydrogen molecules react with F or M centers and make them convert to U centers. However, as mentioned in section 3-1, the F band in "the crystal showing the U, F bands" is stable, so that it is supposed that the hydrogen molecules do not react with F centers. On the other hand, we considered previously[6] that the process might be explained as follows, using the C_{2V} model for M center.

$$(1)\quad H_2+M\rightarrow H_2^{-}+V_-+V_+V_-$$
$$\rightarrow U\ \text{center}+H+\text{vacancy pair},$$
$$(2)\quad H+F\rightarrow U\ \text{center},$$

where V_- and V_+ are the negative and the positive ion vacancy, respectively. On that occasion, we did not consider the possibility of the existence of the second absorption band of the M center superposed on the F band and there was no information on the oscillator strength of the M band.

Now, from the determination of the oscillator strength[13], it is possible to calculate the absolute number of destroyed M centers. The absolute number of increased U centers is also calculated by Eq. (3). From these calculations, it was confirmed that both numbers are nearly equal in the present case. Therefore, it is reasonable to consider that the hydrogen molecules react with M centers and make them convert to U centers and the partial bleaching of the F band is due to the disappearance of the second absorption band of the M center. From these considerations, it is inferred that the height and the half height width of the second absorption band of the M center are nearly equal to that of the first M band (820 mμ) and to that of the F band, respectively. However, for the definite conclusion, mcre detailed experiments will be necessary.

When "the crystal showing the U, F, M, R bands" was kept in dark at room temperature, the M, R_1 and R_2 bands bleached completely and the F band did partially, and the U band recovered too, as shown in the lower figure of Fig. 5. From this result it is supposed that the hydrogen molecules migrate and react with R_2 centers too. However, in this case the transformation of R_2 to M centers might partially cause the bleaching of the R_2 band, because the increment of the U band was much larger than the decrement of the M band.

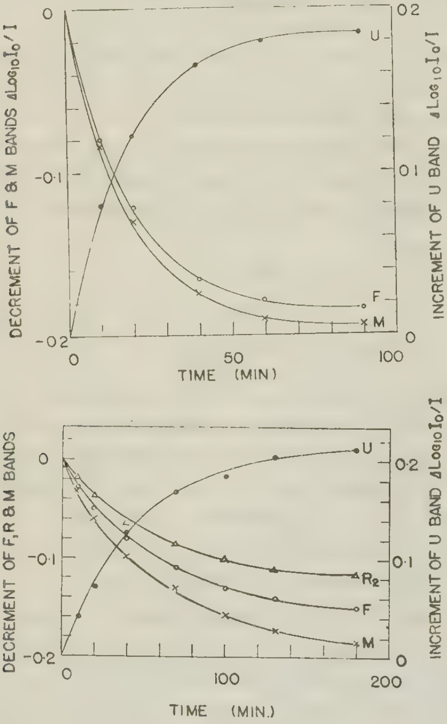

Fig. 5. Thermal bleaching of the F and M bands and recovering of the U band in KCl+U crystals kept in dark at room temperature. The lower figure shows the case in which the R_2 band exists together with the above bands.

If the hydrogen molecules migrate through the crystal, as mentioned above, it is expected that the bleaching rate of the M band will depend on the concentration of the hydrogen molecules. The following experiment was made in this consideration. A numbers of F centers were converted from U centers at 23°C in a specimen of KCl+U crystals, of which thickness was 1.08 mm. Then, by illuminating the crystal with F light, the M band was grown with the optical density of 0.2. The crystal was kept in dark and thermal bleaching of the M band was measured. Curve (1) in Fig. 6 shows the bleaching curve of the M band (first stage). After the complete bleaching of the M band, the crystal was again illuminated with F light so as to produce the M band under the same condition and with the same optical density as in the first stage. The crystal was then kept again in dark and thermal bleaching of the M band was measured (second stage) as shown by curve (2). Such treatments of the crystal for the third and fourth stages were repeated as shown by curves (3) and (4), respectively.

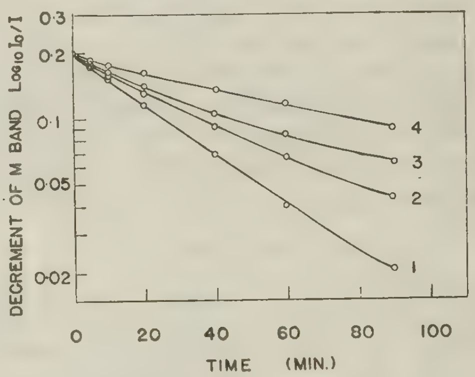

Fig. 6. The dependence of the thermal bleaching of the M band on the concentration of the hydrogen molecules in a specimen of KCl+U crystals.

The fact that the bleaching rates of the M band are smaller at the later stages is due to the smaller concentrations of the hydrogen molecules ($N(O)_t$) at the later stages as tabulated in Table I. The hydrogen molecules return to U centers during successive F light illumination, therefore, the concentrations of them are smaller at the later stages. Determination of the concentration of the hydrogen molecules will be described in section § 4.

3–5. *Thermal bleaching of the Z_1 and Z_2 bands.*

As mentioned above, the M and R_2 bands in KCl+U crystals bleach thermally. In connection with this, thermal bleaching of the Z_1 and Z_2 bands in KCl:Sr, KCl:$\mathrm{C_a}$ and KCl : Ba crystals containing U centers (KCl:Sr+U, KCl:Ca+U and KCl:Ba+U crystals) was also investigated. KCl:Sr, KCl:Ca and KCl:Ba crystals mean the KCl crystals containing halides of Sr, Ca and Ba of about one mol. percent. In these crystals the U band was introduced by the same manner as in the case of the pure crystal. The peak position and the half height width of the U band in these crystals were identical with those of the pure crystal. Fig. 7 (A), (B) and (C) show the absorption measurements on KCl:Sr+U, KCl:Ca+U and KCl:Ba+U crystals, respectively. All measurements were made at liquid air temperature. Curves (a) in the figures show the absorption spectra of the crystals showing only the U band. By the illumination with "the full light", the U band bleached partially, and two or three absorption bands appeared in the visible region. (Curves b). They are ascribed to the F, Z_1 and Z_2 bands. When KCl:Sr+U crystals were warmed up to 80°C and kept in dark for 30 minutes at 80°C, the Z_1 band almost disappeared and the F band slightly did as shown by curve (c) in Fig. 7 (A). In the case of KCl : Ca+U crystals the Z_1 band almost disappeared too, but the F band was enhanced a little. (Curve c in Fig. 7 (B)). However, in both cases the U band did not recover so much in spite of much decreasing of the absorption area in the visible region. In the case of KCl:Ba+U crystals, on the other hand, the Z_1 and Z_2 bands were converted to the F band, but the U band did not recover as shown in Fig. 7 (C).

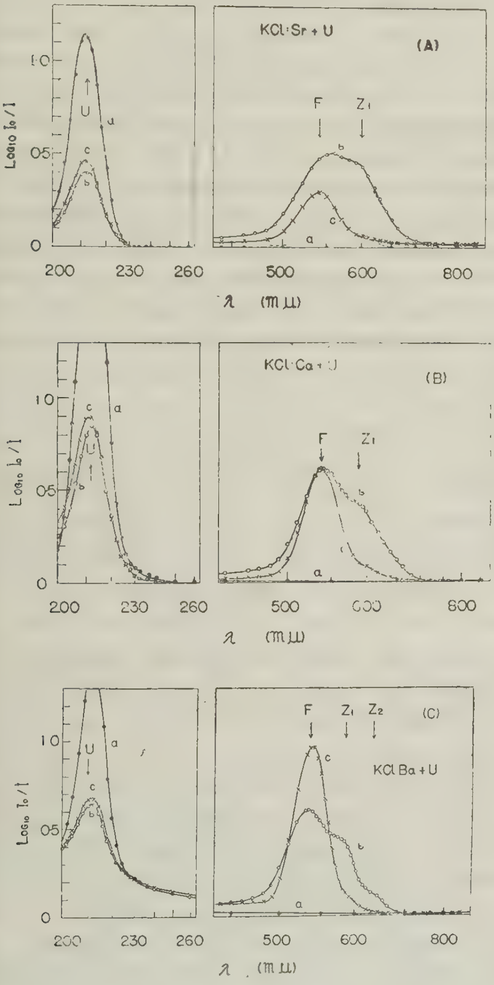

Fig. 7. Thermal bleaching of the Z_1 and Z_2 bands in KCl:Sr, KCl:Ca and KCl:Ba crystals containing U centers. All measurements were made at -193°C.

Curves (a) The initial state showing only the U band.

Curves (b) The state after the illumination with "the full light" at room temperature.

Curves (c) The state after warming the crystals to 80°C for 30 minutes in dark, following curves (b).

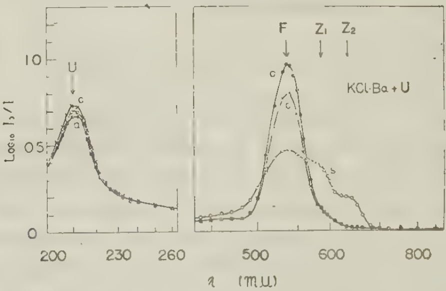

Fig. 8. The growth and the thermal bleaching of the Z_1 and Z_2 bands in KCl:Ba crystals containing U centers.

Curve (a) The same state as in curve (c) in Fig. 7 (C).

Curve (b) The state after the F light illumination at room temperature.

Curve (c) The state after warming the crystals of curve (c) up to 80°C.

Furthermore, when KCl:Ba+U crystals were illuminated with F light at room temperature after the attainment of the state corresponding to curve (c) in Fig. 7 (C), the Z_1 and Z_2 bands appeared again as shown by curve (b) in Fig. 8. By warming the crystals up to 80°C these bands bleached and returned again to the F band as shown by curve (c) in Fig. 8. The behavior of the Z_1 and Z_2 bands differs from that of the crystals containing no U centers[10]. Namely, when the latter crystlas are illuminated with F light at room temperature, only the Z_1 band appears, and the Z_2

band appears by warming the crystals at temperature near 110°C. Furthermore, the Z_1 and Z_2 bands are thermally stable at temperatures up to 110°C and 250°C, respectively.

§ 4. Discussion and Conclusion.

It is generally considered that when KCl+U crystals are illuminated with U light at room temperature, the hydrogen atoms released from U centers combine immediately with each other to form the molecules. From the present results concerning thermal bleaching of the M and Z_1 bands it is concluded that the hydrogen molecules migrate through the crystal, because these bands in the crystal containing no U centers are stable.

From the result shown in Fig. 6 it will be considered how the hydrogen molecules react with M centers. If a hydrogen molecule reacts with an M center as soon as the former collides with the latter, the reaction rate may be given by the equation,

$$-\frac{dn(t)_i}{dt}=\alpha\cdot n(t)_i\cdot N(t)_i=\alpha\cdot n(t)_i\cdot(n(t)_i+a_i), \quad (7)$$

where α is the reaction constant, and $n(t)_i$ and $N(t)_i$, (i=1, 2, 3, 4) are the concentrations of M centers and the hydrogen molecules after t sec's reaction at *i-th* stage of the M band bleaching, respectively. a_i is the concentration of the hydrogen molecules remaining after the finish of all reactions at *i-th* stage. From Eq. (7), $n(t)_i$ is given by the equation

$$n(t)_i=\frac{N(t)_i n(O)_i}{N(O)_i}e^{-\alpha(N(O)_i-n(O)_i)t}, \quad (8)$$

where $n(O)_i$ and $N(O)_i$ are the initial concentrations of M centers and the hydrogen molecules at *i-th* stage, respectively. In the present case it may be put as $N(O)_i \gg n(O)_i$ and $N(t)_i \approx N(O)_i$, because the concentration of the hydrogen molecules is much larger than that of M centers. Therefore, Eq. (8) may be expressed as follows,

$$n(t)_i=n(O)_i e^{-\alpha N(O)_i t},$$

$$\log n(t)_i=\log n(O)_i-\frac{1}{2.3}\alpha\cdot N(O)_i\cdot t. \quad (9)$$

Therefore, if the bleaching curves of the M band plotted on logarithmic scale are the straight lines and the slopes (α_i) are expressed by $-\frac{1}{2.3}\cdot\alpha\cdot N(O)_i$, in other words, if the reaction constant (α) is the same in all curves, it may be supposed that the hydrogen molecules react with M centers by the bimolecular reaction expressed by Eq. (9).

As shown in Fig. 6, the bleaching curves of the M band are expressed by nearly straight lines in all cases. Then, in the next place it is shown that the reaction constant (α) obtained by normalizing α_i by $N(O)_i$ is nearly equall in all curves.

The slope (α_i) of each curve in Fig. 6 is represented by the equation

$$\alpha_i=\frac{\log(n(O)_i/n(t)_i)}{t}$$

$$=\frac{1}{t}\log\frac{(\log I_0/I)_M(O)_i}{(\log I_0/I)_M(t)_i}, \quad (10)$$

where $(\log I_0/I)_M(O)_i$ and $(\log I_0/I)_M(t)_i$ are the optical densities at the M band peak at the initial and after t sec's bleaching of the M band at each curve, respectively. By using the values of $(\log I_0/I)_M(O)_i$, which are 0.200±0.005 in all curves, and the values of $(\log I_0/I)_M(t)_i$ at each *i-th* stage shown in Fig. 6, α_i's were obtained as tabulated in Table I.

Table I.

i	1	2	3	4
$2.3\times\alpha_i$	4.40	3.04	2.41	1.51×10^{-4}/sec.
$N(O)_i$	1.35	0.91	0.77	0.53×10^{-17}/c.c.
α	3.25	3.34	3.13	2.85×10^{-21}/sec.
mean value of α	$(3.15\pm0.20)\times10^{-21}$/sec.			

On the other hand, it may be reasonable to consider that the concentration of the hydrogen molecules $N(O)_i$ is a half of that of F centers at the initial state in each stage, because a hydrogen molecule is created by the destruction of two U centers and the creation of two corresponding F centers. Then, by measuring the height of the F band, $N(O)_i$'s were obtained as tabulated in Table 1. From the values of α_i's and $N(O)_i$'s in Table 1, α was obtained as $(3.15\pm0.20)\times10^{-21}$/sec., as the mean value. The values of α are nearly equal in all cases within the experimental error of about 5%. Namely, as mentioned above, it may be concluded that the hydrogen molecules react with M centers by the bimolecular reaction expressed by Eq. (9).

The hydrogen molecules might exist much near the crystal surface illuminated with "the full light". However, in the present case it is assumed that they are uniformly distributed over the crystal, by the following reason. "The full light" contains light near λ 185 mμ. While the absorption coefficients of KCl+U crystals are comparatively small in the spectral region near λ185 mμ. Therefore, the light can well penetrate into the crystal, and moreover, it makes the conversion of U to F centers with quantum yield of nearly unity[14]. Therefore, it may be considered that the hydrogen molecules are uniformly distributed.

According to Pick[10], the Z_1 and Z_2 bands in KCl:Sr crystals are stable at temperatures above near 110°C and 250°C, respectively. However, the behavior of these bands in the crystals containing U centers differs from that in the above crystals on the following points.

(1) The Z_1 band in KCl:Sr+U and KCl:Ca+U crystals was unstable at 80°C, and in spite of the bleaching of the Z_1 band, the U, F and Z_2 bands were not enhanced.

(2) The Z_2 band appeared by the F light illumination upon KCl:Ba+U crystals showing the U and F bands and it was unstable at temperature even near 80°C. In the present case the Z_1 and Z_2 bands were converted to the F band, but the U band did not recover.

From the fact (1), it is supposed that Z_1 centers do not return to U or F centers but form unknown centers, because the absorption intensity on the shorter wavelength side of the U band was slightly enhanced. This fact may be explained by the character of the model of the Z_1 center shown in Fig. 1, which can not form the U center even if it traps a hydrogen molecule.

From the results concerning optical bleaching of the F band at −70°C, it will be supposed that the free electrons released from F centers do not play any role in the conversion of the hydrogen molecules to U centers.

From the results mentioned above it may be concluded that the hydrogen molecules interact only with complex centers such as M, R_2 or Z_1 centers, but they can not interact with F centers at least near room temperature. These centers except for the Z_1 center consist of the electron and the vacancy cluster, and form comparatively large holes in the crystal. Therefore, it will be supposed that the hydrogen molecules may easily be trapped by these large holes.

The hydrogen molecules may be trapped more stably at the vacancy cluster such as vacancy pair or quartet, which form large holes in the crystal too. However, any absorption band corresponding to such trapping was not observed even in the crystals which were considered to contain a large number of vacancies.

The author wishes to express his cordial thanks to Prof. Masayasu Ueta for constant encouragement and valuable advice throughout the present work.

Effect of Transverse Magnetic Field on the Flow due to an Oscillating Flat Plate, II.

By Tsunehiko KAKUTANI

Department of Physics, Faculty of Science, Kyoto University

(Received March 3, 1960)

This paper deals with the hydromagnetic flow of an electrically conducting fluid due to an oscillating flat plate of *perfect conductor* in the presence of transverse magnetic field. Exact solutions for arbitrary values of R (the Reynolds number), R_m (the magnetic Reynolds number) and S (the magnetic pressure number) are first derived and then some special cases are discussed corresponding to limiting values of the parameters S and R_m in order to clarify the hydromagnetic effect, and especially an interesting special case corresponding to the 'magnetic Stokes approximation' is discussed in some detail.

Next, the drag on the plate is calculated for both cases of *non-conducting* plate and *perfectly conducting* plate. It is found that, in both cases, the amplitudes of the total drag (shear-stress+Maxwell's stress) always *increase* and the initial phases of the total drag are always *retarded* for any values of R, R_m and S compared with those of the well-known classical case, i.e., the case of no magnetic field and/or electrical conductivity of the fluid being zero.

§1. Introduction

In a previous paper[1)], the present writer investigated the effect of magnetic field upon the flow of a conducting fluid due to an oscillating flat plate of *non-conductor*, and obtained exact solutions for the modified Navier-Stokes and Maxwell's equations.

In this paper, we attempt to extend the problem to the case of the flow due to an oscillating plate of *perfect conductor*. It is found that exact solutions of magnetohydrodynamical equations can also be obtained in this case. A principal difference between the results obtained in the previous and the present work is that in the latter case the 'sheet current' flows at the boundary between the fluid and the plate, and H_x, the component of the induced magnetic field along the plate, jumps discontinuously from a finite value in the fluid to zero in the plate, whereas in the former no sheet current flows and there occurs no abrupt change in the magnetic field at the boundary.

These solutions, obtained in the previous and the present papers, may give a bright prospect for studies of the boundary-layer flow. The problems of the boundary-layer flow are generally much complicated even if the 'boundary-layer approximation' is introduced, and exact solutions cannot be obtained except a few fortunate cases. Moreover, there is a clear *dualism* of the viscous boundary-layer and the magnetic boundary-layer characterized respectively by the parameters R and R_m, so that the ordinary boundary-layer approximation used in classical hydrodynamics is not generally applicable to the magnetohydrodynamical cases unless some modifications are made. Fundamental questions in the problem of magnetohydrodynamical boundary-layer flow such as this dualism may be clarified in these simple but *exact* solutions obtained in the previous and the present papers.

The general solutions for arbitrary values of S, R and R_m are first derived and then some special cases are discussed corresponding to limiting values of the parameters S and R_m in order to clarify the hydromagnetic effect.

Next, the drag experienced by the plate is calculated in some detail for both cases of *non-conducting* plate and *perfectly conducting* plate. It is found that, in both cases, the amplitudes of the total drag (shear-stress+Maxwell's stress) always *increase* for any values of S, R and R_m by the hydromagnetic effect compared with that of the well-known classical case. For non-conducting plate, the shear-stress itself increases and Maxwell's stress is identically zero, whereas in the case of *perfectly conducting* plate, the shear-stress decreases compared with that of the classical case but there appears Maxwell's stress exceeding this reduction in shear-stress, so that the net increase in total drag also results. In this context, it is also found that, in both cases, the initial phases of the total drag are always *retarded* for any values of S, R and R_m compared with that of the classical case.

Finally, we discuss an interesting special case corresponding to the 'magnetic Stokes approximation ($R_m \ll 1$, $SR_m = O(1)$)', which is frequently used in magnetohydrodynamics. It is shown that the approximate velocity distributions of the same problem obtained by Ong and Nicholls[2] on the basis of Rossow's assumption[3] (neglect of the induced magnetic field) can be derived as a limiting case of our solutions by putting $R_m \to 0$ and $SR_m = O(1)$. The case of 'the magnetic field being fixed *to the fluid*' corresponds to the case of our *non-conducting* plate, and the case of 'the magnetic field being fixed *to the plate*' corresponds to the case of our *perfectly conducting* plate. Thus we may assert that Rossow's assumption is permissible only for the cases of small magnetic Reynolds number with large magnetic pressure number. Furthermore, it is also found that their respective considerations of the fundamental equations for the cases of the magnetic field being fixed 'to the fluid' or 'to the plate' may become unnecessary by including the electric field E in the analysis as in our paper, and the difference between their respective fundamental equations may be replaced simply by the difference of the boundary conditions expressing the physical properties of the plate.

§ 2. Analysis and Solutions for Perfect Conducting Plate

The fundamental equations for the velocity of the fluid, $\boldsymbol{v}$, and the intensity of the magnetic field, $\boldsymbol{H}$, are derived from the modified Navier-Stokes equations of motion and Maxwell's electromagnetic equations. As usual, assuming Ohm's law to be valid, we have the following dynamical equation and induction equation for $\boldsymbol{v}$ and $\boldsymbol{H}$:

$$\frac{\partial \boldsymbol{v}}{\partial t} + (\boldsymbol{v}\cdot\mathrm{grad})\boldsymbol{v}$$

$$= -\frac{1}{\rho}\,\mathrm{grad}\,p + \nu\nabla^2\boldsymbol{v} + \frac{\mu}{4\pi\rho}(\mathrm{curl}\,\boldsymbol{H}\times\boldsymbol{H})\,, \quad (2.1)$$

$$\frac{\partial \boldsymbol{H}}{\partial t} = \mathrm{curl}\,(\boldsymbol{v}\times\boldsymbol{H}) + \eta\nabla^2\boldsymbol{H}\,, \quad (2.2)^\dagger$$

with the equations of continuity for the velocity and the magnetic fields:

$$\mathrm{div}\,\boldsymbol{v} = 0\,, \quad (2.3)$$

$$\mathrm{div}\,\boldsymbol{H} = 0\,, \quad (2.4)$$

where p is the pressure, ρ the density of the fluid, ν and η $(=1/(4\pi\mu\sigma))$ the kinematic and the magnetic viscosity of the fluid respectively, and μ and σ are the permeability and the electrical conductivity of the fluid respectively. The electromagnetic units of system have been used throughout the present paper.

In the present problem, we take the coordinate origin O at an arbitrary point on the oscillating plate, which is assumed here to be a perfect conductor and to have the same permeability as that of the fluid, and use Cartesian coordinates x, y and z with the axes Ox and Oy along and perpendicular to the plate respectively, and assume that

(1) the flow is parallel to the plate, that is, $\boldsymbol{v} = \boldsymbol{v}(u, 0, 0)$;

(2) the magnetic field imposed is uniform and perpendicular to the plate, so that in the region considered, $\boldsymbol{H} = \boldsymbol{H}(H_x, H_y, 0)$;

(3) all quantities are functions of the space coordinate y and time t only.

The fundamental equations of our problem then become

$$\frac{\partial u}{\partial t} = \nu\frac{\partial^2 u}{\partial y^2} + \frac{\mu}{4\pi\rho}H_y\frac{\partial H_x}{\partial y}\,, \quad (2.5)$$

$$\frac{\partial}{\partial y}\left(\frac{p}{\rho} + \frac{\mu}{8\pi\rho}H_x^2\right) = 0\,, \quad (2.6)$$

$$\frac{\partial H_x}{\partial t} = H_y\frac{\partial u}{\partial y} + \eta\frac{\partial^2 H_x}{\partial y^2}\,, \quad (2.7)$$

$$\frac{\partial H_y}{\partial t} = \eta\frac{\partial^2 H_y}{\partial y^2}\,, \quad (2.8)$$

while the equation of continuity for the velocity field (2.3) is automatically satisfied by the above assumptions.

The boundary donditions for the velocity field are exactly the same as those in classical hydrodynamics, that is, on the oscillating plate the velocity of the fluid coincides with that of the plate, and at far distances from the plate u tends to zero asymptotically. Thus we have

---

† Details for the derivation of Eqs. (2.1) and (2.2) are given in Reference 1.

$$y=0: \quad u=Ue^{i\omega t}; \qquad y\to\infty: \quad u\to 0, \tag{2.9}$$

where U and ω denote respectively the velocity amplitude and the angular frequency of the oscillating plate.

The boundary conditions for the magnetic field may be obtained as follows. Since the velocity tends to zero asymptotically at a great distance from the plate, no interaction exists there. Hence the magnetic field tends to the applied field H_0 as $y\to\infty$. Thus we have the following conditions for large y:

$$y\to\infty: \quad H_y\to H_0; \qquad H_x\to 0. \tag{2.10}$$

At the plate, on the other hand, the normal component of the magnetic field[†] and the tangential component of the electric field $\boldsymbol{E}$ should be continuous. Hence we have

$$y=0: \quad H_y=H_0; \qquad \frac{\partial H_x}{\partial y}=0. \tag{2.11}$$

The former implies that the normal component of the magnetic field is continuous to the applied field H_0, while the latter is derived by requesting the continuity of the tangential component of the electric field. Because, if $\boldsymbol{j}$ denotes the electric current density, we have

$$\boldsymbol{j}=\frac{1}{4\pi}\operatorname{curl}\boldsymbol{H}=\sigma(\boldsymbol{E}+\mu\boldsymbol{v}\times\boldsymbol{H}), \tag{2.12}$$

from which we obtain

$$E_z=-\frac{1}{4\pi\sigma}\frac{\partial H_x}{\partial y}-\mu u H_0.$$

Applying this equation to $y=\pm 0$, and remembering that the conductivity of the plate is infinite, we have

$$E_z\Big|_{y=-0}=-\frac{1}{4\pi\sigma}\frac{\partial H_x}{\partial y}\Big|_{y=+0}-\mu H_0 u_{\text{plate}},$$

and

$$E_z\Big|_{y=-0}=-\mu H_0 u_{\text{plate}}.$$

Equating the left-hand sides of the above two equations, we arrive at the conclusion:

$$\frac{\partial H_x}{\partial y}=0 \quad \text{at} \quad y=0.$$

Our problem is now to determine the four unknowns u, H_x, H_y and p from Eqs. (2.5)∼(2.8) subject to the boundary conditions (2.9), (2.10) and (2.11).

Now, remembering the boundary conditions for H_y, we can easily solve Eq. (2.8) and obtain

$$H_y\equiv H_0, \tag{2.13}$$

which can also be derived from Eq. (2.4) together with the assumption (3). If the pressure at infinity is p_∞, it follows immediately from Eq. (2.6) that

$$p+\frac{\mu}{8\pi}H_x^2=p_\infty, \tag{2.14}$$

which shows the balance between the fluid pressure and the 'magnetic pressure' in the flow field, since H_y is uniform throughout the whole flow field as has been just shown above. Introducing (2.13) into (2.5) and (2.7) and eliminating H_x between them we have

$$\left[\left(\nu\frac{\partial^2}{\partial y^2}-\frac{\partial}{\partial t}\right)\left(\eta\frac{\partial^2}{\partial y^2}-\frac{\partial}{\partial t}\right)-k\frac{\partial^2}{\partial y^2}\right]u=0, \tag{2.15}$$

where $k=\mu H_0^2/(4\pi\rho)$, which represents the square of the characteristic velocity of 'Alfvén's magnetohydrodynamic wave.' If we eliminate u instead of H_x we have an equation for H_x similar to (2.15). Eq. (2.15) and the similar equation for H_x may be interpreted as generalized equations for 'Alfvén's magnetohydrodynamic wave' with finite diffusivities ν and η.

A formal solution of Eq. (2.15) is given as follows:

$$u=\mathop{\mathsf{S}}_{\kappa} e^{\kappa t}[Ae^{\lambda_1 y}+Be^{-\lambda_1 y}+Ce^{\lambda_2 y}+De^{-\lambda_2 y}], \tag{2.16}$$

where A, B, C and D are constants of integration, which depend on the parameter κ, and symbol S denotes the summation or integration over all possible values of κ. The complex decaying factors λ_1 and λ_2 are given as

$$\lambda_{1,2}=\left[\frac{(k+\kappa\nu+\kappa\eta)\pm\{(k+\kappa\nu+\kappa\eta)^2-4\nu\eta\kappa^2\}^{1/2}}{2\nu\eta}\right]^{1/2}, \qquad \operatorname{Re}(\lambda_{1,2})>0, \tag{2.17}$$

[†] Strictly speaking, we should request the continuity of the normal component of the *magnetic induction* instead of the magnetic field itself, but we have assumed that the permeability of the plate is effectively the same as that of the fluid, that is, both of the fluid and the plate are assumed to be non-magnetic. This assumption is not very restrictive and may be easily removed if necessary.

plus and minus signs corresponding to λ_1 and λ_2 respectively. This convention will also be used hereafter.

By virtue of the boundary condition at infinity for u, we have $A=C=0$. On the other hand, the boundary condition on the plate for u requires that

$$\kappa=i\omega \quad \text{and} \quad B+D=U\,. \tag{2.18}$$

Thus we have

$$u(y,t)=e^{i\omega t}[Be^{-\lambda_1 y}+De^{-\lambda_2 y}]\,, \tag{2.19}$$

with

$$\lambda_{1,2}=\left[\frac{(k+i\omega(\nu+\eta))\pm\{(k+i\omega(\nu+\eta))^2+4\nu\eta\omega^2\}^{1/2}}{2\nu\eta}\right]^{1/2}. \tag{2.20}$$

Inserting (2.19) into (2.5) we have

$$\frac{\partial H_x}{\partial y}=\frac{H_0}{k}e^{i\omega t}[(i\omega-\nu\lambda_1^2)Be^{-\lambda_1 y}+(i\omega-\nu\lambda_2^2)De^{-\lambda_2 y}]\,. \tag{2.21}$$

Integrating (2.21) with respect to y and remembering that $H_x\to 0$ as $y\to\infty$, we have

$$H_x(y,t)=-\frac{H_0}{k}e^{i\omega t}\left[\left(\frac{i\omega}{\lambda_1}-\nu\lambda_1\right)Be^{-\lambda_1 y}+\left(\frac{i\omega}{\lambda_2}-\nu\lambda_2\right)De^{-\lambda_2 y}\right]. \tag{2.22}$$

The boundary condition on the plate for H_x requires that

$$(i\omega-\nu\lambda_1^2)B+(i\omega-\nu\lambda_2^2)D=0\,. \tag{2.23}$$

Solving (2.18) and (2.23) for B and D, we obtain

$$B=\frac{i\omega-\nu\lambda_2^2}{\nu(\lambda_1^2-\lambda_2^2)}U\,, \qquad D=-\frac{i\omega-\nu\lambda_1^2}{\nu(\lambda_1^2-\lambda_2^2)}U\,. \tag{2.24}$$

Insertion of B and D thus determined into (2.19) and (2.22) yields the solutions for u and H_x:

$$u(y,t)=-\frac{(\nu\lambda_1^2-i\omega)(\nu\lambda_2^2-i\omega)}{\nu(\lambda_1^2-\lambda_2^2)}Ue^{i\omega t}\left[\frac{1}{\nu\lambda_1^2-i\omega}e^{-\lambda_1 y}-\frac{1}{\nu\lambda_2^2-i\omega}e^{-\lambda_2 y}\right], \tag{2.25}$$

and

$$H_x(y,t)=-\frac{(\nu\lambda_1^2-i\omega)(\nu\lambda_2^2-i\omega)}{k\nu(\lambda_1^2-\lambda_2^2)}H_0Ue^{i\omega t}\left[\frac{1}{\lambda_1}e^{-\lambda_1 y}-\frac{1}{\lambda_2}e^{-\lambda_2 y}\right]. \tag{2.26}$$

Since $\operatorname{curl}\boldsymbol{H}=4\pi\boldsymbol{j}$, we have

$$\left.\begin{aligned} &j_x=0\,, \qquad j_y=0\,, \\ &j_z(y,t)=-\frac{(\nu\lambda_1^2-i\omega)(\nu\lambda_2^2-i\omega)}{4\pi k\nu(\lambda_1^2-\lambda_2^2)}H_0Ue^{i\omega t}[e^{-\lambda_1 y}-e^{-\lambda_2 y}]\,. \end{aligned}\right\} \tag{2.27}$$

With the aid of Ohm's law: $\boldsymbol{j}=\sigma(\boldsymbol{E}+\mu\boldsymbol{v}\times\boldsymbol{H})$, we have

$$\left.\begin{aligned} &E_x=0\,, \qquad E_y=0\,, \\ &E_z(y,t)=-\frac{i\omega(\nu\lambda_1^2-i\omega)(\nu\lambda_2^2-i\omega)}{k\nu(\lambda_1^2-\lambda_2^2)}\mu H_0Ue^{i\omega t}\left[\frac{1}{\lambda_1^2}e^{-\lambda_1 y}-\frac{1}{\lambda_2^2}e^{-\lambda_2 y}\right]. \end{aligned}\right\} \tag{2.28}$$

The above (2.25)~(2.28) together with (2.13) and (2.14) are the general solutions of the present problem, which should be compared with those of the case of non-conducting plate (see (3.11)~(3.14) of Reference 1) and with that of the classical case: $u=Ue^{i\omega t-\sqrt{i\omega/\nu}\cdot y}$.

It will be seen that all quantities consist of two different oscillations whose complex decaying factors are λ_1, λ_2; $\mathrm{Re}\,(\lambda_{1,2})$ and $\mathrm{Im}\,(\lambda_{1,2})$ respectively representing the decaying factors and the wave numbers of the oscillations. Since $H_y = H_0$, the fundamental equations (2.5) $\sim$(2.8) are all linear, so that we can make up more general solutions by superimposing several oscillations of different amplitudes and different angular frequencies.

It should be noted here that H_x jumps discontinuously at $y = \pm 0$. This is the very different point from the case of non-conducting plate. This discontinuity of H_x implies that there flows the sheet current J_s at the boundary. J_s may be evaluated by integrating $\boldsymbol{j} = \mathrm{curl}\,\boldsymbol{H}/(4\pi)$ in the domain of a thin rectangle with unit width and thickness Δl spanning over the boundary between the fluid and the plate (see Fig. 1), and by letting Δl tend to infinitesimal after integration, that is,

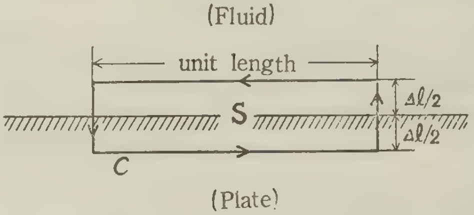

Fig. 1. Sketch of domain to evaluate sheet current.

$$
\begin{aligned}
J_s &= \lim_{\Delta l \to 0} \iint_S (\boldsymbol{j} \cdot d\boldsymbol{S}) \\
&= \lim_{\Delta l \to 0} \frac{1}{4\pi} \iint_S (\mathrm{curl}\,\boldsymbol{H} \cdot d\boldsymbol{S}) \\
&= \frac{1}{4\pi} \lim_{\Delta l \to 0} \oint_c (\boldsymbol{H} \cdot d\boldsymbol{c}) \qquad \text{(by the use of Stokes' theorem)} \\
&= \frac{1}{4\pi} \lim_{\Delta l \to 0} \left[H_x\!\left(-\frac{\Delta l}{2}\right) + H_0 \Delta l - H_x\!\left(\frac{\Delta l}{2}\right) - H_0 \Delta l \right] \\
&= \frac{1}{4\pi} [H_x(-0) - H_x(+0)] \\
&= -\frac{1}{4\pi} H_x(+0) \\
&= -\frac{(\nu\lambda_1^2 - i\omega)(\nu\lambda_2^2 - i\omega)}{4\pi k \nu \lambda_1 \lambda_2 (\lambda_1 + \lambda_2)} H_0 U e^{i\omega t} \, . \qquad (2.29)
\end{aligned}
$$

§ 3. Non-dimensional Forms of the Solutions and their Behaviours in Some Special Cases

Now we proceed to discuss the solutions in non-dimensional forms, and in order to clarify the hydromagnetic effect we shall discuss the behaviours of the solutions in some special cases corresponding to various limiting values of the parameters S and R_m.

We define the following three characteristic parameters:

$$
\left.
\begin{array}{ll}
\text{the Reynolds number:} & R = U^2/(\nu\omega)\,, \\
\text{the magnetic Reynolds number:} & R_m = U^2/(\eta\omega)\,, \\
\text{the magnetic pressure number:} & S = \mu H_0^2/(4\pi\rho U^2)\,,
\end{array}
\right\} \qquad (3.1)
$$

by introducing non-dimensional quantities with asterisk as follows:

$$
\left.
\begin{array}{lll}
u = U u^*\,, & p = \dfrac{1}{2}\rho U^2 p^*\,, & \\
y = \dfrac{U}{\omega} y^*\,, & \boldsymbol{H} = H_0 \boldsymbol{H}^*\,, & \boldsymbol{E} = \mu H_0 U \boldsymbol{E}^*\,, \\
t = \dfrac{1}{\omega} t^*\,, & j = \sigma\mu H_0 U j^*\,, & \\
\lambda_{1,2} = \dfrac{\omega}{U} \lambda_{1,2}^*\,, & J_s = H_0 J_s^*\,. &
\end{array}
\right\} \qquad (3.2)
$$

It is to be noted here that the Hartmann number M frequently used in the analysis of problems in magnetohydrodynamics is equal to $\sqrt{SRR_m}$ in our notations.

Using the non-dimensional quantities defined above, we have the solutions in non-dimensional forms as follows:

$$\left.\begin{aligned}
u^* &= -\frac{(\lambda_1^{*2}-iR)(\lambda_2^{*2}-iR)}{\lambda_1^{*2}-\lambda_2^{*2}}\,e^{it^*}\left[\frac{1}{\lambda_1^{*2}-iR}\,e^{-\lambda_1^* y^*}-\frac{1}{\lambda_2^{*2}-iR}\,e^{-\lambda_2^* y^*}\right],\\
H_x^* &= -\frac{(\lambda_1^{*2}-iR)(\lambda_2^{*2}-iR)}{SR(\lambda_1^{*2}-\lambda_2^{*2})}\,e^{it^*}\left[\frac{1}{\lambda_1^*}\,e^{-\lambda_1^* y^*}-\frac{1}{\lambda_2^*}\,e^{-\lambda_2^* y^*}\right],\\
H_y^* &= 1\,,\\
j_z^* &= -\frac{(\lambda_1^{*2}-iR)(\lambda_2^{*2}-iR)}{SRR_m(\lambda_1^{*2}-\lambda_2^{*2})}\,e^{it^*}[e^{-\lambda_1^* y^*}-e^{-\lambda_2^* y^*}]\,,\\
E_z^* &= -\frac{i(\lambda_1^{*2}-iR)(\lambda_2^{*2}-iR)}{SR(\lambda_1^{*2}-\lambda_2^{*2})}\,e^{it^*}\left[\frac{1}{\lambda_1^{*2}}\,e^{-\lambda_1^* y^*}-\frac{1}{\lambda_2^{*2}}\,e^{-\lambda_2^* y^*}\right],\\
p^* &= -SH_x^{*2}+p_\infty^*\,,\\
J_s^* &= -\frac{(\lambda_1^{*2}-iR)(\lambda_2^{*2}-iR)}{4\pi SR\lambda_1^*\lambda_2^*(\lambda_1^*+\lambda_2^*)}\,e^{it^*}\,,
\end{aligned}\right\} \tag{3.3}$$

with

$$\lambda_{1,2}^* = \left[\frac{SRR_m+i(R+R_m)\pm\{(SRR_m+i(R+R_m))^2+4RR_m\}^{1/2}}{2}\right]^{1/2}. \tag{3.4}$$

It is worthwhile to notice that R and R_m are contained symmetrically in the complex decaying factors $\lambda_{1,2}^*$. This shows that the dualism of the viscous and the magnetic boundary-layers is exactly symmetric with respect to R and R_m in this problem.

Now we consider the behaviours of the solutions corresponding to limiting values of the parameters S and R_m. Since R and R_m are contained symmetrically in $\lambda_{1,2}^*$, we discuss the cases of limiting values of S and R_m instead of those of S, R and R_m. In the following discussions only the first dominant terms are retained in each case.

(1) $S \ll 1$, $R=O(1)$, $R_m=O(1)$.

In this case, if $R>R_m$,

$$\lambda_1^* \sim \sqrt{iR}\left(1-\frac{SRR_m}{2(R-R_m)}i\right), \qquad \lambda_2^* \sim \sqrt{iR_m}\left(1+\frac{SRR_m}{2(R-R_m)}i\right). \tag{3.5}$$

Hence $\dfrac{(\lambda_1^{*2}-iR)(\lambda_2^{*2}-iR)}{\lambda_1^{*2}-\lambda_2^{*2}} \sim -\dfrac{SR^2R_m}{R-R_m}$, so that

$$\left.\begin{aligned}
u^* &\sim \frac{SR^2R_m}{R-R_m}\,e^{it^*}\left[\frac{R-R_m}{SR^2R_m}\,e^{-\sqrt{iR}\,y^*}-\frac{i}{R-R_m}\,e^{-\sqrt{iR_m}\,y^*}\right],\\
H_x^* &\sim \frac{RR_m}{R-R_m}\,e^{it^*}\left[\frac{1}{\sqrt{iR}}\,e^{-\sqrt{iR}\,y^*}-\frac{1}{\sqrt{iR_m}}\,e^{-\sqrt{iR_m}\,y^*}\right],\\
j_z^* &\sim \frac{R}{R-R_m}\,e^{it^*}[e^{-\sqrt{iR}\,y^*}-e^{-\sqrt{iR_m}\,y^*}]\,,\\
E_z^* &\sim \frac{RR_m}{R-R_m}\,e^{it^*}\left[\frac{1}{R}\,e^{-\sqrt{iR}\,y^*}-\frac{1}{R_m}\,e^{-\sqrt{iR_m}\,y^*}\right],\\
J_s^* &\sim \frac{(1-i)\sqrt{RR_m}}{4\sqrt{2}\,\pi(\sqrt{R}+\sqrt{R_m})}\,e^{it^*}\,.
\end{aligned}\right\} \tag{3.6}$$

In the limit of $S\to 0$, u^* reverts to the classical results: $u^*=e^{it^*-\sqrt{iR}\,y^*}$ as expected. The first terms of each quantity (excepting J_s^*) would be appreciable in the domain of

$y^* \lesssim O(1/\sqrt{R})$, which shows a similar character to the viscous boundary-layer, whereas the second terms would be appreciable in the domain of $y^* \lesssim O(1/\sqrt{R_m})$, which shows a similar character to the magnetic boundary-layer, although the domain of $O(1/\sqrt{R})$ or of $O(1/\sqrt{R_m})$ is not necessarily so small as to be called 'boundary-layer,' since we here consider the case of $R=O(1)$ and $R_m=O(1)$.

If $R<R_m$, λ_1^* takes the place of λ_2^* in (3.5) and *vice versa*. Since, however, λ_1^* and λ_2^* are contained symmetrically in u^*, H_x^*, j_z^*, E_z^* and J_s^*, the final expressions of (3.6) remain unaltered.

(2) $S \gg 1$, $R=O(1)$, $R_m=O(1)$.

In this case,

$$\lambda_1^* \sim \sqrt{SRR_m}\left(1+\frac{R+R_m}{2SRR_m}i\right), \quad \lambda_2^* \sim \frac{i}{\sqrt{S}}\left(1-\frac{R+R_m}{2SRR_m}i\right),$$

so that $\dfrac{(\lambda_1^{*2}-iR)(\lambda_2^{*2}-iR)}{\lambda_1^{*2}-\lambda_2^{*2}} \sim -iR$. Hence we have

$$\left.\begin{aligned}
u^* &\sim iRe^{it^*}\left[\frac{1}{SRR_m}e^{-\sqrt{SRR_m}\,y^*}-\frac{i}{R}e^{-i/\sqrt{S}\cdot y^*}\right],\\
H_x^* &\sim \frac{i}{S}e^{it^*}\left[\frac{1}{\sqrt{SRR_m}}e^{-\sqrt{SRR_m}\,y^*}+i\sqrt{S}\,e^{-i/\sqrt{S}\cdot y^*}\right],\\
j_z^* &\sim \frac{i}{SR_m}e^{it^*}\left[e^{-\sqrt{SRR_m}\,y^*}-e^{-i/\sqrt{S}\cdot y^*}\right],\\
E_z^* &\sim -\frac{1}{S}e^{it^*}\left[\frac{1}{SRR_m}e^{-\sqrt{SRR_m}\,y^*}+Se^{-i/\sqrt{S}\cdot y^*}\right],\\
J_s^* &\sim \frac{1}{4\pi\sqrt{S}}e^{it^*}.
\end{aligned}\right\} \tag{3.7}$$

Thus the first terms of each quantity (excepting J_s^*) decay rapidly with increasing y^* and are vanishingly small except the vicinity of the plate. The thickness of this thin layer is of $O(1/\sqrt{SRR_m})$ which depends on both of R and R_m, so that we may interpret this layer as a 'mixed boundary-layer.' Outside this layer become dominant the second terms which represent the oscillations whose phase velocity is the same as that of Alfvén's magnetohydrodynamic wave. Since the most dominant term of the decaying factor of the second terms is purely imaginary, the second terms decay very slowly.

(3) $R_m \ll 1$, $S=O(1)$, $R=O(1)$.

Since

$$\lambda_1^* \sim \sqrt{iR}\left(1-\frac{1}{2}SR_m i\right) \quad \text{and} \quad \lambda_2^* \sim \sqrt{iR_m}\left(1+\frac{1}{2}SR_m i\right),$$

$\dfrac{(\lambda_1^{*2}-iR)(\lambda_2^{*2}-iR)}{\lambda_1^{*2}-\lambda_2^{*2}} \sim -SRR_m$. Hence we have in this case

$$\left.\begin{aligned}
u^* &\sim SRR_m e^{it^*}\left[\frac{1}{SRR_m}e^{-\sqrt{iR}\,y^*}-\frac{i}{R}e^{-\sqrt{iR_m}\,y^*}\right],\\
H_x^* &\sim R_m e^{it^*}\left[\frac{1}{\sqrt{iR}}e^{-\sqrt{iR}\,y^*}-\frac{1}{\sqrt{iR_m}}e^{-\sqrt{iR_m}\,y^*}\right],\\
j_z^* &\sim e^{it^*}\left[e^{-\sqrt{iR}\,y^*}-e^{-\sqrt{iR_m}\,y^*}\right],\\
E_z^* &\sim R_m e^{it^*}\left[\frac{1}{R}e^{-\sqrt{iR}\,y^*}-\frac{1}{R_m}e^{-\sqrt{iR_m}\,y^*}\right],\\
J_s^* &\sim \frac{(1-i)\sqrt{R_m}}{4\sqrt{2}\,\pi}e^{it^*}.
\end{aligned}\right\} \tag{3.8}$$

General character of the solutions is similar to that in case (1), and in the limit of $R_m \to 0$, u^* reverts to the classical result. A different point from the case (1) is that the second terms of each quantity (excepting J_s^*) decrease more slowly than the first terms. This may imply that the thickness of the 'magnetic boundary-layer' becomes too large to say 'boundary-layer' owing to the smallness of R_m.

(4) $R_m \gg 1$, $S=O(1)$, $R=O(1)$.

In this case

$$\lambda_1^* \sim \sqrt{R_m(SR+i)}\left(1+\frac{SR^2 i}{2R_m(SR+i)^2}\right) \quad \text{and} \quad \lambda_2^* \sim i\sqrt{\frac{R}{SR+i}}\left(1-\frac{SR^2 i}{2R_m(SR+i)^2}\right),$$

so that $\dfrac{(\lambda_1^{*2}-iR)(\lambda_2^{*2}-iR)}{\lambda_1^{*2}-\lambda_2^{*2}} \sim -\dfrac{SR^2 i}{SR+i}$. Hence we have

$$\left.\begin{aligned}
u^* &\sim \frac{SR^2 i}{SR+i} e^{it^*}\left[\frac{1}{R_m(SR+i)} e^{-\sqrt{R_m(SR+i)}\,y^*} - \frac{i(SR+i)}{SR^2} e^{-i\sqrt{R/(SR+i)}\,y^*}\right],\\
H_x^* &\sim \frac{iR}{SR+i} e^{it^*}\left[\frac{1}{\sqrt{R_m(SR+i)}} e^{-\sqrt{R_m(SR+i)}\,y^*} + i\sqrt{\frac{SR+i}{R}}\, e^{-i\sqrt{R/(SR+i)}\,y^*}\right],\\
j_z^* &\sim \frac{iR}{R_m(SR+i)} e^{it^*}\left[e^{-\sqrt{R_m(SR+i)}\,y^*} - e^{-i\sqrt{R/(SR+i)}\,y^*}\right],\\
E_z^* &\sim -\frac{R}{SR+i} e^{it^*}\left[\frac{1}{R_m(SR+i)} e^{-\sqrt{R_m(SR+i)}\,y^*} + \frac{SR+i}{R} e^{-i\sqrt{R/(SR+i)}\,y^*}\right],\\
J_s^* &\sim \frac{\sqrt{R}}{4\sqrt{2}\,\pi\sqrt{1+S^2R^2}}\left[\sqrt{\sqrt{1+S^2R^2}+SR} - i\sqrt{\sqrt{1+S^2R^2}-SR}\right] e^{it^*}.
\end{aligned}\right\} \tag{3.9}$$

As in the case (2), the first terms of each quantity (excepting J_s^*) decrease rapidly and the second terms become dominant in the region of $y^* \gtrsim O(1/\sqrt{R_m})$. The thin layer of $O(1/\sqrt{R_m})$ may be regarded as the magnetic boundary-layer. Because this layer is principally characterized by R_m ($\gg 1$) although the decaying factor of the first terms, $\sqrt{R_m(SR+i)}$, contains both R and R_m. In the limit of $R_m \to \infty$, both of the first terms of u^* and H_x^* vanish and hence $u^* \propto H_x^*$, which is a reflection of the so-called 'frozen' effect.

§4. Drag Experienced by the Plate

In this section we shall calculate the drags experienced by the plate for both cases of *non-conducting* plate and *perfectly conducting* plate, and compare them with that of the classical case.

The total drag on the plate generally consists of the shear-stress, τ_f, and Maxwell's stress, τ_m, which are given respectively by the following formulae:

$$\left.\begin{aligned}
\tau_f &= \mathrm{Re}\left(\rho\nu\frac{\partial u}{\partial y}\right)_{y=0},\\
\text{and}\qquad\\
\tau_m &= \mathrm{Re}\left(\frac{1}{4\pi}\mu H_0 H_x\right)_{y=0}.
\end{aligned}\right\} \tag{4.1}$$

For proceeding calculations, it is convenient to define the drag coefficients with reference to $\rho\nu\omega$, that is

$$\tau_f^* = \tau_f/(\rho\nu\omega), \qquad \tau_m^* = \tau_m/(\rho\nu\omega). \tag{4.2}$$

Now we consider the following three cases, (1) the classical case, (2) the case of non-conducting plate, and (3) the case of perfectly conducting plate.

(1) The classical case.

As is well known, there is, of course, no Maxwell's stress in this case, so that the total drag is identical with the shear-stress, $\tau_{f_0}^*$, itself. Thus we have

$$\begin{aligned} \tau_{f_0}^* &= -\mathrm{Re}\,(\sqrt{iR}\,e^{it^*} \\ &= T_0 \sin(t^*+\theta_0)\,, \end{aligned} \tag{4.3}$$

where

$$T_0 = \sqrt{R}\,, \tag{4.4}$$

$$\tan\theta_0 = -1 \qquad (\theta_0 = -\pi/4)\,. \tag{4.5}$$

(2) The case of non-conducting plate.

As shown in Reference 1), Maxwell's stress is identically zero in this case. Therefore, the only contribution to the total drag is the shear stress, $\tau_{f_1}^*$, which is given by[†]

$$\begin{aligned} \tau_{f_1}^* &= -\mathrm{Re}\left[\frac{\sqrt{R}}{\sqrt{R}+\sqrt{R_m}}(\lambda_1^*+\lambda_2^*)e^{it^*}\right] \\ &= T_1 \sin(t^*+\theta_1)\,, \end{aligned} \tag{4.6}$$

with

$$T_1 = \frac{\sqrt{R}}{\sqrt{R}+\sqrt{R_m}}[(a+c)^2+(b+d)^2]^{1/2}\,, \tag{4.7}$$

$$\tan\theta_1 = -\frac{a+c}{b+d} \qquad (-\pi/2 < \theta_1 < 0)\,, \tag{4.8}$$

and

$$a = \mathrm{Re}\,(\lambda_1^*)\,, \qquad b = \mathrm{Im}\,(\lambda_1^*)\,, \qquad c = \mathrm{Re}\,(\lambda_2^*)\,, \qquad d = \mathrm{Im}\,(\lambda_2^*)\,.^{\dagger\dagger} \tag{4.9}$$

(3) The case of perfectly conducting plate.

In this case, both of the shear-stress, $\tau_{f_2}^*$, and Maxwell's stress, τ_m^*, contribute to the total drag. They are given by

$$\begin{aligned} \tau_{f_2}^* &= -\mathrm{Re}\left[\frac{i\sqrt{R}\,(\sqrt{R}+\sqrt{R_m})}{\lambda_1^*+\lambda_2^*}\,e^{it^*}\right] \\ &= T_2 \sin(t^*+\theta_2)\,, \end{aligned} \tag{4.10}$$

with

$$T_2 = \sqrt{R}\,(\sqrt{R}+\sqrt{R_m})[(a+c)^2+(b+d)^2]^{-1/2}\,, \tag{4.11}$$

$$\tan\theta_2 = -\frac{b+d}{a+c} \qquad (-\pi/2 < \theta_2 < 0)\,, \tag{4.12}$$

and

[†] In Reference 1), the shear-stress, τ_{f_1}, is given in dimensional form as

$$\tau_{f_1} = \mathrm{Re}\left[-\rho\nu U e^{i\omega t}\left\{\frac{i\omega(\lambda_1+\lambda_2)}{\lambda_1\lambda_2\nu+i\omega}\right\}\right].$$

[††] Explicit expressions for a, b, c and d are given as follows:

$$\left.\begin{matrix} a \\ b \end{matrix}\right\} = \frac{1}{2}[\{(SRR_m+\alpha)^2+(R+R_m+\beta)^2\}^{1/2} \pm (SRR_m+\alpha)]^{1/2}\,,$$

$$\left.\begin{matrix} c \\ d \end{matrix}\right\} = \frac{1}{2}[\{(SRR_m-\alpha)^2+(R+R_m-\beta)^2\}^{1/2} \pm (SRR_m-\alpha)]^{1/2}\,,$$

where

$$\left.\begin{matrix} \alpha \\ \beta \end{matrix}\right\} = \left[\frac{1}{2}\{[(S^2R^2R_m{}^2-(R-R_m)^2)^2+4S^2R^2R_m{}^2(R+R_m)^2]^{1/2} \pm (S^2R^2R_m{}^2-(R-R_m)^2)\}\right]^{1/2}.$$

$$\tau_m^* = -\mathrm{Re}\left[\frac{SR\sqrt{RR_m}}{\lambda_1^* + \lambda_2^*} e^{it^*}\right]$$
$$= T_m \sin(t^* + \theta_m) , \tag{4.13}$$

with

$$T_m = SR\sqrt{RR_m}\,[(a+c)^2 + (b+d)^2]^{-1/2} , \tag{4.14}$$

$$\tan\theta_m = \frac{a+c}{b+d} \qquad (-\pi < \theta_m < -\pi/2) . \tag{4.15}$$

The total drag is then given by

$$\tau_{2+m}^* = \tau_{f_2}^* + \tau_m^*$$
$$= T_{2+m} \sin(t^* + \theta_{2+m}) , \tag{4.16}$$

where

$$T_{2+m} = \sqrt{R}\left[\frac{S^2R^2R_m + (\sqrt{R} + \sqrt{R_m})^2}{(a+c)^2 + (b+d)^2}\right]^{1/2} , \tag{4.17}$$

$$\tan\theta_{2+m} = -\frac{(a+c)SR\sqrt{R_m} + (b+d)(\sqrt{R} + \sqrt{R_m})}{(a+c)(\sqrt{R} + \sqrt{R_m}) - (b+d)SR\sqrt{R_m}} \qquad (-\pi < \theta_{2+m} < 0) . \tag{4.18}$$

Now, by tedious but elementary calculations it is shown for any values of the parameters S, R and R_m[†] that

$$T_1 \geqq T_0$$
$$\text{(equal sign holds when } SR_m = 0) , \tag{4.19}$$

which shows that the drag amplitude in the case of non-conducting plate always *increases* in comparison with that of the classical case. Comparing (4.7) with (4.11), we can see immediately that T_2 is exactly inverse to T_1 except the classical factor $\sqrt{R}$. Thus we may conclude that

---

[†] Here and hereafter we exclude the trivial case of $R=0$.

$$T_2 \leqq T_0$$
(equal sign holds when $SR_m=0$) , (4.20)

which shows that the amplitude of the shear-stress in the case of perfectly conducting plate always *decreases* in comparison with that of the classical case.

By elementary calculations similar to those for obtaining (4.19), we can easily show for any values of S, R and R_m that

$$T_{2+m} \geqq T_1 \geqq T_0$$
(equal signs hold when $SR_m=0$) , (4.21)

which shows that the amplitude of the total drag in the case of perfectly conducting plate is always greater than that of the case of non-conducting plate, and hence we may conclude that irrespective of whether the plate is non-conductor or perfect conductor, the amplitude of the total drag experienced by the plate always *increases* compared with that of the classical case. Numerical values of the drag for various values of S are tabulated in Table I and are shown graphically inF ig. 2.

On the other hand, it is easily shown for any values of S, R and R_m that

$$\left|\frac{(a+c)SR\sqrt{R_m}+(b+d)(\sqrt{R}+\sqrt{R_m})}{(a+c)(\sqrt{R}+\sqrt{R_m})-(b+d)SR\sqrt{R_m}}\right| \geqq \frac{a+c}{b+d} \geqq 1, \quad \text{(equal signs hold when } SR_m=0\text{)}, \tag{4.22}$$

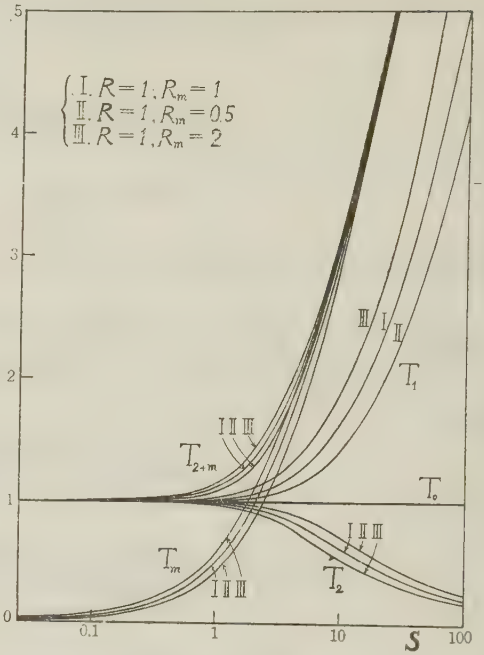

Fig. 2. Amplitudes of drags *versus* magnetic pressure number.

so that we have

$$\left.\begin{aligned} &-\pi/2<\theta_1 \leqq -\pi/4\ , \\ &-\pi/4 \leqq \theta_2 < 0\ , \\ &-3\pi/4 \leqq \theta_m < -\pi/2\ , \\ &-3\pi/4 < \theta_{2+m} \leqq -\pi/4\ , \\ &\theta_{2+m} \leqq \theta_1 \leqq \theta_0(=-\pi/4) \leqq \theta_2\ , \end{aligned}\right\}$$
(equal signs hold when $SR_m=0$) , (4.23)

which imply that the initial phases of the total drags, θ_1 (non-conducting plate) and θ_{2+m} (perfectly conducting plate), are always *retarded* in comparison with that of the classical case. It is to be noted, however, that the initial phase of the shear-stress in the case of perfectly conducting plate, θ_2, always *proceeds* compared with that of the classical case. Noting that $\tan\theta_1=\cot\theta_2=-\tan\theta_m$ and remembering (4.23), we have

$$\left.\begin{aligned} &\theta_1+\theta_2=-\pi/2\ , \\ &\theta_1+\theta_m=-\pi\ , \\ &\theta_2-\theta_m=\pi/2\ . \end{aligned}\right\} \tag{4.24}$$

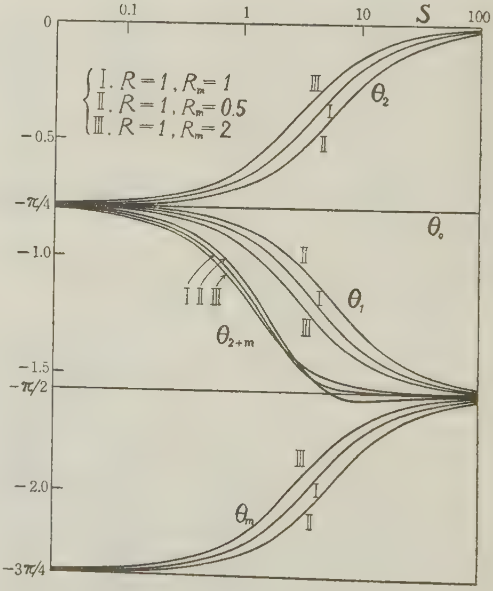

Fig. 3. Initial phases of drags *versus* magnetic pressure number.

Several numerical values of the initial phases *versus* S are tabulated in Table II and are shown graphically in Fig. 3. It is found from Fig. 3 that when $R=1$ and $R_m=0.5$, θ_{2+m} becomes $-\pi/2$ at about $S=6.2$ and makes shallow minimum at about $S=10$ then tends again to $-\pi/2$ as S becomes larger. This is due to the fact that

$$(a+c)(\sqrt{R}+\sqrt{R_m})-(b+d)SR\sqrt{R_m}$$

becomes zero for $R=1$, $R_m=0.5$ and $S \fallingdotseq 6.2$.†

In the special cases corresponding to limiting values of S and R_m, the amplitudes and the initial phases of the drags become as follows.

Table II. Initial phases of drags *versus* magnetic pressure numbers.

(1) $S \ll 1$, $R=O(1)$, $R_m=O(1)$.

$$\left.\begin{aligned}
&T_1 \sim \sqrt{R}\left[1+\frac{S^2R^2R_m^2}{4(\sqrt{R}+\sqrt{R_m})^4}\right], &&\tan\theta_1 \sim -\left[1+\frac{SRR_m}{(\sqrt{R}+\sqrt{R_m})^2}\right],\\
&T_2 \sim \sqrt{R}\left[1-\frac{S^2R^2R_m^2}{4(\sqrt{R}+\sqrt{R_m})^4}\right], &&\tan\theta_2 \sim -\left[1-\frac{SRR_m}{(\sqrt{R}+\sqrt{R_m})^2}\right],\\
&T_m \sim \frac{SR\sqrt{RR_m}}{\sqrt{R}+\sqrt{R_m}}, &&\tan\theta_m \sim \left[1+\frac{SRR_m}{(\sqrt{R}+\sqrt{R_m})^2}\right],\\
&T_{2+m} \sim \sqrt{R}\left[1+\frac{S^2R^2R_m^2}{4(\sqrt{R}+\sqrt{R_m})^4}\left(1+\frac{2R}{R_m}+\frac{4\sqrt{R}}{\sqrt{R_m}}\right)\right],\\
&&&\tan\theta_{2+m} \sim -\left[1+\frac{SRR_m}{(\sqrt{R}+\sqrt{R_m})^2}\left(1+\frac{2\sqrt{R}}{\sqrt{R_m}}\right)\right].
\end{aligned}\right\} \tag{4.25}$$

(2) $S \gg 1$, $R=O(1)$, $R_m=O(1)$.

---

† General relationship between S, R and R_m which makes $(a+c)(\sqrt{R}+\sqrt{R_m})-(b+d)SR\sqrt{R_m}$ zero is rather complicated to write down explicitly.

$$\left.\begin{aligned}
&T_1\sim R\sqrt{S}\left[\frac{\sqrt{R_m}}{\sqrt{R}+\sqrt{R_m}}\right], && \tan\theta_1\sim-\frac{2SRR_m}{(\sqrt{R}+\sqrt{R_m})^2}\,,\\
&T_2\sim\frac{1}{\sqrt{S}}\left[\frac{\sqrt{R}+\sqrt{R_m}}{\sqrt{R_m}}\right], && \tan\theta_2\sim-\frac{(\sqrt{R}+\sqrt{R_m})^2}{2SRR_m}\,,\\
&T_m\sim R\sqrt{S}\,, && \tan\theta_m\sim\frac{2SRR_m}{(\sqrt{R}+\sqrt{R_m})^2}\,,\\
&T_{2+m}\sim R\sqrt{S}\,, \quad \tan\theta_{2+m}\sim && \begin{cases}-\dfrac{2SRR_m}{R_m-R} & (R-R_m\neq 0 \ \text{ or } \ R-R_m\gg O(S^{-2}))\\[2mm] -\dfrac{2S^3R^3}{16+S^2R(R_m-R)} & (R-R_m\approx O(S^{-2}))\\[2mm] -S^3R^3/8 & (R-R_m=0 \ \text{ or } \ R-R_m\ll O(S^{-2}))\end{cases}
\end{aligned}\right\} \quad (4.26)$$

It will be seen that the amplitude of the total drag in the case of perfectly conducting plate, T_{2+m}, is essentially equal to that of Maxwell's stress, T_m, and that the initial phases θ_1, θ_m and θ_{2-m} are nearly equal to $-\pi/2$ and θ_2 is nearly equal to zero. When $R\doteqdot R_m$, $\tan\theta_{2+m}=O(S^3)$ so that θ_{2+m} tends to $-\pi/2$ more rapidly with increasing S for $R\doteqdot R_m$ than otherwise and when $R>R_m$, $\tan\theta_{2+m}>0$ so that θ_{2+m} tends to $-\pi/2$ from smaller values than $-\pi/2$ with increasing S, while otherwise θ_{2+m} tends to $-\pi/2$ from larger values than $-\pi/2$ (see Fig. 3).

(3) $R_m\ll 1$, $S=O(1)$, $R=O(1)$.

$$\left.\begin{aligned}
&T_1\sim\sqrt{R}\left[1+\frac{1}{4}S^2R_m^2\right], && \tan\theta_1\sim-[1+SR_m]\,,\\
&T_2\sim\sqrt{R}\left[1-\frac{1}{4}S^2R_m^2\right], && \tan\theta_2\sim-[1-SR_m]\,,\\
&T_m\sim SR\sqrt{R_m}\left[1-\sqrt{\frac{R_m}{R}}\right], && \tan\theta_m\sim[1+SR_m]\,,\\
&T_{2+m}\sim\sqrt{R}\left[1+\frac{1}{2}S^2RR_m\right], && \tan\theta_{2+m}\sim-[1+2S\sqrt{RR_m}\,]\,.
\end{aligned}\right\} \quad (4.27)$$

(4) $R_m\gg 1$, $S=O(1)$, $R=O(1)$.

$$\left.\begin{aligned}
&T_1\sim\sqrt{R}\,[1+S^2R^2]^{1/4}\,, && \tan\theta_1\sim-\left[\frac{\sqrt{1+S^2R^2}+SR}{\sqrt{1+S^2R^2}-SR}\right]^{1/2},\\
&T_2\sim\sqrt{R}\,[1+S^2R^2]^{-1/4}\,, && \tan\theta_2\sim-\left[\frac{\sqrt{1+S^2R^2}-SR}{\sqrt{1+S^2R^2}+SR}\right]^{1/2},\\
&T_m\sim SR\sqrt{R}\,[1+S^2R^2]^{-1/4}\,, && \tan\theta_m\sim\left[\frac{\sqrt{1+S^2R^2}+SR}{\sqrt{1+S^2R^2}-SR}\right]^{1/2},\\
&T_{2+m}\sim\sqrt{R}\,[1+S^2R^2]^{1/4}\,, && \tan\theta_{2+m}\sim-\left[\frac{\sqrt{1+S^2R^2}+SR}{\sqrt{1+S^2R^2}-SR}\right]^{1/2}.
\end{aligned}\right\} \quad (4.28)$$

It is to be noted that all of the amplitudes and the corresponding initial phases do not depend on R_m in this limit. It is also interesting to notice that the total drags in both cases of non-conducting plate and perfectly donducting plate are essentially identical with each other in this case.

§ 5. A Special Case Corresponding to 'Magnetic Stokes Approximation'

It may be worthwhile to discuss a special case corresponding to the so-called 'magnetic Stokes approximation' ($R_m\ll 1$, $SR_m=O(1)$) which is frequently used in many investigations of magnetohydrodynamics.

In the limit of $R_m\ll 1$ and $SR_m=O(1)$, we have from (3.4)

$$\left.\begin{aligned} \lambda_1^* &\sim \sqrt{R(SR_m+i)}\left[1+\frac{iSR_m}{2(SR_m+i)^2}\left(\frac{R_m}{R}\right)\right], \\ \lambda_2^* &\sim i\sqrt{R_m/(SR_m+i)}\left[1-\frac{iSR_m}{2(SR_m+i)^2}\left(\frac{R_m}{R}\right)\right]. \end{aligned}\right\} \tag{5.1}$$

We shall consider first the case of non-conducting plate, and next the case of perfectly conducting plate.

(1) The case of non-conducting plate.

From (4.3)∼(4.6) of Reference 1),† we have

$$\left.\begin{aligned} u^* &\sim \frac{SRR_m}{\sqrt{R(SR_m+i)}}e^{it^*}\left[\frac{\sqrt{R(SR_m+i)}}{SRR_m}e^{-\sqrt{R(SR_m+i)}\,y^*}+\frac{\sqrt{R_m/(SR_m+i)}}{R}e^{-i\sqrt{R_m/(SR_m+i)}\,y^*}\right] \\ &\to e^{it^*-\sqrt{R(SR_m+i)}\,y^*} \qquad (\text{as} \quad R_m\to 0)\,, \\ H_x^* &\sim \frac{R_m}{\sqrt{R(SR_m+i)}}e^{it^*}\left[e^{-\sqrt{R(SR_m+i)}\,y^*}-e^{-i\sqrt{R_m/(SR_m+i)}\,y^*}\right]\to \mathrm{O}(R_m)\,, \\ E_z^* &\sim \frac{iR_m}{\sqrt{R(SR_m+i)}}e^{it^*}\left[\frac{1}{\sqrt{R(SR_m+i)}}e^{-\sqrt{R(SR_m+i)}\,y^*}+i\sqrt{\frac{SR_m+i}{R_m}}e^{-i\sqrt{R_m/(SR_m+i)}\,y^*}\right] \\ &\to \mathrm{O}(\sqrt{R_m})\,, \\ j_z^* &\sim \frac{1}{\sqrt{R(SR_m+i)}}e^{it^*}\left[\sqrt{R(SR_m+i)}\,e^{-\sqrt{R(SR_m+i)}\,y^*}-i\sqrt{\frac{R_m}{SR_m+i}}e^{-i\sqrt{R_m/(SR_m+i)}\,y^*}\right] \\ &\to e^{it^*-\sqrt{R(SR_m+i)}\,y^*} \qquad (\text{as} \quad R_m\to 0)\,. \end{aligned}\right\} \tag{5.2}$$

Taking the real part of the expression for u^*, we have

$$\mathrm{Re}\,[u^*]=e^{-ay^*}\cos(t^*-by^*)\,,$$

where

$$\left.\begin{aligned} a&=\mathrm{Re}\,[\sqrt{R(SR_m+i)}\,]=\left[\frac{R}{2}(\sqrt{1+S^2R_m^2}+SR_m)\right]^{1/2}, \\ b&=\mathrm{Im}\,[\sqrt{R(SR_m+i)}\,]=\left[\frac{R}{2}(\sqrt{1+S^2R_m^2}-SR_m)\right]^{1/2}. \end{aligned}\right\} \tag{5.3}$$

This is exactly the same, excepting the notations, as the approximate velocity distribution obtained by Ong and Nicholls[2] on the basis of Rossow's assumption[3] (neglect of the induced magnetic field) for the case of 'the magnetic field being fixed *to the fluid*' (see Eq. (5) of Reference 2)). The other quantities such as H_x^*, E_z^* that are neglected in their analysis vanish in the limit of $R_m\to 0$ as shown in (5.2). Therefore, their approximate solution for the case of the magnetic field being fixed to the fluid may be adequate for the case of non-conducting plate when R_m is very small and $SR_m=\mathrm{O}(1)$.

The drag in this case is given by

---

† From Reference 1)

$$\left\{\begin{aligned} &(4.3) \qquad u^*=-\frac{(\lambda_1^{*2}-iR)(\lambda_2^{*2}-iR)}{(\lambda_1^*-\lambda_2^*)(\lambda_1^*\lambda_2^*+iR)}e^{it^*}\left[\frac{\lambda_1^*}{\lambda_1^{*2}-iR}e^{-\lambda_1^*y^*}-\frac{\lambda_2^*}{\lambda_2^{*2}-iR}e^{-\lambda_2^*y^*}\right], \\ &(4.4) \qquad H_x^*=-\frac{(\lambda_1^{*2}-iR)(\lambda_2^{*2}-iR)}{SR(\lambda_1^*-\lambda_2^*)(\lambda_1^*\lambda_2^*+iR)}e^{it^*}[e^{-\lambda_1^*y^*}-e^{-\lambda_2^*y^*}]\,, \\ &(4.5) \qquad E_z^*=-\frac{i(\lambda_1^{*2}-iR)(\lambda_2^{*2}-iR)}{SR(\lambda_1^*-\lambda_2^*)(\lambda_1^*\lambda_2^*+iR)}e^{it^*}\left[\frac{1}{\lambda_1^*}e^{-\lambda_1^*y^*}-\frac{1}{\lambda_2^*}e^{-\lambda_2^*y^*}\right], \\ &(4.6) \qquad j_z^*=-\frac{(\lambda_1^{*2}-iR)(\lambda_2^{*2}-iR)}{SRR_m(\lambda_1^*-\lambda_2^*)(\lambda_1^*\lambda_2^*+iR)}e^{it^*}[\lambda_1^*e^{-\lambda_1^*y^*}-\lambda_2^*e^{-\lambda_2^*y^*}]\,. \end{aligned}\right.$$

$$\left.\begin{aligned} &\tau_{f_1}^* \sim \sqrt{R}\,(1+S^2R_m^2)^{1/4}\sin(t^*+\theta_1)\,, \\ \text{where}\qquad & \\ &\tan\theta_1 \sim -\left[\frac{\sqrt{1+S^2R_m^2}+SR_m}{\sqrt{1+S^2R_m^2}-SR_m}\right]^{1/2}. \end{aligned}\right\} \tag{5.4}$$

(2) The case of perfectly conducting plate.

In this case, making use of (5.1), we have from (3.6)

$$\left.\begin{aligned} u^* &\sim \frac{iSRR_m}{SR_m+i}e^{it^*}\left[\frac{1}{SRR_m}e^{-\sqrt{R(SR_m+i)}}+\frac{1}{iR}e^{-i\sqrt{R_m/(SR_m+i)}\,y^*}\right], \\ H_x^* &\sim \frac{iR_m}{SR_m+i}e^{it^*}\left[\frac{1}{\sqrt{R(SR_m+i)}}e^{-\sqrt{R(SR_m+i)}\,y^*}+i\sqrt{\frac{SR_m+i}{R_m}}\,e^{-i\sqrt{R_m/(SR_m+i)}\,y_*}\right] \\ &\to O(\sqrt{R_m})\,, \\ E_z^* &\sim -\frac{R_m}{SR_m+i}e^{it^*}\left[\frac{1}{R(SR_m+i)}e^{-\sqrt{R(SR_m+i)}\,y^*}+\frac{SR_m+i}{R_m}e^{-i\sqrt{R_m/(SR_m+i)}\,y^*}\right] \\ &\to -e^{it^*-i\sqrt{R_m/(SR_m+i)}\,y^*} \qquad (\text{as}\quad R_m\to 0)\,, \\ j_z^* &\sim \frac{i}{SR_m+i}e^{it^*}\left[e^{-\sqrt{R(SR_m+i)}\,y^*}-e^{-i\sqrt{R_m/(SR_m+i)}\,y^*}\right], \\ J_s^* &\sim \frac{1}{4\pi}\sqrt{\frac{R_m}{SR_m+i}}\,e^{it^*}\to O(\sqrt{R_m})\,. \end{aligned}\right\} \tag{5.5}$$

If R_m is so small as to make $\sqrt{R_m}\,y_M^* \ll 1$ even for fairly large values of y^*, say y_M^*, we may put $e^{-i\sqrt{R_m/(SR_m+i)}\,y^*}\sim 1$ for the region of $y^* \lesssim y_M^*$. Then the real part of the expression for u^* gives

$$\mathrm{Re}\,[u^*]=\frac{e^{-ay^*}}{1+S^2R_m^2}\left[\cos(t^*-by^*)-SR_m\sin(t^*-by^*)\right]+\frac{SR_m}{1+S^2R_m^2}\left[SR_m\cos t^*+\sin t^*\right], \tag{5.6}$$

which is exactly identical, excepting the notations, with the approximate solution obtained by Ong and Nicholls[2] for the case of 'the magnetic field being fixed *to the plate*' (see Eq. (10) of Reference 2)). It should be noted here that (5.6) is valid only for the region of $y^* \lesssim y_M^*$, and the smaller the magnetic Reyeolds number R_m becomes, the wider becomes the region of the validity of (5.6). Thus the magnetic Stokes approximation may be useful to obtain the velocity field in the region comparatively near the plate in this case. The induced magnetic field H_x^* neglected by Ong and Nicholls[2] tends to zero as the order of $\sqrt{R_m}$, and E_z^* $(\sim -e^{it^*})$ corresponds to the additional term '$-mu_0\cos nt$' in the second term of left-hand side of Eq. (6) of Reference 2).

The drags in this case are given as

$$\left.\begin{aligned} \text{shear-stress:}\qquad & \tau_{f_2}^* \sim \sqrt{R}\,(1+S^2R_m^2)^{-1/4}\sin(t^*+\theta_2)\,, \\ & \tan\theta_2 \sim -\left[\frac{\sqrt{1+S^2R_m^2}-SR_m}{\sqrt{1+S^2R_m^2}+SR_m}\right]^{1/2}, \\ \text{Maxwell's stress:}\qquad & \tau_m^* \sim SR\sqrt{R_m}\,(1+S^2R_m^2)^{-1/4}\sin(t^*+\theta_m)\,, \\ & \tan\theta_m \sim \left[\frac{\sqrt{1+S^2R_m^2}+SR_m}{\sqrt{1+S^2R_m^2}-SR_m}\right]^{1/2}, \\ \text{total drag:}\qquad & \tau_{2+m}^* \sim SR\sqrt{R_m}\,(1+S^2R_m^2)^{-1/4}\sin(t^*+\theta_{2+m})\,, \\ & \tan\theta_{2+m} \sim \left[\frac{\sqrt{1+S^2R_m^2}+SR_m}{\sqrt{1+S^2R_m^2}-SR_m}\right]^{1/2} \end{aligned}\right\} \tag{5.7}$$

As will be seen from (5.7), the total drag is essentially equal to Maxwell's stress, which implies that the contribution from the shear-stress to the total drag is negligible compared with that from Maxwell's stress. Furthermore, noting that $SR_m=O(1)$, we shall find that the amplitudes of Maxwell's stress and the total drag tend to infinity as the order of $O(1/\sqrt{R_m})$. Thus, when the plate is a perfect conductor, the magnetic Stokes approximation is not adequate to obtain the drag on the plate. The state of affairs is quite similar to that in Rossow's solutions[3] for the hydromagnetic boundary-layer flow past a flat plate and the hydromagnetic Rayleigh's problem in the case of 'the magnetic field being fixed to the plate' in which case the drag due to Maxwell's stress does also diverge.

From the above discussions we may assert that Rossow's assumption, i.e., neglect of the induced magnetic field, is valid only for the cases of small magnetic Reynolds number R_m with large magnetic pressure number S, namely, his assumption is permissible only for the cases such that the magnetic Stokes approximation is valid. Moreover, it has been found that the respective considerations of the fundamental equations according as the magnetic field is fixed 'to the fluid' or 'to the plate' are not necessary if the electric field $\boldsymbol{E}$ is included in the analysis as is done in this paper. If one include $\boldsymbol{E}$ in the analysis, the difference between the respective fundamental equations may be replaced simply by that of the boundary conditions expressing the physical properties of the plate, and the physical meaning of 'the magnetic field being fixed *to the fluid* or *to the plate*' may now be clarified.

§ 6. Concluding Remarks

We have obtained the exact solutions for the hydromagnetic flow of an electrically conducting fluid due to an oscillating flat plate under transverse magnetic field for two cases in which the plate is a *non-conductor* (see Reference 1) and a *perfect conductor*. Combining these two kinds of solutions we may infer, at least, qualitative characters of more general cases of the plate having a finite electrical conductivity.

The restriction that the magnetic field is applied *transversely* to the plate may be easily relaxed, and we may extend the problem to the case of the *oblique* magnetic field so far as it has no z-component, because x-component of the applied magnetic field would not interact with the flow field.

The writer wishes to express his cordial thanks to Professor S. Tomotika for his continual encouragement and kind inspection of the manuscript. The writer's thanks are also due to Professor I. Imai for his helpful advices. During the course of this study, the writer has been in receipt of a grant-in-aid for the fundamental scientific research from the Ministry of Education.

Steady Temperature Field in a Composite Doubly Infinite Strip

By Václav VODIČKA
Plzeň, Czechoslovakia

(Received March 3, 1960)

The present paper extends the classical results on two-dimensional stationary temperature distribution in an infinite plate to the case of a composite strip. General deductions are applied to some special cases leading partly to new results not given in the literature.

§ 1. Statement of the Problem

The doubly infinite strip

$$x_0 \leq x \leq x_n\,, \quad -\infty < y < +\infty\,, \quad -\infty < z < +\infty$$

consists of n homogeneous isotropic layers

$$x_{k-1} \leq x \leq x_k\,, \quad -\infty < y < +\infty\,, \quad -\infty < z < +\infty\,, \quad 1 \leq k \leq n$$

with thermal conductivities λ_k, respectively.

The question is about the steady temperature distribution in the solid provided that its front face $x=x_0$ is maintained at the given temperature $f(y)$ and its back face $x=x_n$ at $g(y)$. Assumed is the continuity both of the temperature and of the flux of heat over the surfaces of separation between several layers of the body.

Mathematically speaking one has to find the solution $u_k=u_k(x, y)$ of the harmonic equations

$$\frac{\partial^2 u_k}{\partial x^2}+\frac{\partial^2 u_k}{\partial y^2}=0\,, \quad x_{k-1}<x<x_k\,, \quad -\infty<y<+\infty\,, \quad 1\leq k\leq n \tag{1.1}$$

with the following conditions:

$$u_1(x_0, y)=f(y)\,, \quad -\infty<y<+\infty \tag{1.2}$$

$$\left.\begin{aligned} &u_{k+1}(x_k, y)=u_k(x_k, y)\,, \quad -\infty<y<+\infty \\ &\frac{\partial u_{k+1}}{\partial x}=\Lambda_k\frac{\partial u_k}{\partial x}\,, \quad x=x_k\,, \quad -\infty<y<+\infty\,, \quad \Lambda_k=\frac{\lambda_k}{\lambda_{k+1}}\,, \quad 1\leq k\leq n-1 \end{aligned}\right\} \tag{1.3}$$

$$u_n(x_n, y)=g(y)\,, \quad -\infty<y<+\infty\,. \tag{1.4}$$

§ 2. The Fourier Transforms of $u_k(x, y)$

Making usual assumptions the familiar transformation

$$\left.\begin{aligned} \bar{h}(\eta)&=F[h(y)]=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{+\infty} h(y)\, e^{i\eta y}\, dy \\ h(y)&=F^{-1}[\bar{h}(\eta)]=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{+\infty} \bar{h}(\eta)\, e^{-i\eta y}\, d\eta \end{aligned}\right\} \tag{2.1}$$

changes our problem (1.1)-(1.4) into the following equations for determining the Fourier transforms $\bar{u}_k=\bar{u}_k(x, \eta)$ of the required functions $u_k(x, y)$:

$$\frac{d^2\bar{u}_k}{dx^2}-\eta^2\bar{u}_k=0\,, \quad x_{k-1}<x<x_k\,, \quad 1\leq k\leq n \tag{2.2}$$

$$\bar{u}_1(x_0, \eta)=\bar{f}(\eta) \tag{2.3}$$

$$\left.\begin{aligned}&\bar{u}_{k+1}(x_k,\eta)=\bar{u}_k(x_k,\eta)\\&\frac{d\bar{u}_{k+1}}{dx}=\Lambda_k\frac{d\bar{u}_k}{dx}\,,\qquad x=x_k\,,\qquad 1\le k\le n-1\end{aligned}\right\}\tag{2.4}$$

$$\bar{u}_n(x_n,\eta)=\bar{g}(\eta)\,.\tag{2.5}$$

Integrating (2.2) gives generally

$$\bar{u}_k(x,\eta)=A_k\operatorname{ch}\eta(x-x_{k-1})+B_k\operatorname{sh}\eta(x-x_{k-1})\,,\qquad 1\le k\le n\tag{2.6}$$

whereby the coefficients $A_k=A_k(\eta)$, $B_k=B_k(\eta)$ are to be determined from the conditions (2.3)-(2.5), i.e. from the equations

$$A_1=\bar{f}(\eta)\,,\qquad A_n\operatorname{ch}l_n\eta+B_n\operatorname{sh}l_n\eta=\bar{g}(\eta)\,,\qquad l_n=x_n-x_{n-1}\tag{2.7}$$

$$\left.\begin{aligned}&A_{k+1}=A_k\operatorname{ch}l_k\eta+B_k\operatorname{sh}l_k\eta\\&B_{k+1}=\Lambda_k(A_k\operatorname{sh}l_k\eta+B_k\operatorname{ch}l_k\eta)\,,\qquad l_k=x_k-x_{k-1}\,,\qquad 1\le k\le n-1\,.\end{aligned}\right\}\tag{2.8}$$

Introducing the matrices

$$K_k=\begin{Vmatrix}A_k\\B_k\end{Vmatrix}\,,\qquad 1\le k\le n\,,\qquad M_k(\eta)=\begin{Vmatrix}\operatorname{ch}l_k\eta & \operatorname{sh}l_k\eta\\ \Lambda_k\operatorname{sh}l_k\eta & \Lambda_k\operatorname{ch}l_k\eta\end{Vmatrix}\,,\qquad 1\le k\le n-1\tag{2.9}$$

the Eq. (2.8) can be written in the form

$$K_{k+1}=M_k(\eta)K_k\,,\qquad 1\le k\le n-1$$

which gives, with regard to the first formula (2.7),

$$K_{k+1}=Q_k(\eta)\begin{Vmatrix}\bar{f}(\eta)\\B_1\end{Vmatrix}\,,\qquad Q_k(\eta)=M_k(\eta)M_{k-1}(\eta)\cdots M_1(\eta)\,,\qquad 1\le k\le n-1\,.\tag{2.10}$$

Now the last of the Eq. (2.10) yields

$$A_n=q_{n-1}^{(11)}(\eta)\bar{f}(\eta)+q_{n-1}^{(12)}(\eta)B_1\,,\qquad B_n=q_{n-1}^{(21)}(\eta)\bar{f}(\eta)+q_{n-1}^{(22)}(\eta)B_1\,,$$

$q_{n-1}^{(r,s)}(\eta)$, $r,s=1,2$, being the elements of $Q_{n-1}(\eta)$. Combining this with the second condition (2.7) gives the value of B_1 in terms of η, namely

$$B_1(\eta)=\frac{1}{q_{n-1}^{(12)}(\eta)\operatorname{ch}l_n\eta+q_{n-1}^{(22)}(\eta)\operatorname{sh}l_n\eta}\{\bar{g}(\eta)-\bar{f}(\eta)[q_{n-1}^{(11)}(\eta)\operatorname{ch}l_n\eta+q_{n-1}^{(21)}(\eta)\operatorname{sh}l_n\eta]\}$$

and one comes to the following expressions for the coefficients A_k, B_k:

$$\begin{aligned}&A_1=\bar{f}(\eta)\,,\qquad B_1=\frac{1}{N(\eta)}[-\bar{f}(\eta)Z(\eta)+\bar{g}(\eta)]\,,\\&\begin{Vmatrix}A_{k+1}\\B_{k+1}\end{Vmatrix}=\frac{Q_k(\eta)}{N(\eta)}\left\{\bar{f}(\eta)\begin{Vmatrix}N(\eta)\\-Z(\eta)\end{Vmatrix}+\bar{g}(\eta)\begin{Vmatrix}0\\1\end{Vmatrix}\right\}\,,\qquad 1\le k\le n-1\\&N(\eta)=q_{n-1}^{(12)}(\eta)\operatorname{ch}l_n\eta+q_{n-1}^{(22)}(\eta)\operatorname{sh}l_n\eta\,,\qquad Z(\eta)=q_{n-1}^{(11)}(\eta)\operatorname{ch}l_n\eta+q_{n-1}^{(21)}(\eta)\operatorname{sh}l_n\eta\,;\end{aligned}\tag{2.11}$$

$\bar{f}(\eta)$, $\bar{g}(\eta)$ are the Fourier transforms of the functions $f(y)$, $g(y)$.

§ 3. Solution of the Problem (1.1)-(1.4)

Calculating the coefficients $A_k=A_k(\eta)$, $B_k=B_k(\eta)$ from (2.11) and inserting into (2.6) gives the Fourier transforms $\bar{u}_k(x,\eta)$ of the required functions $u_k(x,y)$. From this one obtains the solution of our problem by (2.1) in the form

$$u_k(x, y)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}[A_k \operatorname{ch}\eta(x-x_{k-1})+B_k \operatorname{sh}\eta(x-x_{k-1})]\, e^{-i\eta y}\, d\eta\,, \qquad 1\leq k\leq n\,. \tag{3.1}$$

Looking at (2.11) shows how the problem in question can be treated as split in two simpler cases letting see the influence of each of the given functions $f(y)$, $g(y)$, separately. The usual difficulty lies in that it is very hard to establish a closed formula for the matrices $Q_k(\eta)$ as defined in (2.10).

§ 4. The First Matrices $Q_k(\eta)$

Intending to prepare the possibility of treating explicitly at least the cases with the smallest values of n, we write down the expressions of the matrices $Q_1(\eta)$, $Q_2(\eta)$ and $Q_3(\eta)$:

$$Q_1(\eta)=\begin{Vmatrix}\operatorname{ch} l_1\eta, & \operatorname{sh} l_1\eta\\ \operatorname{sh} l_1\eta, & \operatorname{ch} l_1\eta\end{Vmatrix}+(A_1-1)\begin{Vmatrix}0\ , & 0\\ \operatorname{sh} l_1\eta, & \operatorname{ch} l_1\eta\end{Vmatrix}$$

$$\begin{aligned}Q_2(\eta)=&\begin{Vmatrix}\operatorname{ch}(l_1+l_2)\eta, & \operatorname{sh}(l_1+l_2)\eta\\ \operatorname{sh}(l_1+l_2)\eta, & \operatorname{ch}(l_1+l_2)\eta\end{Vmatrix}+(A_1-1)\begin{Vmatrix}\operatorname{sh} l_1\eta \operatorname{sh} l_2\eta, & \operatorname{ch} l_1\eta \operatorname{sh} l_2\eta\\ \operatorname{sh} l_1\eta \operatorname{ch} l_2\eta, & \operatorname{ch} l_1\eta \operatorname{ch} l_2\eta\end{Vmatrix}+\\ &+(A_2-1)\begin{Vmatrix}0\ , & 0\\ \operatorname{sh}(l_1+l_2)\eta, & \operatorname{ch}(l_1+l_2)\eta\end{Vmatrix}+(A_1-1)(A_2-1)\operatorname{ch} l_2\eta\begin{Vmatrix}0\ , & 0\\ \operatorname{sh} l_1\eta, & \operatorname{ch} l_1\eta\end{Vmatrix}\end{aligned}$$

$$\begin{aligned}Q_3(\eta)=&\begin{Vmatrix}\operatorname{ch}(l_1+l_2+l_3)\eta, & \operatorname{sh}(l_1+l_2+l_3)\eta\\ \operatorname{sh}(l_1+l_2+l_3)\eta, & \operatorname{ch}(l_1+l_2+l_3)\eta\end{Vmatrix}+\\ &+(A_1-1)\begin{Vmatrix}\operatorname{sh} l_1\eta \operatorname{sh}(l_2+l_3)\eta, & \operatorname{ch} l_1\eta \operatorname{sh}(l_2+l_3)\eta\\ \operatorname{sh} l_1\eta \operatorname{ch}(l_2+l_3)\eta, & \operatorname{ch} l_1\eta \operatorname{ch}(l_2+l_3)\eta\end{Vmatrix}+\\ &+(A_2-1)\begin{Vmatrix}\operatorname{sh}(l_1+l_2)\eta \operatorname{sh} l_3\eta, & \operatorname{ch}(l_1+l_2)\eta \operatorname{sh} l_3\eta\\ \operatorname{sh}(l_1+l_2)\eta \operatorname{ch} l_3\eta, & \operatorname{ch}(l_1+l_2)\eta \operatorname{ch} l_3\eta\end{Vmatrix}+\\ &+(A_3-1)\begin{Vmatrix}0\ , & 0\\ \operatorname{sh}(l_1+l_2+l_3)\eta, & \operatorname{ch}(l_1+l_2+l_3)\eta\end{Vmatrix}+\\ &+(A_1-1)(A_2-1)\operatorname{ch} l_2\eta\begin{Vmatrix}\operatorname{sh} l_1\eta \operatorname{sh} l_3\eta, & \operatorname{ch} l_1\eta \operatorname{sh} l_3\eta\\ \operatorname{sh} l_1\eta \operatorname{ch} l_3\eta, & \operatorname{ch} l_1\eta \operatorname{ch} l_3\eta\end{Vmatrix}+\\ &+(A_2-1)(A_3-1)\operatorname{ch} l_3\eta\begin{Vmatrix}0\ , & 0\\ \operatorname{sh}(l_1+l_2)\eta, & \operatorname{ch}(l_1+l_2)\eta\end{Vmatrix}+\\ &+(A_3-1)(A_1-1)\operatorname{ch}(l_2+l_3)\eta\begin{Vmatrix}0\ , & 0\\ \operatorname{sh} l_1\eta, & \operatorname{ch} l_1\eta\end{Vmatrix}+\\ &+(A_1-1)(A_2-1)(A_3-1)\operatorname{ch} l_2\eta \operatorname{ch} l_3\eta\begin{Vmatrix}0\ , & 0\\ \operatorname{sh} l_1\eta, & \operatorname{ch} l_1\eta\end{Vmatrix}\,.\end{aligned} \tag{4.1}$$

These formulae show clearly the merits of the main difficulties arising at treating problems on composite continua. They give us a much more detailed insight into the inner structure of such questions than has been given in numerous former papers of the author—see ref. 1–3.

§ 5. A Homogeneous Plate

As a first example let us treat the elementary case $A_1=A_2=\cdots=A_{n-1}=1$ corresponding to a homogeneous isotropic strip $x_0\leq x\leq x_n$, $-\infty<y<+\infty$, $-\infty<z<+\infty$.

The matrices $Q_k(\eta)$ can be expressed in closed form

$$Q_k(\eta)=\begin{Vmatrix}\operatorname{ch}(x_k-x_0)\eta, & \operatorname{sh}(x_k-x_0)\eta\\ \operatorname{sh}(x_k-x_0)\eta, & \operatorname{ch}(x_k-x_0)\eta\end{Vmatrix}\,, \qquad 1\leq k\leq n-1 \tag{5.1}$$

and the formulae (2.11) give

$$N(\eta)=\operatorname{sh}(x_n-x_0)\eta\,, \qquad Z(\eta)=\operatorname{ch}(x_n-x_0)\eta$$

$$A_1 \operatorname{ch}(x-x_0)\eta+B_1 \operatorname{sh}(x-x_0)\eta=\bar{f}(\eta)\frac{\operatorname{sh}(x_n-x)\eta}{\operatorname{sh}(x_n-x_0)\eta}+\bar{g}(\eta)\frac{\operatorname{sh}(x-x_0)\eta}{\operatorname{sh}(x_n-x_0)\eta}$$

$$A_{k+1} \operatorname{ch}(x-x_k)\eta+B_{k+1} \operatorname{sh}(x-x_k)\eta=\bar{f}(\eta)\frac{\operatorname{sh}(x_n-x)\eta}{\operatorname{sh}(x_n-x_0)\eta}+\bar{g}(\eta)\frac{\operatorname{sh}(x-x_0)\eta}{\operatorname{sh}(x_n-x_0)\eta}\,, \qquad 1\leq k\leq n-1\,.$$

Introducing this in (3.1) gives the solution in the form

$$u(x, y)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{+\infty}\left[\bar{f}(\eta)\frac{\operatorname{sh}(x_n-x)\eta}{\operatorname{sh}(x_n-x_0)\eta}+\bar{g}(\eta)\frac{\operatorname{sh}(x-x_0)\eta}{\operatorname{sh}(x_n-x_0)\eta}\right]e^{-i\eta y}\,d\eta \tag{5.2}$$

which is valid in the whole extent of the body in question.

This result can be expressed in yet another form. For, regarding the well-known relation4)

$$\int_{-\infty}^{+\infty}\frac{\operatorname{sh}\alpha\eta}{\operatorname{sh}\beta\eta}\,e^{i\gamma\eta}\,d\eta=\frac{\pi}{\beta}\cdot\frac{\sin\dfrac{\pi\alpha}{\beta}}{\cos\dfrac{\pi\alpha}{\beta}+\operatorname{ch}\dfrac{\pi\gamma}{\beta}}\,, \qquad |\alpha|<\beta\,,$$

one finds without difficulty

$$\int_{-\infty}^{+\infty}\bar{h}(\eta)\frac{\operatorname{sh}\alpha\eta}{\operatorname{sh}\beta\eta}\,e^{-i\eta y}\,d\eta=\frac{1}{\beta}\sqrt{\frac{\pi}{2}}\,\sin\frac{\pi\alpha}{\beta}\int_{-\infty}^{+\infty}\frac{h(\rho)}{\cos\dfrac{\pi\alpha}{\beta}+\operatorname{ch}\dfrac{\pi(\rho-y)}{\beta}}\,d\rho\,, \qquad |\alpha|<\beta \tag{5.3}$$

and the solution (5.2) appears in its usual form

$$\begin{aligned}u(x, y)=\frac{1}{2(x_n-x_0)}\sin\frac{\pi(x-x_0)}{x_n-x_0}\int_{-\infty}^{+\infty}\Bigg[&\frac{f(\rho)}{\operatorname{ch}\dfrac{\pi(\rho-y)}{x_n-x_0}-\cos\dfrac{\pi(x-x_0)}{x_n-x_0}}+\\&+\frac{g(\rho)}{\operatorname{ch}\dfrac{\pi(\rho-y)}{x_n-x_0}+\cos\dfrac{\pi(x-x_0)}{x_n-x_0}}\Bigg]d\rho\,.\end{aligned} \tag{5.4}$$

Naturally, the integrals entering in the above deductions may be considered in the sense of Cauchy's principal values, as usual in the theory of Fourier transforms.

§ 6. A Two-Layer Plate

In this case we have $n=2$ and the calculations become much more difficult.

One has to do with a single matrix $Q_1(\eta)$, determined by (4.1), and the relations (2.11) give

$$N(\eta)=\operatorname{sh}(l_1+l_2)\eta+(A_1-1)\operatorname{ch}l_1\eta\operatorname{sh}l_2\eta$$

$$Z(\eta)=\operatorname{ch}(l_1+l_2)\eta+(A_1-1)\operatorname{sh}l_1\eta\operatorname{sh}l_2\eta$$

$$\begin{aligned}N(\eta)[A_1\operatorname{ch}(x-x_0)\eta+B_1\operatorname{sh}(x-x_0)\eta]=\bar{f}(\eta)[&\operatorname{sh}(x_2-x)\eta+\\&+(A_1-1)\operatorname{sh}l_2\eta\operatorname{ch}(x_1-x)\eta]+\bar{g}(\eta)\operatorname{sh}(x-x_0)\eta\end{aligned}$$

$$\begin{aligned}N(\eta)[A_2\operatorname{ch}(x-x_1)\eta+B_2\operatorname{sh}(x-x_1)\eta]=A_1\bar{f}(\eta)&\operatorname{sh}(x_2-x)\eta+\\&+\bar{g}(\eta)[\operatorname{sh}(x-x_0)\eta+(A_1-1)\operatorname{ch}l_1\eta\operatorname{sh}(x-x_1)\eta]\,.\end{aligned}$$

Introducing this into (3.1), the solution of the present problem follows in the form

$$\begin{aligned}u_1(x, y)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{+\infty}\frac{e^{-i\eta y}}{N(\eta)}\{\bar{f}(\eta)[&\operatorname{sh}(x_2-x)\eta+\\+(A_1-1)\operatorname{sh}l_2\eta\operatorname{ch}(x_1-x)\eta]&+\bar{g}(\eta)\operatorname{sh}(x-x_0)\eta\}\,d\eta\,, \qquad x_0\leq x\leq x_1\end{aligned}$$

$$\left.\begin{aligned} u_2(x, y) &= \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{+\infty} \frac{e^{-i\eta y}}{N(y)} \{ A_1 \bar{f}(\eta) \operatorname{sh} (x_2 - x)\eta + \\ &\quad + \bar{g}(\eta) [\operatorname{sh} (x - x_0)\eta + (A_1 - 1) \operatorname{ch} l_1\eta \operatorname{sh} (x - x_1)\eta] \} \, d\eta \,, \qquad x_1 \leq x \leq x_2 \,; \\ N(\eta) &= \operatorname{sh} (l_1 + l_2)\eta + (A_1 - 1) \operatorname{ch} l_1\eta \operatorname{sh} l_2\eta \,. \end{aligned} \right\} \tag{6.1}$$

Further manipulation with (6.1) depends upon the given functions $f(y)$, $g(y)$. Nevertheless, the integrations required in (6.1) are exceedingly difficult and the author does not know of any closed form for those integrals, even in the case of the simplest functions $f(y)$, $g(y)$.

Apart from the trivial special case $A_1 = 1$ leading to the homogeneous strip, there exists perhaps a single favourable situation where it is possible to get a closed form of the solution (6.1), namely the case characterised by $l_1 = l_2 = l$. Let us examine this state of things.

We have

$$2N(\eta) = (A_1 + 1) \operatorname{sh} 2l\eta$$

and using the above auxiliary relation (5.3) in common with the analogous formula

$$\int_{-\infty}^{+\infty} \bar{h}(\eta) \frac{\operatorname{ch} \alpha\eta}{\operatorname{ch} \beta\eta} e^{-i\eta y} \, d\eta = \frac{\sqrt{2\pi}}{\beta} \cos \frac{\pi\alpha}{2\beta} \int_{-\infty}^{+\infty} h(\rho) \frac{\operatorname{ch} \frac{\pi(\rho - y)}{2\beta}}{\cos \frac{\pi\alpha}{\beta} + \operatorname{ch} \frac{\pi(\rho - y)}{\beta}} \, d\rho \,, \qquad |\alpha| < \beta \,, \tag{6.2}$$

the expressions (6.1) become

$$\left.\begin{aligned} u_1(x, y) &= \frac{1}{2(A_1 + 1)l} \sin \frac{\pi(x - x_0)}{2l} \left\{ \int_{-\infty}^{+\infty} f(\rho) \left[\frac{1}{\operatorname{ch} \frac{\pi(\rho - y)}{2l} - \cos \frac{\pi(x - x_0)}{2l}} + \right.\right. \\ &\quad \left.\left. + \frac{2(A_1 - 1) \operatorname{ch} \frac{\pi(\rho - y)}{2l}}{\operatorname{ch} \frac{\pi(\rho - y)}{l} - \cos \frac{\pi(x - x_0)}{l}} \right] d\rho + \int_{-\infty}^{+\infty} \frac{g(\rho)}{\operatorname{ch} \frac{\pi(\rho - y)}{2l} + \cos \frac{\pi(x - x_0)}{2l}} \, d\rho \right\} \\ u_2(x, y) &= \frac{1}{2(A_1 + 1)l} \sin \frac{\pi(x - x_0)}{2l} \left\{ A_1 \int_{-\infty}^{+\infty} \frac{f(\rho)}{\operatorname{ch} \frac{\pi(\rho - y)}{2l} - \cos \frac{\pi(x - x_0)}{2l}} \, d\rho + \right. \\ &\quad \left. + \int_{-\infty}^{+\infty} g(\rho) \left[\frac{1}{\operatorname{ch} \frac{\pi(\rho - y)}{2l} + \cos \frac{\pi(x - x_0)}{2l}} - \frac{2(A_1 - 1) \cos \frac{\pi(x - x_0)}{2l}}{\operatorname{ch} \frac{\pi(\rho - y)}{l} - \cos \frac{\pi(x - x_0)}{l}} \right] d\rho \right\} . \end{aligned} \right\} \tag{6.3}$$

Circulation Preserving Motions

By A. C. SRIVASTAVA

Department of Mathematics, Indian Institute of Technology, Kharagpur

(Received April 5, 1960)

Two theorems concerning circulation preserving motions have been stated and proved. Two particular examples to illustrate them are also given. It is deduced that two circulation preserving motions in a Newtonian fluid when their sum is circulation preserving are mutually superposable but in a non-Newtonian fluid this proposition is true only if one more condition is satisfied. Similar results have been deduced for self-superposability also.

§ 1. *Circulation preserving motions are defined to be those motions in which the circulation of a reducible circuit does not change.*

The circulation of $\dot{\mathbf{x}}$ round any material circuit is given by $\int_c d\mathbf{x}\cdot\dot{\mathbf{x}}$, where $\mathbf{x}$ is the Eulerian coordinate and the dot denotes the material derivative. For circulation preserving motions

$$\frac{\delta}{\delta t}\int_c d\mathbf{x}\cdot\dot{\mathbf{x}}=0\,, \qquad (1)$$

where $\delta/\delta t$ denotes the material derivative. Truesdell[1] has shown that the condition (1) can be alternatively expressed as

$$\operatorname{curl}\ddot{\mathbf{x}}=0\,. \qquad (2)$$

This condition is known as d'Alembert-Euler conditions. It has been proved that (2) is the necessary and sufficient condition for a motion to be circulation preserving. The conditions (1) and (2) are purely kinematical, valid for arbitrary media.

§ 2. *We state and prove the following two theorems about circulation preserving and superposable fluid motions.*

Theorem 1.

For a fluid whose equations of motion are such that the acceleration is the sum of a linear function of velocity, vorticity and the gradient of a scalar function, the condition that $\mathbf{v}_1+\mathbf{v}_2$ *is circulation preserving provided that* $\mathbf{v}_1$ *and* $\mathbf{v}_2$ *are circulation preserving, is identical with the condition of superposability of* $\mathbf{v}_1$ *and* $\mathbf{v}_2$*; but, if the acceleration is a non-linear function of velocity and its derivatives the above two conditions are quite different.*

Proof:

(a) Let us suppose that the acceleration is a linear function of vorticity, velocity etc. and has the form

$$\ddot{\mathbf{x}}=\Phi_1(\mathbf{v})+\Phi_2(\omega)+\nabla\chi\,, \qquad (3)$$

where Φ_1 and Φ_2 are linear operators $[\Phi(A+B)=\Phi(A)+\Phi(B)]$ and χ is a scalar function. The condition that $\mathbf{v}_1+\mathbf{v}_2$ is circulation preserving, when $\mathbf{v}_1$ and $\mathbf{v}_2$ are circulation preserving, is obtained by Truesdell[1]

$$\operatorname{curl}(\boldsymbol{\omega}_1\times\mathbf{v}_2+\boldsymbol{\omega}_2\times\mathbf{v}_1)=0\,. \qquad (4)$$

This is purely kinematical and does not depend on the form of the equation of motion.

Performing curl operation on (3), we get

$$\operatorname{curl}\ddot{\mathbf{x}}=\operatorname{curl}\Phi_1(\mathbf{v})+\operatorname{curl}\Phi_2(\boldsymbol{\omega})\,. \qquad (5)$$

If $\mathbf{v}_1$, $\mathbf{v}_2$ and $\mathbf{v}_1+\mathbf{v}_2$ satisfy (5), we get

$$\operatorname{curl}\ddot{\mathbf{x}}_1=\operatorname{curl}\Phi_1(\mathbf{v}_1)+\operatorname{curl}\Phi_2(\boldsymbol{\omega}_1)\,, \qquad (6)$$

$$\operatorname{curl}\ddot{\mathbf{x}}_2=\operatorname{curl}\Phi_1(\mathbf{v}_2)+\operatorname{curl}\Phi_2(\boldsymbol{\omega}_2)\,, \qquad (7)$$

$$\begin{aligned}\operatorname{curl}\ddot{\mathbf{x}}_1+\operatorname{curl}\ddot{\mathbf{x}}+\operatorname{curl}(\boldsymbol{\omega}_1\times\mathbf{v}_2+\boldsymbol{\omega}_2\times\mathbf{v}_1)\\=\operatorname{curl}\Phi_1(\mathbf{v}_1+\mathbf{v}_2)+\operatorname{curl}\Phi_2(\boldsymbol{\omega}_1+\boldsymbol{\omega}_2)\,. \qquad (8)\end{aligned}$$

Using (6), (7) and (8), the condition of superposability is

$$\operatorname{curl}(\boldsymbol{\omega}_1\times\mathbf{v}_2+\boldsymbol{\omega}_2\times\mathbf{v}_1)=0\,. \qquad (9)$$

which is same as (4).

This proves the first part of the theorem.

(b) Let us now suppose that acceleration is a non-linear function of velocity and it derivatives and has the form

$$\ddot{\mathbf{x}}=\Phi_1(\mathbf{v})+\Phi_2(\boldsymbol{\omega})+\psi(\mathbf{v})+\nabla\chi\,, \qquad (10)$$

where $\psi(\mathbf{v})$ is a non-linear function of its argument and its derivatives.

The condition of superposability of two motions $\mathbf{v}_1$ and $\mathbf{v}_2$ of a fluid, whose equation of motion is (10), can be derived as in (a). It is

$$\begin{aligned}&\operatorname{curl}(\boldsymbol{\omega}_1\times\mathbf{v}_2+\boldsymbol{\omega}_2\times\mathbf{v})\\&=\operatorname{curl}\psi(\mathbf{v}_1+\mathbf{v}_2)-\operatorname{curl}\psi(\mathbf{v}_1)-\operatorname{curl}\psi(\mathbf{v}_2)\,. \qquad (11)\end{aligned}$$

In general the right-hand member of (11) is not zero, and hence this condition is quite different from (4).

This proves the second part of the theorem.

For $\mathbf{v}_1+\mathbf{v}_2$ to be circulation preserving provided that $\mathbf{v}_1$ and $\mathbf{v}_2$ are circulation preserving, the condition (11) with the help of (4) reduces to

$$\psi(\mathbf{v}_1+\mathbf{v}_2)-\psi(\mathbf{v}_1)-\psi(\mathbf{v}_2)\equiv\operatorname{grad}\Theta\,. \tag{12}$$

Theorem 2.

For a fluid whose equations of motion are such that the accerlation is the sum of a linear function of velocity, vorticity and a gradient of a scalar, a self-superposable motion with steady vorticity is circulation preserving; but, if the acceleration is a non-linear function of velocity and its derivatives, the above statement is not necessarily true.

Proof:

The condition for a motion $\mathbf{v}$ with steady vorticity to be circulation preserving can be deduced from (2) as follows.

$$\ddot{\mathbf{x}}=\operatorname{grad}\left|\frac{1}{2}\dot{\mathbf{x}}\right|^2+(\operatorname{curl}\dot{\mathbf{x}})\times\dot{\mathbf{x}}\,.$$

Taking curl of $\ddot{\mathbf{x}}$, we get

$$\operatorname{curl}(\boldsymbol{\omega}\times\mathbf{v})=0\,. \tag{13}$$

The condition of self-superposability in a fluid, whose equation of motion is (3), can be deduced from (9) by putting $\boldsymbol{\omega}_1=\boldsymbol{\omega}_2=\boldsymbol{\omega}$, $\mathbf{v}_1=\mathbf{v}_2=\mathbf{v}$

$$\operatorname{curl}(\boldsymbol{\omega}\times\mathbf{v})=0\,,$$

which is the same as (13). This proves the first part of the theorem.

In a fluid whose equation of motion is given by (10) the condition of self-superposability is [put $\boldsymbol{\omega}_1=\boldsymbol{\omega}_2=\boldsymbol{\omega}$, $\mathbf{v}_1=\mathbf{v}_2=\mathbf{v}$ in (11)]

$$\operatorname{curl}(\boldsymbol{\omega}\times\mathbf{v})=\operatorname{curl}\psi(2\mathbf{v})-2\operatorname{curl}\psi(\mathbf{v})\,, \tag{14}$$

which is quite different from (13).

If the motion is circulation preserving, (14) gives

$$\psi(2\mathbf{v})-2\psi(\mathbf{v})\equiv\operatorname{grad}\Theta\,. \tag{15}$$

In other words if the condition (15) is satisfied, any self-superposable motion with steady vorticity is circulation preserving, even though the acceleration is a non-linear function of velocity and its derivatives.

§ **3.** *We give two examples to illustrate the theorems 1 and 2.*

Example 1.

The equation of motion for a viscous incompressible Newtonian fluid is

$$\ddot{\mathbf{x}}=-\operatorname{grad}\left(\frac{p}{\rho}\right)-\nu_v\operatorname{curl}\boldsymbol{\omega}\,. \tag{16}$$

Hence we conclude from the first parts of the theorems (1) and (2) that

i) If $\mathbf{v}_1$, $\mathbf{v}_2$ be any two circulation preserving motions in Newtonian incompressible fluids and if $\mathbf{v}_1+\mathbf{v}_2$ is also circulation preserving, then $\mathbf{v}_1$ and $\mathbf{v}_2$ are mutually superposable.

ii) Any circulation preserving motion with steady vorticity is self-superposable.

These conclusions were also drawn by Truesdell1).

Example 2.

The equation of motion for incompressible non-Newtonian fluid [Reiner-Rivlin fluid] is2)

$$\begin{aligned}\ddot{\mathbf{x}}=-\nu_v\operatorname{curl}\boldsymbol{\omega}-2\nu_c\Big[&\frac{\partial\mathbf{v}}{\partial x}\times\frac{\partial\boldsymbol{\omega}}{\partial x}+\frac{\partial\mathbf{v}}{\partial y}\times\frac{\partial\boldsymbol{\omega}}{\partial y}\\&+\frac{\partial\mathbf{v}}{dz}\times\frac{\partial\boldsymbol{\omega}}{\partial z}+(\operatorname{curl}\boldsymbol{\omega}\cdot\nabla)\mathbf{v}+\frac{1}{2}(\boldsymbol{\omega}\cdot\nabla)\boldsymbol{\omega}\Big]\\&-\frac{1}{\rho}\operatorname{grad}\cdot[p+s]\,,\end{aligned} \tag{17}$$

where ν_c is kinematic coefficient of cross- viscosity

$$\frac{s}{\rho}=-2\nu_c\left[\left|\frac{\partial\mathbf{v}}{\partial x}\right|^2+\left|\frac{\partial\mathbf{v}}{\partial y}\right|^2+\left|\frac{\partial\mathbf{v}}{\partial z}\right|^2\right].$$

In this case condition (12) becomes

$$\begin{aligned}&\frac{\partial\mathbf{v}_1}{\partial x}\times\frac{\partial\boldsymbol{\omega}_2}{\partial x}+\frac{\partial\mathbf{v}_2}{\partial x}\times\frac{\partial\boldsymbol{\omega}_1}{\partial x}+\frac{\partial\mathbf{v}_1}{\partial y}\times\frac{\partial\boldsymbol{\omega}_2}{\partial y}+\frac{\partial\mathbf{v}_2}{\partial y}\times\frac{\partial\boldsymbol{\omega}_1}{\partial y}\\&\quad+\frac{\partial\mathbf{v}_1}{\partial z}\times\frac{\partial\boldsymbol{\omega}_2}{\partial z}+\frac{\partial\mathbf{v}_2}{\partial z}\times\frac{\partial\boldsymbol{\omega}_1}{\partial z}+(\operatorname{curl}\boldsymbol{\omega}_1\cdot\nabla)\mathbf{v}_2\\&\quad+(\operatorname{curl}\boldsymbol{\omega}_2\cdot\nabla)\mathbf{v}_1+\frac{1}{2}(\boldsymbol{\omega}_1\cdot\nabla)\boldsymbol{\omega}_2\\&\quad+\frac{1}{2}(\boldsymbol{\omega}_2\cdot\nabla)\boldsymbol{\omega}_1\equiv\operatorname{grad}\Theta\,,\end{aligned} \tag{18}$$

and condition (15) becomes

$$\begin{aligned}&\frac{\partial\mathbf{v}}{\partial x}\times\frac{\partial\boldsymbol{\omega}}{dx}+\frac{\partial\mathbf{v}}{\partial y}\times\frac{\partial\boldsymbol{\omega}}{\partial y}+\frac{\partial\mathbf{v}}{\partial z}\times\frac{\partial\boldsymbol{\omega}}{\partial z}+(\operatorname{curl}\boldsymbol{\omega}\cdot\nabla)\mathbf{v}\\&\quad+\frac{1}{2}(\boldsymbol{\omega}\cdot\nabla)\boldsymbol{\omega}\equiv\operatorname{grad}\Theta\,.\end{aligned} \tag{19}$$

Hence we conclude that

i) The condition that $\mathbf{v}_1+\mathbf{v}_2$ is a circulation preserving motion in non-Newtonian fluid, when $\mathbf{v}_1$, $\mathbf{v}_2$ are circulation preserving, is identical with the condition of superposability of $\mathbf{v}_1$ and $\mathbf{v}_2$ if and only if, (18) is satisfied.

ii) Any circulation preserving motion with steady vorticity is self-superposable in non-Newtonian fluid, if and only if, condition (19) is satisfied.

Thickness-Dependence of Stress in Vacuum Deposited Silver Films

By Koreo KINOSITA and Hideki KONDO*
Department of Physics and Chemistry, Gakushuin University, Mejiro, Tokyo

(Received May 6, 1960)

Recently we carried out measurement of the tensile stress in silver films of 30~2,500 Å thickness vacuum deposited on thin pieces of mica. Fig. 1, reproduced from the previous note[1], shows the magnitude of the stress σ *vs.* the film thickness d.

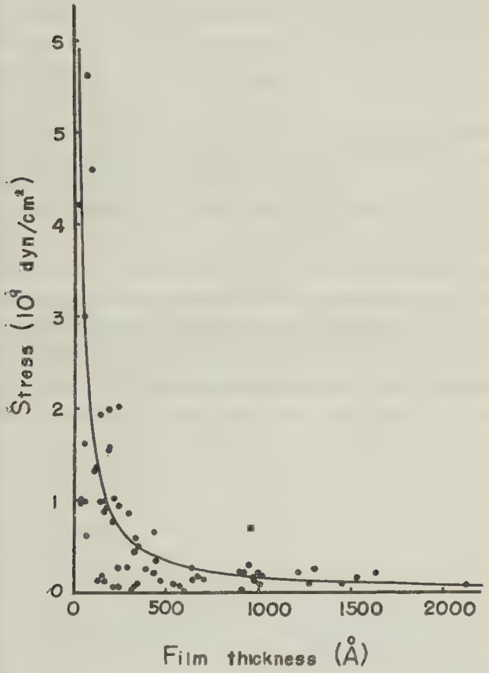

Fig. 1. Stress *vs.* film thickness.

The purpose of the present note is to point out that the relation between σ and d can be very well approximated by an orthogonal hyperbola of the type

$$\sigma d = \text{const}\,. \qquad (1)$$

This will be best illustrated by the curve in Fig. 1, which represents

$$\sigma d = 177 \times 10^9\ (\text{dyn/cm}^2)\ \text{Å}\,. \qquad (2)$$

A tentative explanation of Eq. (1) can be obtained if we admit the following assumptions (refer to Fig. 2):

1° The stress in the film is localized in a very thin *surface layer*.

2° The thickness of this surface layer, d_0, which must be of the order of 10 Å, is constant, irrespective of the total film thickness d.

3° The stress in this layer, σ_0, is constant, irrespective of d.

Obviously it follows that the mean stress in the film, σ, is given by

$$\sigma = \sigma_0 d_0 / d\,, \qquad (3)$$

in accordance with Eq. (1). Eq. (2) will mean that $\sigma_0 d_0 = 177 \times 10^9$ (dyn/cm²) Å. At present separate evaluation of σ_0 and d_0 is not possible.

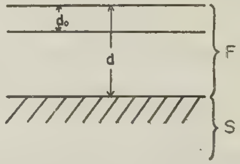

Fig. 2. Model on which Eq. (3) is based. *F* and *S* represent film and substrate respectively.

The *surface layer* mentioned above may be the one adjacent to the free surface of the film, or it may be the one adjacent to the surface of the substrate. If there is tensile stress in either of them, the film as a whole will contract and bend the substrate (mica) as is observed[1]. It is more plausible, however, that the stress is concentrated in a layer adjacent to the free surface, because it has been observed that silver films deposited on the wall of the bell-jar often curl up with the free surface concave.

The reality of the model proposed here will have to be put to severe test because it does not seem to be consistent with the current view that very thin silver films (say $d < 100$ Å) consist of isolated crystallites while thicker ones are continuous. For further discussion the reader is referred to reference 1).

Electron Spin Resonance of Mn^{++} in $SrCl_2$, $CdCl_2$ and $CdBr_2$

By Hiroshi KOGA, Kazumi HORAI
and On MATUMURA

Department of Physics, Faculty of Science,
Kyusyu University

(Received March, 22, 1960)

In Connection with the alkali-halide:Mn[1], the electron spin resonance of Mn^{++} ions in the single crystals of $SrCl_2$,$CdCl_2$ and $CdBr_2$ have been measured at room temperature and at the wavelengths of 3 and 0.8 cm.

The crystals were grown from the melt which contained a small amounts of $MnCl_2$ in a closed quartz tube under a vacuum of about 10^{-3} mm Hg.

(1) $SrCl_2$:Mn.

At low Mn concentrations ($<3\times10^{-3}$), the observed spectra are composed of six hyperfine lines. These spectra are interpreted with the usual spin Hamiltonian

$$\mathscr{H}=g\beta\boldsymbol{H}\cdot\boldsymbol{S}+\boldsymbol{A}\cdot\boldsymbol{S}\cdot\boldsymbol{J}+\frac{1}{6}a\Big[S_x{}^4+S_y{}^4+S_z{}^4 -\frac{1}{5}S(S+1)(3S^2+35-1)\Big]$$

with S and $I=5/2, g=2.004$ and $A=82.7\times10^{-4}\,\mathrm{cm}^{-1}$. No significant changes are observed in the spectra for various angular variations of the magnetic field with respect to the crystal axes, and the order of a is estimated as $a<5\times10^{-4}\,\mathrm{cm}^{-1}$. At high Mn concentrations ($>7\times10^{-3}$), only a single line is observed with the apparent g-values are 2.0073 at 3 cm and 2.0015 at 0.8 cm. This difference is supposed to be due to the lower symmetry of the crystalline field and the random distribution of its tetragonal axes orintation. The cause of this lower symmetry is thought to be the difference of ionic radii or depolarzing powers of Mn^{++} and Sr^{++} ions in near sites. From these g-values, the tetragonal field parameter D is estimated as $240\times10^{-4}\,\mathrm{cm}^{-1}$ and the true g-value is 2.000.

(2) $CdCl_2$ and $CdBr_2$:Mn.

Same as $MnCl_2$, these crystals belong to the D^5_{3d} space group and have a layer structure. The spectra have been analysed with the following spin Hamiltonian

$$\mathscr{H}=g\beta\boldsymbol{H}\cdot\boldsymbol{S}+\boldsymbol{A}\cdot\boldsymbol{S}\cdot\boldsymbol{I}+DS_z{}^2+E(S_x{}^2-S_y{}^2)$$

The obtained values of the parameters are listed in the table.

Table I.

Crystal	Mn-concentration	g	A $\times10^{-4}$ cm^{-1}	D $\times10^{-4}$ cm^{-1}	E $\times10^{-4}$ cm^{-1}
$CdCl_2$	1×10^{-3}	2.066	81.6	<15	—
$CdBr_2$	2×10^{-3}	2.014	79.8	202	<10

In the case of $CdCl_2$[2] the spectrum consists of only six hyperfine lines of about 11 gauss width of nearly Lorentzian shape. Thus the upper limit to the value of D has been estimated. In $CdBr_2$, as shown in Fig., the spectrum has 30 lines of about 40 gauss width. This width remains nearly constant for some crystals of the different Mn-concentrations and under various conditions of the crystal growth. The stacking fault in the crystal or the hyperfine interaction between the Mn electrons and the surrounding eight Br nuclei may be the origin of this large line width.

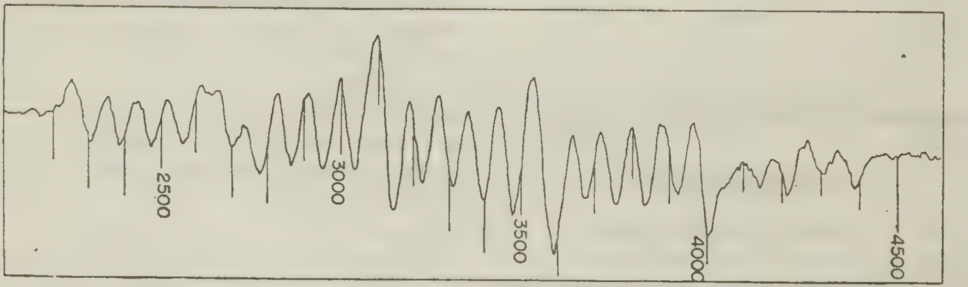

Fig. 1. $CdBr_2$:Mn spectrum. The magnetic field is parallel to |001| axis.

The resonance of $MgBr_2$:Mn and $BaCl_2$:Mn are also measured with the results of $g=2.001$ and $A=82\times10^{-4}\,\mathrm{cm}^{-1}$, and $g=2.003$ (single line) respectively.

The more detailed experiments are being carried out and the full report will be given in the near future. This research is partially supported by the Grant for Promotion of Science from the Ministry of Education.

Ultrasonic Measurement of Magnetization in Mn-ferrite Single Crystal

By Kazuo HUSIMI, Katsumi NISHIGUCHI
and Toshimasa SUZUKI

Electrical Communication Laboratory
Musashino-shi Tokyo

(Received May 6, 1960)

The ultrasonic method whicn has been developed as a new measuring technique of ferroelectric polarization without disturbing the domain configuration has several advantages and is shown to be useful for the study of ferroelectrics[1]). It has been pointed out by analogy that the similar means can be available for magnetism by using the dependence of the magnetostriction on the magnetization, and this is applied on the magnetization switching study of Mn-ferrite single crystal grown by the Stockbarger method.

The block diagram of experimenial arrangement is shown in Fig. 1. The sample is always kept in ultrasonic excitation by a quartz crystal. The magnetostrictive output voltage is amplified and displayed on the cathode ray tube CRT-1, and its amplitude is determined by comparing with the signal of a standard attenuator. The direction of magnetization is also detected from the Lissajou figure trajectory on CRT-1. For calibration, double pulses shown in Fig. 1 are applied on the input terminal, and the switching voltage responses are integrated and are displayed on CRT-2 after amplification. From this figure the magnetic flux changes can be measured. The calibration curve of the magnetostrictive output voltages relative to the remanent magnetic flux densities is shown in Fig. 2. In this mesaurement, the magnetic flux density was adjusted by varing the amplitude of the input double pulses.

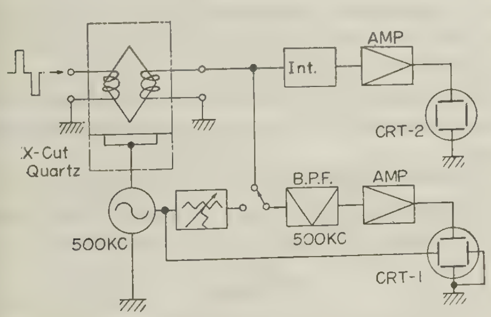

Fig. 1. Block diagram of experimental arrangement.

Differing from the case of ferroelectrics, the ultrasonic output voltage V has no linear relaitonship to the magnetic flux density B, and can be expressed approximately as;

$$V \propto B^{0.7}$$

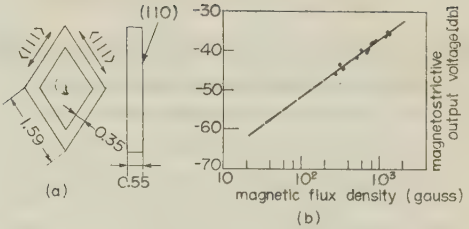

Fig. 2. (a) Dimension of the sample (mm). (b) Calibration curve of magnetostrictive output voltage relative to remanent magnetic flux density.

The magnetization switching processes by single pulses with different amplitudes are shown in Fig. 3. with the pulse width as parameter. In every case, initial negative remanent setting was performed by manual application of the negative field with strength of 2.04 oe for several seconds.

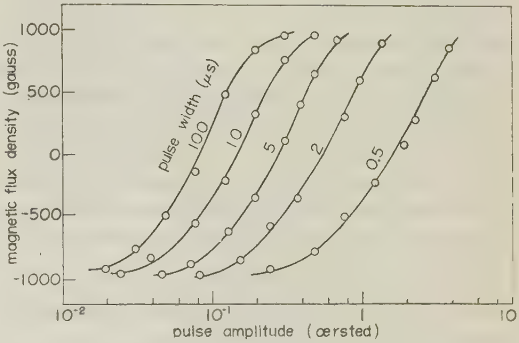

Fig. 3. Magnetization switching processes by single pulses.

The electromechanical transducer, in which the test crystal is mounted, is the same type used for ferroelectrics[1]), and the exciting quartz crystal disk has a fundamental resonant frequency of thickness mode near 500 Kc.

The crystal was finished by the ultrasonic cutter as also shown in Fig. 2[2]) and was annealed.

Unfortunately it was found by x-ray analysis that the legs of the rhombic frame did not precisely lie along <111> direction, therefore we could not carry out farther analysis of domain wall motion of the crystal. But from these experiments, we have made clear that this new method is also adequate for the nondestructive measurement of magnetization, though the magnetostrictive output voltage is small and not proportional to remanent magnetization being different from ferroelectrics.

We wish to thank Dr. M. Hatoyama and Dr. N. Sakamoto of Electrotechnical Laboratory for kind furnish of the single crystal Mn-ferrite, and Dr. Y. Niizeki for x-ray analysis.

The Temperature and Pressure Dependence of the Nuclear Resonance of Co^{59} in Face-Centered-Cubic Cobalt Metal

By Yoshitaka Kōi, Akira Tsujimura and Yoshinori Yukimoto

Faculty of Engineering, Tokushima University, Tokushima

(Received March 2, 1960)

Recently the nuclear resonance of Co^{59} in ferromagnetic f.c.c. cobalt metal was observed by Gossard and Portis[1]. The resonance frequency is 213.1 Mc/sec in zero external magnetic field at room temperature. This indicates an effective magnetic field of 213 400 oersteds at the site of the nucleus, since the nucleus has a magnetic moment of 4.583 nuclear magnetons and a spin number of 7/2. The effective field arises from the hyperfine interaction between the nucleus and both the core and the conduction electrons, as has been discussed by Marshall[2], and can be written as

$$H_{eff}=\lambda AM,$$

where λ is a constant, A represents the hyperfine interaction and M the magnetization.

As in the case of the fluorine resonance in antiferromagnetic MnF_2[3)4)], knowledge of the temperature and the pressure dependence of the resonance frequency will give detailed information about the hyperfine interaction. Therefore, measurements were made in the range from liquid oxygen temperature to 550°C[5] and in the pressure range 1 to 8000 kg/cm². The spectrometer was the one used by one of the authors for the line-width study of pure quadrupole resonance, which has been described elsewhere.[6] It was frequency-modulated, and the resonance was displayed on an oscilloscope. The probable error in the determination of the resonance frequency was ±0.1 Mc/sec.

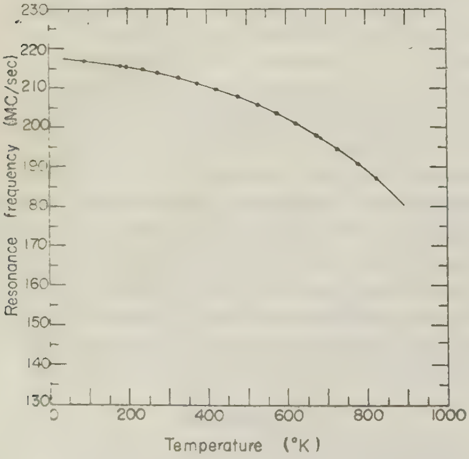

Fig. 1. The temperature dependence of the resonance frequency at atmospheric pressure.

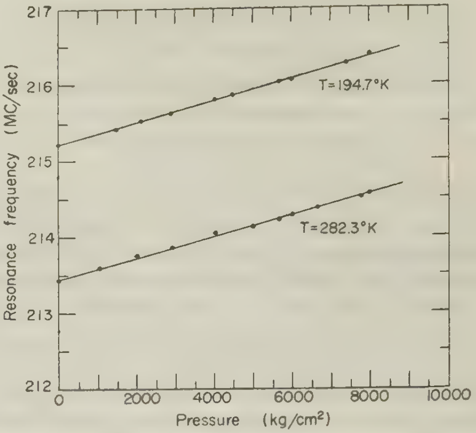

Fig. 2. The pressure dependence of the resonance frequency at 194.7° and 282.3°K.

The results of the measurements are shown in Figs. 1 and 2. The resonance frequency seems to have the same temperature dependence as M, so the temperature dependence would be primarily due to the change in M. However, the change in A would be responsible for the pressure dependence, since M is likely to depend little on pressure[7]. In order to obtain a definite conclusion as to these points, and to know the detailed nature of the interaction, measurements of the temperature and the pressure dependence of M are necessary and now in preparation.

The details of the experimental procedures and the discussions of the results will be published later.

The authors wish to express their sincere thanks to Professor T. Kushida of Hiroshima University for arousing their interest in this problem.

The Ferromagnetism of the Compound γ-FeSn

By Mitsuru Asanuma

Department of Physics, Faculty of Science, Hokkaido University

(Received May 21, 1960)

The B8 type structure is frequently formed by alloying the iron group transition elements T with some of the elements B of IIIB, IVB, VB and VIB groups in the periodic table, and is extended in a wide range between the composition T_2B and $T_{1-x}B$ depending on the variety of the components[1,2]. There are a number of ferromagnetic or ferrimagnetic compounds in this structure, and many investigations have been done to the equiatomic structure TB and defect structure $T_{1-x}B$, But excess structure $T_{1+x}B$ has never been sufficiently investigated.

The study was started by taking tin as a B component. According to the phase diagram in the system of iron-tin by Hansen[3], a number of intermediate phases are formed in this system, as shown in Fig. 1. Among them γ-FeSn, having a B8 type structure, is formed peritectically at 940°C in the composion of about 43.5～44 atomic per cent Sn, and decomposes at 780°C. Since the alloy of iron and tin has two immiscible phases in molten state, the specimen was prepared by sintering method. After heating the mixture of iron and tin sealed in evacuated silica tube at 1200°C for a day, it was crushed, baked at 850°C (this is the temperature of formation of B8 structure) for a week, and then quenched in water. The composition of the compound prepared is $Fe_{1.3}Sn$.

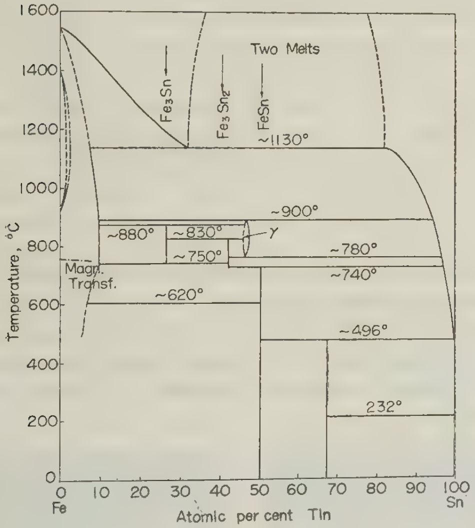

Fig. 1. The phase diagram of the system of iron-tin.

The examination by X-ray diffraction showed that the specimen was mostly constructed of γ-FeSn and contained a few amount of tin. The lattice parameter are $a=4.216$Å, $c=5.244$Å and $c/a=1.243$.

The saturation magnetization was measured by Sucksmith's ring balance, and the result is shown in Fig. 2. The value of the saturation magnetization per mol at absolute zero temperature is estimated as $2.3\mu_B$, i.e. $1.8\mu_B$ per iron atom, and the Curie temperature of this specimen is 676°K. Although the specimen contains a few amount of tin phase and small change of the composition from $Fe_{1.3}Sn$ is expected, there is no doubt that the ferromagnetism shown in Fig. 2 is due to the compound γ-FeSn and not due to the eventual coexistence of α-Fe.

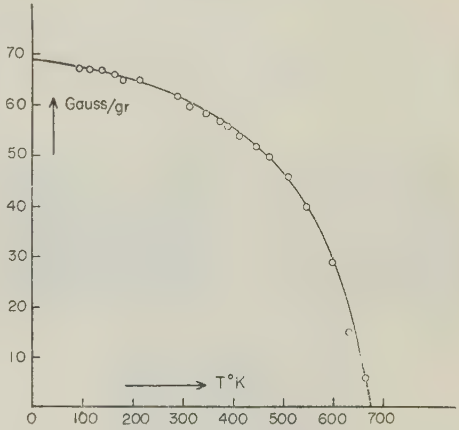

Fig. 2. The depeddence of the saturation magnetization on the temperature.

The magnetic susceptibility above the Curie temperature could not be measured, because γ-FeSn is only stable from 780°C to 940°C and it decomposes by keeping the specimen between the Curie temperature and 780°C for a long time.

In order to explain the measured value of the saturation magnetization, another transition elements-tin systems, i.e. Co-Sn and Ni-Sn systems have been investigated. The results will be published in this Journal.

Optical Absorption of Localized Exciton in KCl:I and NaCl:I Single Crystals

By Kuniya FUKUDA, Riso KATO, Kaizo NAKAMURA and Yoichi UCHIDA

Department of Physics, Faculty of Science, Kyoto University

(Received May 6, 1960)

The first fundamental optical absorption of alkali halides is attributed to the electronic transition from halide ion to neighboring alkali ion[1]. The displacement of the optical absorption due to an impurity halide ion from the first fundamental one of the pure base substance was early found by Hilsch and Pohl on I^- impurity ion in NaCl, KCl and RbCl, but their measurements at room temperature were not made on single crystals[2]. Later, Delbecq *et al.* reported the similar displacement of the absorption of I^- ion substitutionally embedded in NaBr and KBr single crystals[3]. In this case the absorption peak of I^- ion was observed at liquid nitrogen temperature with a definite separation from those of host crystals, and they considered this separation to be due mainly to the difference in electron affinities of Br and I.

In this note, results are given on the absorption band due to I^- impurity in KCl and NaCl single crystals, which may be ascribed to the localized excitation at I^- ion. Single crystals of KCl and NaCl, each containing 0.05 mole % of I^- impurity in melt, were grown up by the Kyropoulos method. Absorption measurements were carried out at room temperature by Seya-Namioka type vacuum ultraviolet monochromator recently constructed in our laboratory[4]. Figure 1 shows the absorption curves of NaCl:I and KCl:I. The absorption peaks of I^- ion are at 188 mμ (189.5 mμ) and 182 mμ (185 mμ) for KCl:I and NaCl:I, respectively, differing slightly from the results of Hilsch and Pohl which are shown above in the brackets. Their results seem to contain some ambiguities concerning peak position and absorption shape because they used quartz spectrophotometer in air. In longer wavelength region, no absorption band was found which might be associated with coaguration of I^- ions.

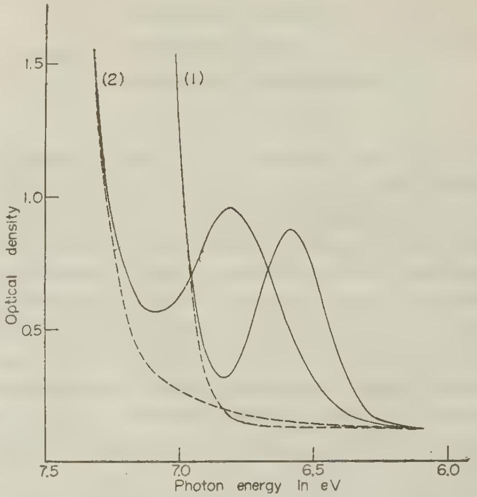

Fig. 1. The optical absorption curves of (1) KCl:I of 0.3 mm in thickness and (2) NaCl:I of 0.5 mm in thickness, at room temperature. Dotted curves show those of pure crystals.

The separation between the I^- band and the first fundamental absorption of host crystal is 1.1 ev for KCl:I and 1.0 eV for NaCl:I. These separations, which are larger than those expected from the difference of 0.6 eV in electron affinities of Cl and I, are considered to contain considerable large contributions from "size-effect" perturbations, that is, the changes of Madelung potential and repulsive energy due to the difference in ionic radii of Cl^- and I^- ions, in comparison with the case of I^- ion in KBr and NaBr . In addition, of course, polarization energy difference in excited state may not be neglected. The band shape of I^- ion absorption, though slightly asymmetric, is approximately Gaussian in both cases of KCl:I and NaCl:I. Obtained results are tabulated in Table I below.

Table I. Energy difference between iodide impurity absorption and fundamental absorption in KCl and NaCl at room temperature.

	(1) first fundamental band of host crystal[5] (eV)	(2) peak of I^- band (eV)	Half-width (eV)	Separation (1)−(2) ΔE (eV)
KCl:I	~7.7 (161 mμ)	6.85 (188 mμ)	~0.27	~1.1
NaCl:I	~7.8 (159 mμ)	6.82 (182 mμ)	~0.35	~1

Similar attempt was made on Br^- impurity in chlorides at room temperature and no separated Br^- band was observed, but the fundamental absorption edge shifted to the longer wavelength side.

The temperature and concentration dependence of I^- band and other phenomena concerning I^- impurity will be reported in a near future.

Avalanche Breakdown in CdS Single Crystal

By Sigeru IIZIMA and Makoto KIKUCHI

Electrotechnical Laboratory, Nagatacho, Tokyo, Japan

(Received May 25, 1960)

In the previous note1) we described the avalanche breakdown in CdS single crystal that had an ohmic In contact and a non-ohmic Ag-paste contact, showing that this breakdown was accompanied with the electroluminescence. The construction of CdS cell in the present study is shown in Fig. 1, which is somewhat different from that in the previous note. This construction is convenient to observe through a microscope what part of the crystal luminescens. The feature of the light emission is shown by microphotograph in Fig. 2. The spacing between In and Ag contact is about 0.3 mm, and the light is emitted only when Ag contact is positively biased. 50 cps ac potential of about 200 volts is applied in this case. It should be noted that the light is emitted only at the neighbour of Ag contact. This fact seems to suggest that Ag-paste contact at high positive potential injects positive holes which induce the avalanche breakdown in the neighbourhood of Ag contact.

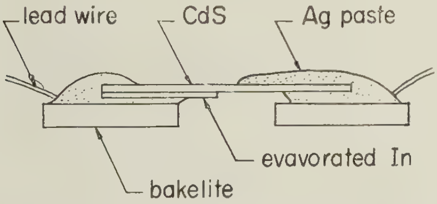

Fig. 1. Construction of the experimental cell.

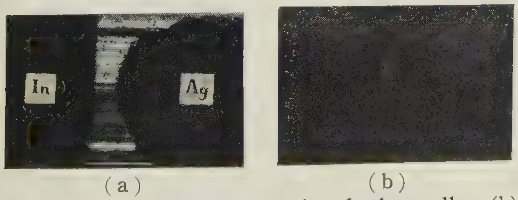
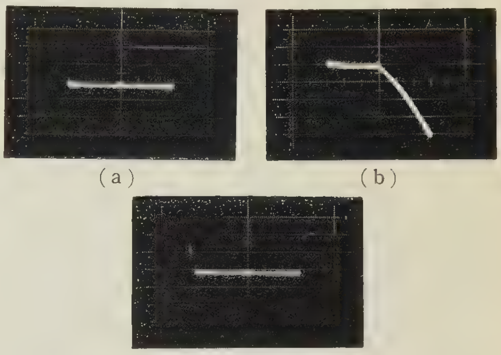


(a) (b)

Fig. 2. (a) Photomicrograph of the cell. (b) Light emission of the cell.

It has been found that this avalanche can be triggered and quenched by illuminating the cell with visible and infrared light, respectively. Fig. 3(a) shows the V-I characteristic on the oscilloscope using 50 cps ac voltage when the cell is in the dark and the avalanche breakdown has not yet occurred. Keeping ac voltage at a proper value so that the avalanche does not occur in the dark, the avalanche breakdown can be triggered on when the cell is illuminated by visible light. The avalanche is maintained even after removing the light. Fig. 3(b) shows the V-I characteristic of such a state after 1 sec exposure to the light of 510 mμ in wavelength. Such a on-(or conducting-) state can be quenched by infrared illumination. Fig. 3(c) shows the V-I characteristic of quenched state after 1 sec exposure to 1350 mμ infrared light.



(a) (b)

(c)

Fig. 3. (a) V-I characteristic in the dark. (b) After 1 sec exposure to visible light. (c) After 1 sec exposure to infrared light. (Ordinate: 200μA per division. Abscissa: 50 V per division.)

The triggering effect is induced by increased primary carriers which are generated by the visible light. Once a highly conducting state has been attained, it is maintained by itself even after removing the light, just as in a gas discharge tube which sustains the discharge. Since we observe the conducting or non-conducting state by the V-I characteristics on the oscilloscope using 50 cps ac voltage and the exposure time is 1 sec, it is suggested that the time constant in this phenomenon is at least larger than 20 msec and at most shorter than 1 sec. The quenching effect in the present study is likely concerned with the so-called infrared quenching in the photoconductor, but the detailed mechanism of the present effect is rather ambiguous.

Pulse Photoconduction and Carrier Lifetime in CdS Single Crystals

By Junji SHIRAFUJI and Yoshio INUISHI

Faculty of Engineering, Osaka University, Osaka

(Received May 5, 1960)

The decay time constants and peak value of photocurrent in CdS single crystals were measured with short duration light pulse (0.5 μ sec) from Xe discharge tube or with chopped light of 5 m sec width. The CdS samples were prepared by the sublimation (S-1 and 2) and by the melt (M-1 and 2) without any impurity added intentionally. With 0.5 μsec light pulse, two components of photocurrent decay were observed on synchroscope figure with time constants of the order of 1 μsec (τ_1) and 30 μsec (τ_2), respectively, at room temperature as shown in Photo. 1. With chopped light pulse (5 msec), two components in photocurrent decay were observed with the decay time constants of 10 msec (τ_3) and 40 msec (τ_4), respectively, at room temperature.

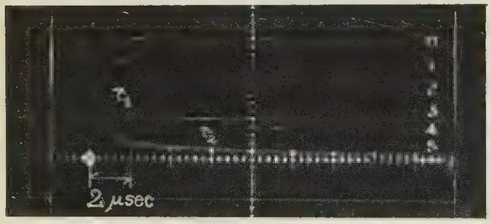

Photo. 1.

Fig. 1 (solid lines) shows the temperature dependence of decay time constants τ_1 and τ_2 in several samples. The temperature dependency of τ_1 was similar in all samples, which shows exponential decrease with decreasing inverse temperature, and τ_2 was rather temperature insensitive in this range. If we assume well known Shockley-Read formula[1)] of recombination in n-type high resistivity sample,

$$\tau = \tau_0 \exp\left[(E_t - E_f)/kT\right],$$

the value of $(E_t - E_f)$, namely the difference between trap level and Fermi level, was estimated from Fig. 1 as 0.052 eV. The dotted line in Fig. 1 shows the temperature dependence of the peak value of photoresponse induced by a 0.5 μsec Xe light pulse of a definite intensity. The photocurrent shows approximately similar temperature dependency to the time constant τ_1. It was proved that τ_1 is sensitive to the surface condition; τ_1 decreases to the half value when exposed to water vapor. The similar phenomena have been reported in CdSe crystals[2)].

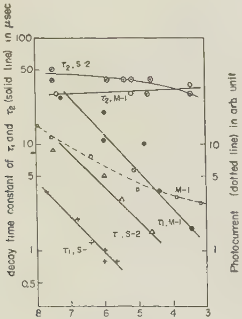

Fig. 1.

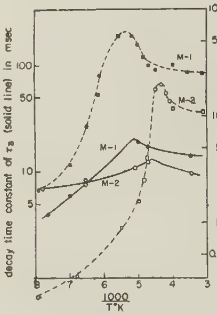

Fig. 2.

Fig. 2 (solid lines) shows the temperature dependence of τ_3 in M-1 and 2 samples, which have a maximum at about 200 °K. The dotted lines in Fig. 2 show the peak value of photocurrent induced by chopped light of 5 msec as a function of temperature, which show remarkable maximum also. We can see that the temperature dependence is similar in both curves.

To clarify the mechanism of the photocurrent decay, we are now proceeding our experiments to the effects of the wavelength, the ambients and the crystal imperfections.

Some Observations on Plastic Deformation and Slip Lines of Sodium Chloride Whisker

By Kan-Ichi KAMIYOSHI and Tsutomu YAMAKAMI

Research Institute for Scientific Measurements, Tohoku University, Sendai, Japan

(Received May 6, 1960)

According to the results obtained by Gyulai1), tensile strength of NaCl whisker was strongly dependent on size below 10 μ. Recently, Webb2) found that relatively large NaCl whiskers have low elastic limit but large plastic deformation, whereas whiskers with small cross-sectional area could be expected to show high elastic limit but brittle fracture.

The present authors have made the tensile test of NaCl whiskers which were prepared by the cellophane method following Amelinckx3), and have determined the relation between tensile strength and cross-sectional area (Fig. 1), and the relation between plastic deformation at fracture and cross-sectional area (Fig. 2). Though the experimental values differ considerably from one whisker to another, it may be seen from these results that the tensile strength increases rapidly when the cross-sectional area decreases to below 1×10^{-3} mm². On the contrary, the plastic deformation at first increases with decreasing cross-sectional area, but it decreases sharply to zero when the cross-sectional area decreases further. The point A in Fig. 2 represents the results that the plastic deformation is zero (elastic deformation only) in spite of high tensile strength (11 kg/mm²). Therefore, the property of NaCl whisker may be classified into three groups according to the size:

(1) high yield strength but brittle fracture (whiskers of very small size),

(2) low yield strength but large plastic deformation (whiskers of intermediate size), and

(3) low yield strength and small plastic deformation (whiskers of large size, or normal bulk crystal).

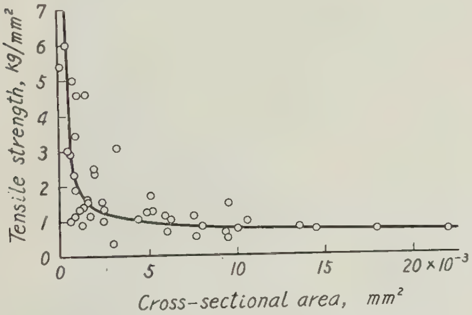

Fig. 1. Dependence of the tensile strength of NaCl whisker on the cross-sectional area.

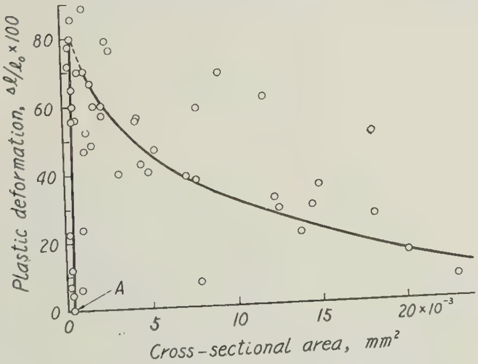

Fig. 2. Dependence of the plastic deformation of NaCl whisker on the cross-sectional area.

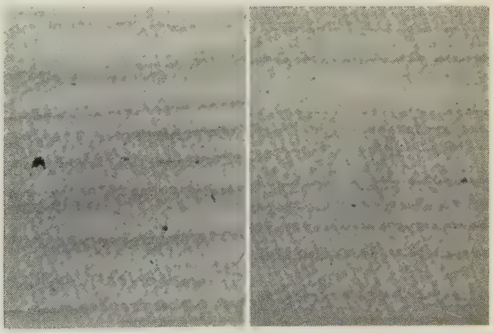
Plastic deformation produces the slip lines on the surface. They have been observed by optical microscope and by electron microscope. The slip usually occurs on the single set of (110) slip plane systems. Cross slips are rarely observed. The slip lines are, in some cases, straight and parallel (Fig. 3-b), but in other cases, they are wavy and the branching is observed (Fig. 3-a).



(a) (b)

Fig. 3. Electron micrographs of the slip lines of NaCl whisker. Cr-shadowing. (×2,000)

The authors wish to express their sincere appreciation to Mr. Yada for taking many electron micrographs.

The details of the present results will be published in Sci. Rep. of the Research Institute, Tohoku Univ.

Dislocation Etch Pits on *a*- and *b*-Faces of GASH Crystal

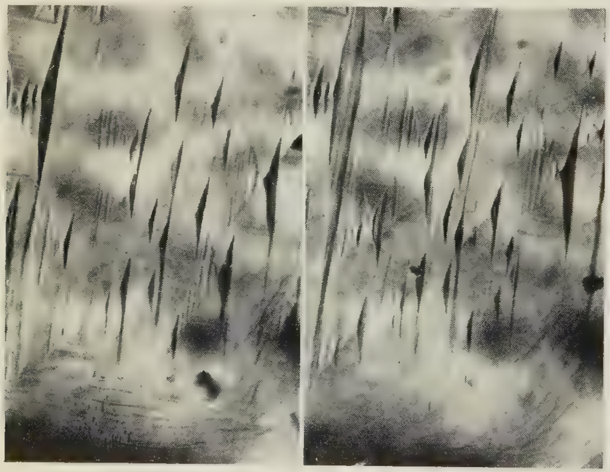
By Terutaro NAKAMURA and Kikuo OHI

Department of Physics, Ochanomizu University, Otsuka, Tokyo

(Received April 26, 1960)

Dislocation etch pits on cleavage surface (that is {0001} face) of ferroelectric GASH crystal has been reported by one of the authors[1]. Present paper reports the observation of etch pits on a surface of *a*- and *b*-plate crystals of GASH. GASH crystal is reported to have the space group $P\text{-}31m$[2] and grow in hexagonal prismatic form.

a- and *b*-plate crystals were cut out from as grown crystals by "thread-and-water-method", and etched by distilled water for about thirty seconds, followed by drying on some kind of blotting paper. Surface of the crystal cut by the thread-and-water-method is rather irregular. By the etching, however, the surface is smoothed out and rectangular etch pits shown in Fig. 1 are observed. Longer sides of the etch pits are of the order of 50μ and shorter sides 20μ. An etch pit has quadrangular pyramidal form, and the depth is of the order of a few microns. The deepest point is displaced by a certain amount from the center of the periphery of the etch pit. This assymmetry of the shape of the etch pit is accompanied by every pit and it can be detected that even the pit, which corresponds to the emergence point of dislocation running perpendicular to the surface of the crystal, is assymmetric. This assymmetry is due to crystal symmetry. *a*-axes of the crystal are defined as normals of edgs of a triangular etch pit on (0001) face, while *b*-axes are defined as normals of edges of a etch pit on $(000\bar{1})$ face, which is related to that on (0001) by two fold axes normals to the *a*-axes, following Wood[2]. The displacement of the deepest point on *a*-face is towards (0001) face and that on *b*-face is towards $(000\bar{1})$ face.



(a) (b)

Fig. 1. Photomicrograph of dislocation etch pits on *a* face. Face shown in (b) is about 50μ below (a), and obtained by continuous dissolution.

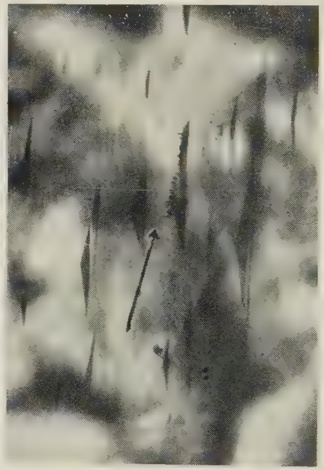


Fig. 3. Photomicrograph of dislocation etch pits produced by mechanical stresses.

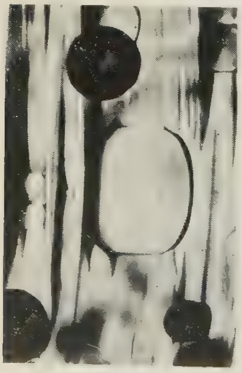

Fig. 2. Penetrating dissolution along the dislocation lines.

By dripping a drop of distilled water on the crystal, continuous change of etched surface is observed. In the dissolution process of the crystal, the etch pits stay at certain sites (Fig. 1. a, b), while shape and size is deformed gradually, untill the water is saturated and the dissolution ceases. In a subsequent addition of water drop, dissolution takes place again, and etch pits are formed at the same sites, as in the previous dissolution process.

By the continuous observation of the dissolution process of *a*- and *b*-cut plate crystals, spacial distribution of the dislocation lines was traced to a certain extent. When the dislocation runs obliquely to the surface of the crystal, it is observed that the pit moves during dissolution process.

When the dissolution process of thin crystal is observed, preferential dissolution takes place at the emergence points of dislocation lines on the top and the bottom surfaces of the crystal, until the “penetrating dissolution” results along the dislocation line (Fig. 2).

a- and *b*-faces of this crystal is mechanically shocked by a contact of point of a needle and etched. An example of this result is illustrated in Fig. 3. This result seems to indicate that dislocations are nucleated by the mechanical shock.

Linear array of etch pits are sometimes observed on *a*- and *b*-faces. It will be likely that some arrays of etch pits correspond to grain boundary.

Above mentioned aspects of the etch pits are quite in parallel with the dislocation etch pits on the cleavage surface of GASH crystal1), and we cannot avoid to conclude that the etch pits on the surface of *a*- and *b*-cut crystals also correspond to emergence points of the dislocation lines.

The pit density or *a*- and *b*-faces is generally of the same order or a little larger than on the cleavage face.

The crystal, in which the distribution of the dislocation lines is highly complex, does not exhibit *P*-*E* hysteresis loop but usual linear *P*-*E* relation. It seems very likely that the dislocation may have very interesting interactions with ferroelectric behavior of GASH crystal.

This work was finantially supported in part by the Grant in Aid from the Ministry of Education.

On A-centers in Colored KCl Crystals

By Hiroshi Ohkura and Katsunobu Awane

Department of Applied Physics, Osaka City University, Osaka Japan

(Received April 27, 1960)

Since the discovery by Petroff1), no further research for *A*-centers has been conducted within the color center research program. Recently, Hirai2) and Tomiki3) noticed the presence of *A*-centers when they carried out the optical absorption measurements at room temperature. We measured the *A*-band absorption at liquid air temperature. To avoid the coagulation of *F*-centers, specimens having low concentrations of *F*-centerswere used.

Single crystals of KCl made by the repetitions of the Kyropoulos method were colored additively. Optical absorption measurements and *F*-light irradiations were made by using the Hitachi EPU-2 type spectrophotometer. The wave-length of *F*-light used to convert *F*-centers to complex conters at room temperature was 530 mμ having band-width of 5 mμ so as not to excite the *A*-band.

At the early stage of *F*-light irradiation, the *A*-band increases exclusively together with a simultaneous rapid decrease of the *F*-band. A typical example of opitical absorption measurements of *F*-bleaching for KCl containing 1.5×10^{16}/cc *F*-centers is shown in Fig. 1, in which the solid curve shows the absorption curve before irradiation and dotted shows that after 30 min. irradiation with *F*-light. The peak of the *A*-band is located at 2.23 eV with half-width of 0.13 ev at liquid air temperature. With the successive irradiation with *F*-light, the *M*- and *R*-band appear and the *A*-band tends to vanish until *F*-bleaching reaction reaches its stationary state. The changes of peak heights of these bands are shown in Fig. 2 against the periods of irradiation with *F*-light.

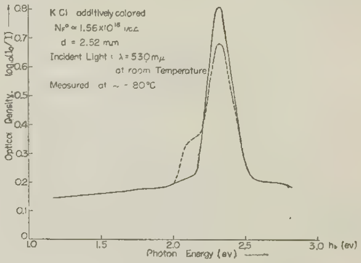

Fig. 1. Optical densities versus photon energies. Solid curve shows before irradiation with *F*-light. Dotted curve shows after 30 min. irradiation with *F*-light at room temperature. All measurements are carried out at liquid air temperature.

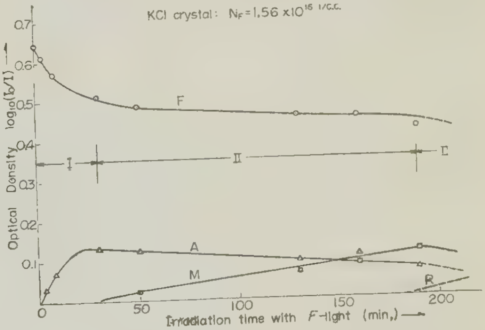

Fig. 2. Changes of peak height of optical density of various color centers versus irradiation periods of *F*-light at room temperature.

At the region I as shown in Fig. 2, products of absorption coefficients and the half-width of the

A-band are plotted against those decrements of the F-band in Fig. 3. If we assume a one to one conversion from F-centers to A-centers and further that the excited states of A-centeas do not overlap with F-band, we obtain a ratio of oscillator strength of the A- and F-band to be 0.62. from the gradient of Fig. 3. Thus we get 0.5C for f_A adopting $f_F=0.81$.

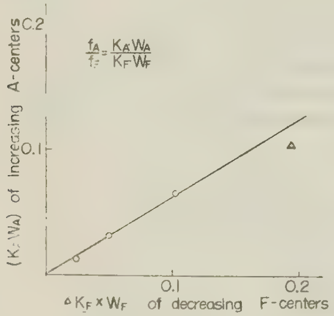

Fig. 3. Products of absorption coefficients and the half-width of A-band versus those decrements for F-band. ⊙: for the same sample as Fig. 1. and 2. △: for the sample having 4.0×10^{16} F-centers per cc. The gradient of this line shows the ratio of the oscillator strength of the A-band to that of the F-band.

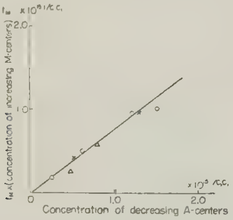

Fig. 4. The concentrations of increasing M-centers versus decreasing A-centers for various concentrations of F-centers. Ordinate is $f_M n_M$ and abscissa is $(N_{A_0}-N_A)$. ⊙; for the same sample as Fig. 1 and 2. △; for the sample having 1.6×10^{16} and ×; for 4.0×10^{16} F-centers per cc.

In the second stage (region II), linear dependence of the concentrations of decreasing A-centers upon those of increasing M-band was held till the R-band is enhanced by further illumination as shown in Fig. 4. Since the variation of the F-band in this region was insignificant, it may be concluded that the M-band appears at the expences of the A-band by F-irradiation.

The studies of the last stage (region III) has been already carried out by several authors[4].

We wish to express our thanks to Professor H. Kawamura for giving us his whole-hearted guidances in the course of this work.

This work was supported by the Scientific Rsesarch Fund of the Ministry of Education.

Absorption Band due to a Presence of Impurity Bromine in KCl Crystal*

By Koichi KOBAYASHI and Tetsuhiko TOMIKI

Department of Physics,
Tohoku University, Sendai

(Received April 27, 1960)

During the course of our study in preparing pure alkali chloride crystals, we have found an absorption band due to the presence of impurity bromine in KCl at the edge of its fundamental absorption. It is a purpose of this note to report it briefly.

Crystals studied are listed in Table I. These were grown in air by Kyropoulos technique. The crystal, KCl-aK-1, was made from KCl powder prepared from $KHCO_3$ and HCl[1]. KCl-HA-1 is a Harshaw crystal. Others were grown directly from KCl powders of reagent grade obtained from different sources. n/cc is a concentration of electric carriers estimated from low temperature ionic conductivity, which may be a measure of concentration of multivalent metallic ion impurities. The amount of OH ions was estimated optically from the absorption band at 204 mμ[2]. The concentration of bromine in the crystal was determined chemically[3] and is shown in mole fraction.

Table I.

Crystal	n/cc	OH/cc	[Br]
KCl-aK-1	1×10^{15}	2×10^{15}	9×10^{-6}
KCl-HA-1	9×10^{15}	8×10^{15}	7.1×10^{-5}
KCl-bc2K-1	8×10^{15}	2×10^{15}	1.1×10^{-4}
KCl-bK-1	4×10^{15}	2×10^{15}	1.3×10^{-4}
KCl-dK-1	7×10^{15}	2×10^{15}	3.6×10^{-4}
KCl-bc2K-2	1×10^{16}	2×10^{15}	8.1×10^{-4}

Absorption curves at the fundamental absorption edge were measured at 12°C. Those are shown in Fig. 1. The reflection loss was considered for

---

* A part of the present work has been carried out during our temporary stay in Prof. Kanzaki's laboratory of the Institute for Solid State Physics, University ofTokyo.

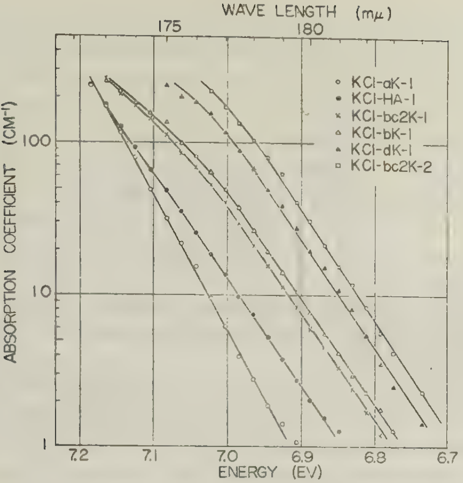

Fig. 1. Absorption curves of KCl crystals.

correcting data. It may be seen from this figure and Table I that the location of the edge does not depend upon the concentration of multivalent metallic ion impurities or hydroxyl ions, but is related to the bromine concentration in such a way that it is shifted to longer wave length side with an increase of bromine concentration.

Results in Fig. 1 suggest a presence of a unique absorption band at the edge. Curves in Fig. 2 were obtained by subtracting the absorption curve for KCl-aK-1, which contains the least bromine, from curves for other crystals. They are bands which grow certainly with an increase of bromine concentration. Therefore, one may conclude that they are due to the presence of bromine in KCl. The half width characteristic of these bands is found to be 0.18 eV if their shape is symmetric. The oscillator strength is estimated roughly as 0.07 assumed that the absorption is due to bromine itself. The long wave length side of this band below one third of its maximum fits nicely to the Urbach rule of constant temperature.

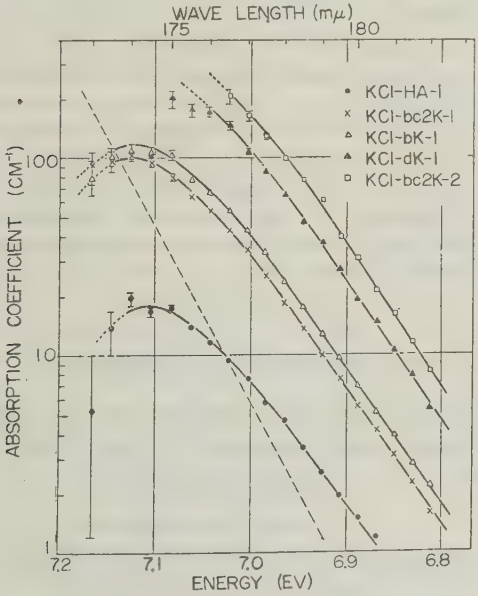

Fig. 2. Absorption bands due to the presence of bromine in KCl. The fundamental absorption edge for KCl-aK-1 is shown as a broken line.

We wish to thank Professor M. Ueta for giving us an opportunity to use his spectrometer and to Professor H. Kanzaki and Mr. S. Tamura for their helpful discussions. A part of this work was supported by the Research Grant from the Ministry of Education.

Induced Magnetic Anisotropy of Evaporated Ni–Fe Films

By Minoru TAKAHASHI, Denjiro WATANABE
Tatsuo KŌNO and Shiro OGAWA

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received May 7, 1960)

The systematic and detailed study on the induced magnetic anisotropy of evaporated films of metals and alloys has recently done by Andrä *et al.*[1], but any quantitative and direct measurement of the anisotropy of Ni–Fe alloys has never been carried out over a wide range of Ni composition. It has been, therefore, desired to study the magnitude and the composition dependence of induced magnetic anisotropy of these evaporated alloy films.

The alloy films were evaporated on a quartz plate under a magnetic field of $H_a=250$ Oe.. The thickness was kept at 600 Å. The apparatus for measuring the torque is the same as reported before[2]. Some examples of torque curves are shown in Fig. 1 for 65% Ni–Fe films. Each torque curve represents an average value of two curves which were measured clockwise and counter-clockwise. The rotational hysteresis loss, $W_r=-\int_0^{2\pi} L d\theta$, is plotted against the measuring field in Fig. 2. As seen from Figs. 1 and 2, the torque curves are considerably deformed at the field strength corres-

×; Temperature of substrate is at 300°C.
△; The substrate was held at 300°C, heated to 450°C and annealed at this temperature for 2.5 hours in magnetic field.

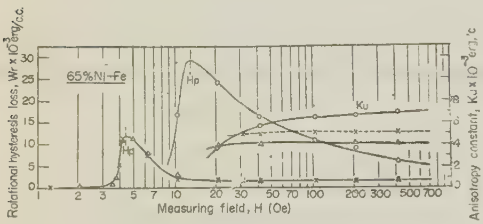

Fig. 2. Rotational hysteresis loss and anisotropy constant as a function of field strength in measurements. Meaning of the marks is the same as in Fig. 1.

ponding nearly to the peak of the rotational loss $(H_p=2K_u/I_s\approx H_c)$. At very low field on the other hand, the curves are almost unidirectional and are expressed in $K_1\sin\theta$. As the field strength increases ($>H_p$), the torque curves begin to be proportional to $\sin 2\theta$. These facts are analogous to the case of small particle permanent magnet[3]. The torque curves corresponding to the field strength more than 20 Oe were analyzed by the Fourier method, and values of the coefficient of $\sin 2\theta$ were shown in Fig. 2. As seen from this figure, K_u is not saturated even at 400 Oe for the films evaporated on the substrate held at room temperature. Therefore the saturated values of K_u were obtained by extraporation to the infinite measuring field. These saturated values are plotted in Fig. 3, where the curve obtained by Chikazumi[4] for bulk specimens is also illustrated. The interesting features are as follows: (i) The anisotropy values are extremely large in thin films and the maximum value exists at 50% Ni-Fe. The

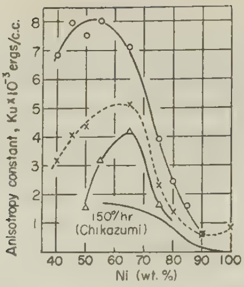

Fig. 3. Uniaxial anisotropy constant against Ni composition. Meaning of the marks is the same as in Fig. 1.

substrate was held at room temperature in this case. (ii) When the substrate was held at 300°C on evaporation and cooled or annealed at 450°C for 2.5 hours after evaporation, the maximum value is displaced to 65% Ni-Fe.

The origin of the extremely large value and large sensibility to heat treatment of the anisotropy may not be explained by the atomic pair orientation theory alone[5]. The detailed report will be published in the near future.

Fixing of Magnetic Moment of Ferromagnetic Fine Precipitates in Cu-Co Alloy during Aging

By Kazuo KOBAYASHI

Geophysical Institute, University of Tokyo

(Received May 13, 1960)

Recent investigations[1),4)] have shown that, in the isothermal aging of Cu-Co alloy, the separation of Co-rich ferromagnetic phasme fro the nonmagnetic Cu matrix is completed in the initial stage of precipitation, and with increasing time the average particle size increases in such a way that the total volume of precipitates remains constant. It has been concluded that the particles are first superparamagnetic, then stable single domains and finally become multidomain particles. In the present study this sequence of magnetic behaviours has been examined more explicitly by a successive measurement of both reversible and remanent magnetizations during annealing in various intensities of magnetic field.

The specimen containing ca. 2wt% Co, balance Cu was formed into a rod of about 4 cm in length, 0.8 cm in diameter and was appropriately heat-treated to form a uniform solid solution. Measurements were made with a high temperature ballistic method during the annealing at 750°C in various intensities of magnetic field up to 500 Oe.

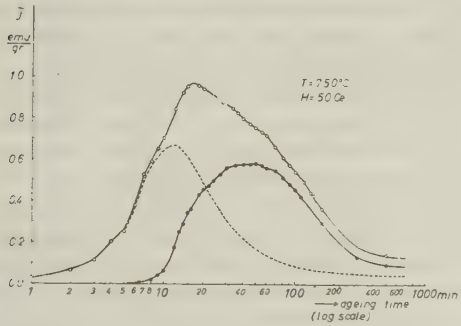

Fig. 1. Change of total, remanent and reversible component of magnetization (hollow and solid circle and broken line, respectively) as a function of aging time.

Fig. 1 shows an example of these measurements. Reversible magnetization due to superparamagnetism (except in later stages of precipitation) is assumed to be equal to the difference between the magnetization with applied field and remanent magnetization. It is noted that the intensities of superparamagnetism and remanent magnetization arrive at their maximum values after constant time of aging, almost independently of the intensity of the applied field. The curves show that the magnetic moments of precipitated particles are fixed along the direction of the magnetic field within a short time interval after the appearance of the maximum superparamagnetism, and the remanent magnetization first increases and then gradually decreases as a result of the formation of magnetic domains.

Fixing of magnetization of the system of superparamagnetic particles may be interpreted in terms of so called "freezing" of magnetization in the similar form as the theory of thermoremanent magnetization given by Néel²⁾, as already suggested by Haigh³⁾. Néel derived the following formula of relaxation time τ for the reversal of spontaneous magnetization of single domain grains due to the thermal Brownian agitation in zero field;

$$\frac{1}{\tau}=f_0\exp\left(-\frac{Kv}{kT}\right).$$

In this expression, v is the volume of the particle, K the anisotropy per volume, f a frequency factor of the order of $10^{-9}\,\mathrm{sec}^{-1}$. Because of the exponential dependence of τ on v/T, there is a fairly well defined value of $\alpha_c=(v/T)_c$ at which the transition from $\tau\ll t$ to $\tau\gg t$ occurs (t; time for experiment). When $v/T<\alpha_c$ the magnetization of each grain is aligned statistically along the direction of applied field in a manner analogous to the Langevin paramagnetism of moment-bearing atoms. This state of magnetization is frozen and memorized when v/T exceeds α_c on the account of the decrease in temperature or owing to the growth in the size of the particles. The former is the case treated by Néel, while the latter will be the case of the remanent magnetization observed in the present study.

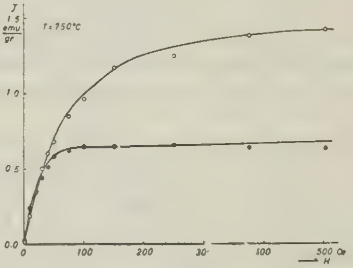

Fig. 2. Field dependence of peak intensities of superparamagnetism (hollow circles) and remanent magnetization (solid circles).

Field dependence of maximum intensities of superparamagnetism and remanent magnetization is shown in Fig. 2. It is remarkable that the intensity of remanent magnetization approaches saturation in an applied field below 100 Oe, which is very weak compared with the coercive force of the alloy in a magnetically-stable stage (several hundreds oersted, by Mitui⁴⁾). This fact also indicates that the remanent magnetization is due to the freezing mechanism.

The analysis of the present study can be extended to the interpretation of some problems in rock-magnetism, especially to that of chemical remanent magnetization of ferromagnetic minerals. Detailed consideration, however, will be discussed elsewhere⁵⁾.

Ferrimagnetic Resonance in a Single Crystal of Europium-Iron Garnet

Tomonao Miyadai, Hisao Takata
Yūzō Shichijō
Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Musashino-shi, Tokyo, Japan
and Noboru Tsuya
Research Institute of Electrical Communication, Tohoku University, Sendai, Japan

(Received May 25, 1960)

It was shown previously by us[1] that the g-value of polycrystalline europium-iron garenet ($Eu_3Fe_5O_{12}$) has an appreciable temperature dependence and the full line width (~1200 Oe at room temperature) increased rapidly at low temperatures. Data are now taken for a single crystal specimen, and these have shown good agreements with the recent theory of Kittel[2][3] on the ferrimagnetic resonance in garnets.

Measurements were made on a single crystal sphere of 0.59 mm in diameter in the temperature range between liquid nitrogen and Curie point (~300°C). The microwave frequency used was 18,320 Mc/sec. The sample was mounted such that it could be rotated about a <110> direction.

g-values and K_1/M_s were calculated from the resonance fields for three principal axes[4] and are shown as functions of temperature in Fig. 1.

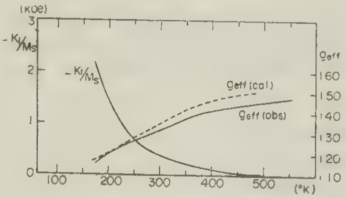

Fig. 1. g_{eff} and $-K_1/M_s$ (cubic anisotropy field) *vs* temperature, dashed curve represents the calculated one by Kittel's formula.

Below room temperature, g-values for the single crystal are slightly smaller than those for polycrystalline sample and show a somewhat stronger temperature dependence; this is a conclusion derived from Schlömann's theory[5] on internal fields for ferromagnetic reasonance in polycrystalline ferrites. K_1/M_s of *EuIG* is negative and an order or more larger than that of YIG. The line width varies with temperature as shown in Fig. 2. Although, in all temperatures investigated, $\Delta H_{<100>}$ seemed to be the narrowest, differences among the line widths for three principal axes are within the experimental errors (~10%) except near −70°C where $\Delta H_{<111>}$ is fairly broader than the others.

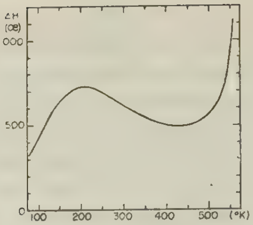

Fig. 2. Line width ($\Delta H_{<111>}$)*vs* temperature.

The line width at room temperature is about 600 Oe and equal to half the one for polycrystalline sample.

Both the g-value and its temperature variation can be explained very well by Kittel's theory which assumes that the spins of rare earth ions are highly damped while ferric ion spins are not. Kittel's theory[2] predicts that the effective g-value for ferrimagnetic resonance in garnets is expressed by $g_{eff}=g(Y)\{M_s(M)/M_s(Y)\}$ where M_s is the saturation moment and Y refers to *YIG* and M to *MIG*. In Fig. 1 is also shown g_{eff} for *EuIG* calculated by the above relation using the data[6] for the saturation moments of *YIG* and *EuIG*. As can be seen, the calculated and the observed curves are in good agreement. Kittel's theory[3] further predicts that the line width increases with increasing temperature at low temperatures, passes through a maximum, then decreases and at last increases rapidly just below the Curie temperature. The observed line width for *EuIG* shows the same temperature dependence as thetheory predicts.

Kittel noted that the theory does not apply to the ions in $L=0$ or $J=0$ states. Since the ground state of Eu^{3+} has $J=0$, the theory would not apply. The theory, however, seems to hold very well in the case of *EuIG* as described above. It may be expected that excited states with $J\neq 0$ are mixed with $J=0$ ground state.

The authors wish to express their thanks to Mr. T. Ito of Nippon Television Company for measurements.

Electrical Properties of Chromium Sulfides

By Takahiko KAMIGAICHI, Kan-ichi MASUMOTO
Minami Brach, Hiroshima University
and Tadamiki HIHARA
Department of Physics, Hiroshima University

(Received May 17, 1960)

The electrical conductivity and the thermoelectric power of chromium sulfides, CrS_x with $1.00 \leq x \leq 1.20$, were measured between the liquid nitrogen temperature and 600°C in order to clarify the mechanism of conduction in these materials.

The specimens were prepared in the following way. A proper quantity of chromium metal blocks and sulfur powder were put into an evacuated silica tube, and then the tube was heated at 1000°C to make a direct reaction between chromium and sulfur.

The specimens thus obtained were examined by means of X-ray. The specimens with $1.00 \leq x \leq 1.13$ have two phases of the monoclinic and the NiAs structures, and those with $1.14 \leq x \leq 1.20$ a single phase of the NiAs structure. These results are in agreement with those obtained by Jellinek[1]. For all the specimens a superlattice structure was found, the unit cell of which was twenty four times $((2\sqrt{3}\,a)^2 \times 2c)$ as large as that of the pure NiAs structure, a and c being the lattice constant in the hexagonal lattice and given by 3.47 Å and 5.75Å, respectively. This superlattice structure is the same as that previously reported by Haraldsen[2] and Yuzuri et al.[3]

The specimens with $x \leq 1.12$ are p-type semiconductors ($10^{-1} \sim 1$ ohm^{-1} cm^{-1}) at room temperature, but their conductivities increase about 10^3 times between 300°C and 500°C. On the other hand, those with $x \geq 1.13$ are metallic conductors (10^3 ohm^{-1} cm^{-1}) with negative thermoelectric powers. Some results of electrical conductivity and thermoelectric power measurements are shown in Figs. 1 and 2. In order to clarify the nature of the anomalous increase of conductivity with increasing temperature for $x \leq 1.12$, a powder photograph of $x = 1.00$ was taken at 570°C. It showed patterns of pure NiAs structure with $a = 3.44$ Å and $c = 5.63$ Å. This results indicates that the anmalous increase of conductivity is due to the transition from the two phases of the monoclinic and the NiAs structures to the single phase of the pure NiAs structure. Similar X-ray analysis of $x = 1.17$ at 570°C showed that the superlattice structure vanishes and the specimen also has the pure NiAs structure.

The poor conduction in the two-phase region may be ascribed to the monoclinic structure in which the ionic binding might play a predominant role. The metallic conduction in the NiAs structure is due to the increase in the covalent or metallic nature of bonding in this structure.

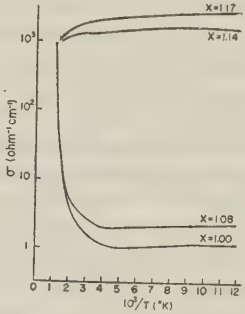

Fig. 1. Electrical conductivity of CrS_x as a function of temperature.

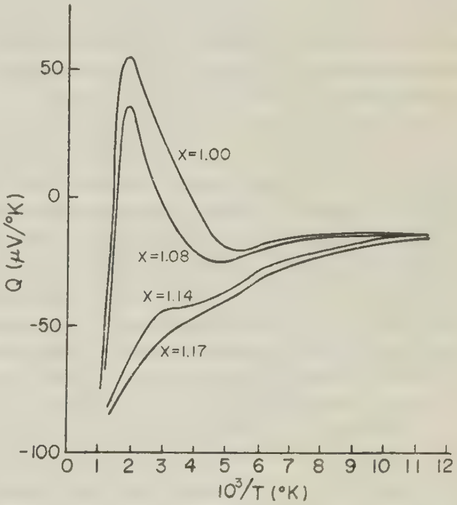

Fig. 2. Thermoelectric power of CrS_x with respect to copper as a function of temperature.

It is to be noted that the conductivity of $x = 1.17$ does not show even slightest anomalies at −120°C where the ferrimagnetism disappears suddenly.

The authors wish to thank Prof. H. Tazaki for his interest and encouragement and Prof. E. Hirahara for the allowance for using the high temperature X-ray camera.

Exciton-Induced Photoconductivity of U Centers in KCl Crystal

By Masayasu UETA and Masamitsu HIRAI

Department of Physics, The Faculty of Science, Tohoku University, Sendai

(Received May 25, 1960)

Previously[1] we have reported on the measurement of the quantum efficiency of the exciton-induced photo-chemical conversion of a *U* center to an *F* center, and it was determined to have a value of nearly unity with light of wavelength shorter than 183 mμ and 203 mμ in KCl and KBr crystals, respectively. These wavelengths are in the exciton absorption band of the crystals.

Several mechanisms of the exciton energy-transfer to *U* center are considered; i.e., ionization, excitation or thermal destruction with the thermal spike as proposed by Seitz[2]. Photoconductivity measurements will be valuable to make choice of the most probable mechanism among them.

A KCl crystal (Harshaw Chemical Co.) of $10\times10\times1.4\,\text{mm}^3$ containing *U* centers with a concentration of 4.3×10^{17}/c.c. was clamped between electrodes and an electric field of 1400 volt/cm. was applied to it. Light illuminations were performed along the direction of the electric field through holes drilled in one electrode. The ultra violet light from a hydrogen discharge lamp was monochromated with a vacuum grating monochromator. The purity of the monochromatic light was 1 mμ and the intensity was the order of 10^{11} and 5×10^{11} photons/cm^2. sec. in the region of 170 mμ-200 mμ and 200 mμ-240 mμ, respectively. Photocurrents were measured with a Cary Model 31 vibrating reed electrometer. When the photocurrent was below 5×10^{-14} amp., the polarization effect was negligibly small.

Curve (A) in Fig. 1 is a result showing the photocurrent as a function of photon energy of the illuminating light at the room temperature in a virgin KCl crystal containing *U* centers. Curve A in Fig. 2 shows the spectral distribution of photocurrent obtained from curve A in Fig. 1, with corrections of light intensity and the absorption spectrum of the crystal.

For the comparison, the spectral distribution of the quantum efficiency of $U\rightarrow F$ conversion by light was referred in Fig. 2 curve B, which was reported previously. From these figures, it is seen that the correspondence between the spectral variations of the photoconductivity and the quantum efficiency of the photo-chemical conversion of $U\rightarrow F$ is quite satisfactory. Therefore, the conversion of $U\rightarrow F$ by the exciton will be due to the induced ionization of *U* centers.

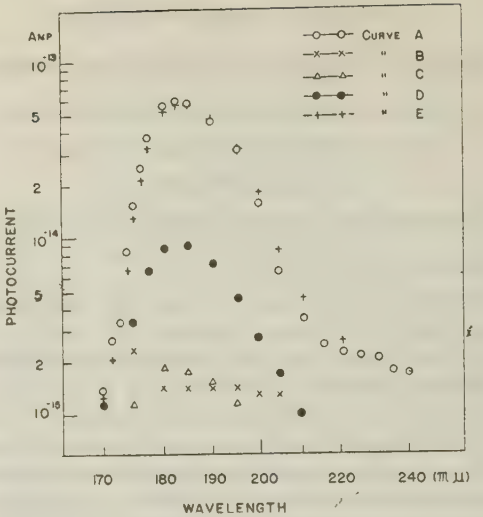

Fig. 1. Photocurrents in KCl crystal containing *U* centers at 20°C.

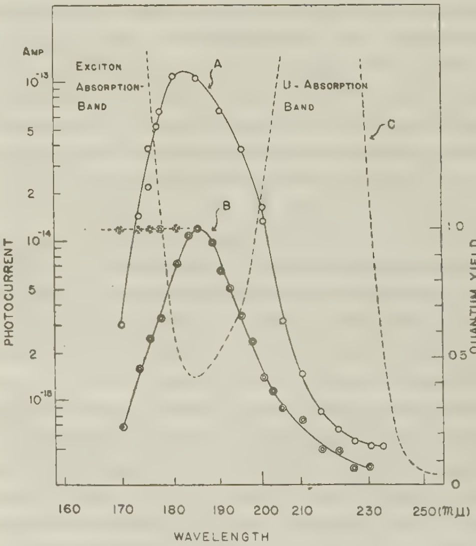

Fig. 2.

Curve A: Spectral distribution of photoconductivity.

Curve B: Spectral distribution of quantum efficiency of the photo-chemical $U\rightarrow F$ conversion.

Curve C: Absorption curve of the KCl crystal containing *U* centers.

When the crystal was suffered from long period illumination of ultra violet lights from the hydrogen lamp through a fused quartz window, more than 50 per cent of *U* centers were converted to *F* centers. In this crystal, the photoconcuctivity was found to decrease to quite a small value as shown in Fig. 1 curve B. If the crystal was successively illuminated by white light, *F* centers disappeared and the concentration of *U* centers recovered to the initial state. In spite of the *U* center recovery, the photoconductivity was still small as shown in curve C. However, after the crystal was annealed at 200°C for one hour, photoconductivity began to recover as shown in curve D, and after the thirty hours' annealing at the same temperature, it was found to have nearly the same photocurrents as the initial virgin crystal as shown by curve E.

In a crystal containing OH ion the photocurrent was not detected.

The results of very small photoconduction in the crystal treated optically in such a manner as $U \rightarrow F \rightarrow U$, and the recovery with annealing, will be attributed to the formation of vacancies and some other imperfections by the irradiation of ultra violet light. These imperfections will be effective to the trapping of electrons released from U centers and will cause the shortening of the Schubweg of electrons.

A full report will be submitted in this journal.

Errata

Excitation Functions for Alpha-Induced Reactions on Manganese-55

By Sigeo TANAKA, Michiaki FURUKAWA, Takashi MIKUMO, Shiro IWATA
Masuo YAGI and Hiroshi AMANO

J. Phys. Soc. Japan **15** (1960) 545

The measured cross sections for the reactions resulting Mn^{54}, Co^{58}, and Co^{56} (in Figure 3 and Figure 4) should be multiplied by 1.23, 1.23, and 1.67, respectively. The disintegration rates of Mn^{54}, Co^{58} and 1.67, respectively. The disintegration rates of Mn^{54}, Co^{58} and Co^{58} and Co^{56} were calculated from the γ-ray measurement in a poorly defined geometry (in § 3 on p. 548). However, it has become clear from the present authors' subsequent work that the calculated photopeak efficiency (the 26th to the 32nd line from the top on p. 546, right) is not correctly applicable to this experiment. The above corrections are based on the γ-ray measurements calibrated by the various standard sources, the disintegration rates of which have been determined by a γ-γ coincidence counting and a $4\pi\beta$-counting.

Angular Distribution of n-p Scattering at 14.1 MeV

By Teruo NAKAMURA

Department of Physics, Faculty of Science, Kyoto University

(Received April 18, 1960)

The angular distribution for the scattering of neutrons by protons was obtained at 14.1 MeV by observing the recoil protons by the use of a counter-telescope consisting of a polyethylene target, two proportional counters and a CsI scintillator. The data obtained at scattering angles of 165°, 146°, 118° and 89° in C.M.-system were given with statistical errors of about 1%. The ratio of the cross sections at 180° and 90° in the center-of-mass system was found to be 1.080 ± 0.016 from a least square fit to the form $A+B\cos^2\theta$. Therefore it may be concluded that anisotropy of the angular distribution is confirmed quite clearly.

The absolute values of differential cross sections at various angles were normalized using the total cross section 689 ± 5 mb measured by transmission. The values are in good agreement with the results predicted from the nuclear potentials with "one-pion-exchange-tail" proposed by members of the Nuclear Force Group in Japan.

§ 1. Introduction

Hitherto the angular distributions of fast neutrons scattered by protons were studied by many authors[1] to obtain the information about the nature of the interaction between neutrons and protons. All experimental results in the energy range of less than 10 MeV are consistent with the assumption of spherically symmetric scattering predicted by theories[2]. For neutron energies above 10 MeV appreciable deviation from symmetry is predicted, depending upon the nature of the forces assumed for the neutron-proton interaction, and was confirmed quite clearly by experiments at somewhere above 10 MeV neutron energy. At 17.9 MeV the ratio of the neutron scattering cross sections at 180° and 90° in the center-of-mass system has been reported as 1.08 ± 0.03 by Galonsky and Judisch[3]. The ratio becomes more larger as the neutron energy increases, and has been reported as 3.15 ± 0.10 at 90 MeV by Stahl and Ramsey[4].

At the neutron energies in the region between 10 and 15 MeV, however, it seems that no decisive conclusion has been obtained, although some reports[5] have been presented.

The present work was undertaken to obtain more reliable information about the anisotropy of the angular distribution of neutrons scattered by protons, using a counter-telescope under an improved condition of decreasing systematic and statistical errors. Furthermore, another purpose of the present work is to check the nuclear potential with "one-pion-exchange-tail" proposed by members[6] of the Nuclear Force Group in Japan.

§ 2. Experimental Apparatus and Procedure

The experimental arrangement is shown schematically in Fig. 1. Neutrons were provided by the T-d reaction, employing magnetically analyzed atomic deuteron of 300 keV

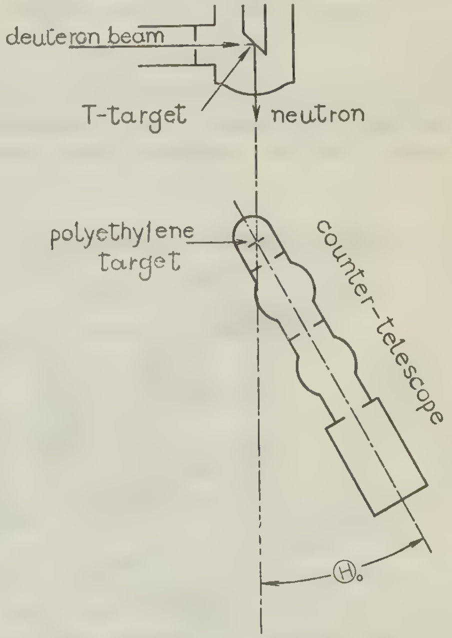

Fig. 1. Experimental arrangement (schematically).

from a Cockcroft-Walton machine. The tritium target consisted of 14 curies absorbed in a 6.6 mg/cm^2 titanium thick foil and was bombarded with a steady beam of several μA. Neutron production was estimated to be about 5×10^8 neutrons/sec. Neutron flux was monitored by counting the recoil alpha particles from the $T(d, n)He^4$ reaction using a proportional counter filled with argon and 5% CO_2 at a pressure of 38 cm Hg. The monitor counter was placed at 150° direction with respect to the deuteron beam. A typical pulse-height distribution of the alpha particles is shown in Fig. 2. During the experiment, all pulses above a certain bias (shown by an arrow in Fig. 2) were counted for monitoring neutron flux.

The interaction of neutrons with protons was studied by observing recoil protons originating in a polyethylene foil in the counter-telescope. The polyethylene target was located at a distance of 14.8 cm from the neutron source, and at 90° direction with respect to the deuteron beam. At this position the incident neutrons were monoenergetic with an energy of 14.10 ± 0.05 MeV. The counter-telescope was mounted on an indexed stand and could be rotated in a horizontal plane about a vertical axis lying in the plane of the polyethylene foil. The foil was 2.45 cm in diameter, and 10.1 mg/cm^2 in thickness. It was backed by a lead sheet (1 mm) to reduce the background. A small bar magnet was mounted on the top of the axle, at the other end of which was the polyethylene target. And the bar magnet allowed the target to be rotated inside the counter-telescope by means of an external magnet in order to expose either the polyethylene foil or the lead blank to the counters and the scintillator of the instrument.

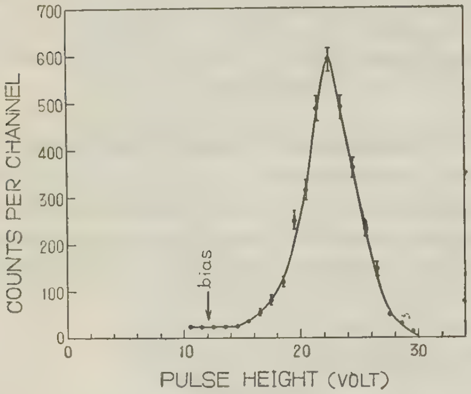

Fig. 2. Pulse-height distribution of alpha particles from the $T(d, n)He^4$ reaction in the monitor counter. Bias limit is indicated by an arrow.

The counter-telescope consisted essentially of two proportional counters and a CsI scintillation crystal with light-pipe coupling to a photomultiplier as shown in Fig. 3. Neutrons impinge on the polyethylene target and recoil protons emitted along the telescope axis travel through the two counters and strike the CsI crystal of the scintillation detector.

The proportional counters were filled with argon and 5% CO_2 at a pressure of 7.6 cm Hg. They were made of brass cylinders, and the inner wall of the first counter was lined with a lead sheet (1 mm) to reduce the background of charged particles produced in the wall.

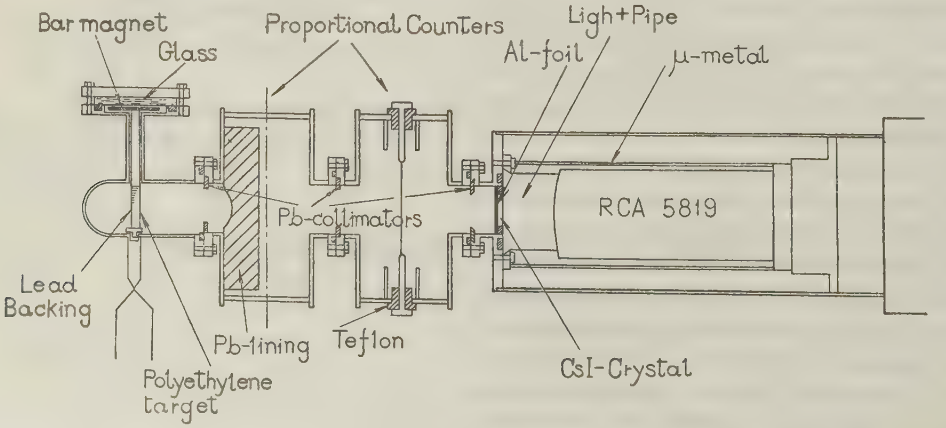

Fig. 3. Counter-telescope.

The CsI crystal was in the form of a disk of 2.5 cm in diameter and 1 mm in thickness. The crystal was pasted with grease on the surface of the lucite light-pipe leading to the photocathode of an RCA type 5819 photomultiplier.

The pulses resulting from the ionization in the two proportional counters and from the scintillation in the CsI crystal were amplified and fed into a triple coincidence circuit. The coincidence output pulses opened the gate of a ten channel pulse-height analyzer in time to receive the delayed pulse-height representations of the scintillation detector. A schematic representation of the counters and the associated electronics are given in Fig. 4. Overall stability of their electronic circuits was found to be sufficiently good and the fluctuation did not exceed 2% a day.

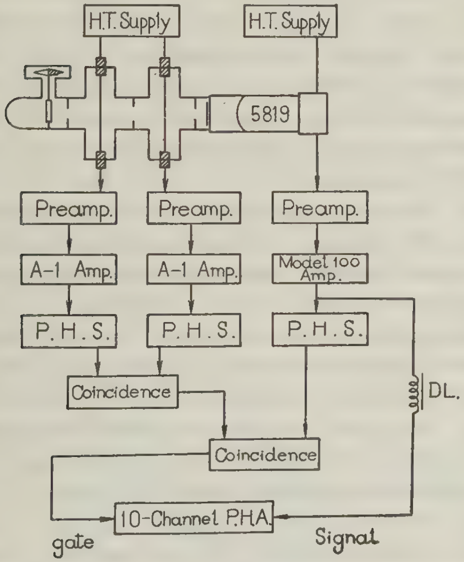

Fig. 4. Schematic representation of the counters and the associated electronics.

In the present work the coincidence counting rate of the counter-telescope was about one count per second, with single counting rates of about 900, 600 and 15 per second in the proportional counters and the scintillation detector, respectively. Therefore, the counting rate of the accidental coincidence was estimated to be less than 10^{-3}/sec from the resolving time of the coincidence circuit. The ratio of the background in the coincidence counts to the true counts of recoil protons from the polyethylene target was measured to be about few per cent from the blank test.

For the test of the proportional counters, the pulse-height distribution of "*dE*/*dx* pulses" of recoil protons in a proportional counter was taken by the ten channel pulse-height analyzer gated by triple coincidence pulses. The pulse-height distribution obtained is in agreement with a Landau curve7) as shown in Fig. 5. During the experiment, all pulses above a certain bias (shown by an arrow in

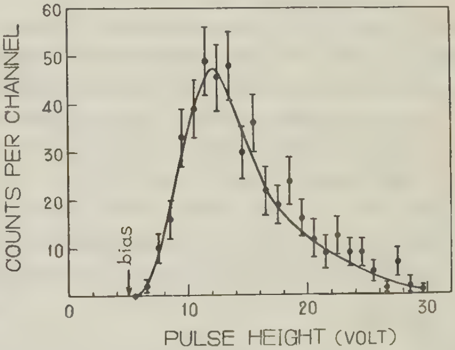

Fig. 5. Pulse-height distribution of "*dE*/*dx* pulses" in a proportional counter. The smooth curve represents the distribution calculated from the Landau and Symon theory.

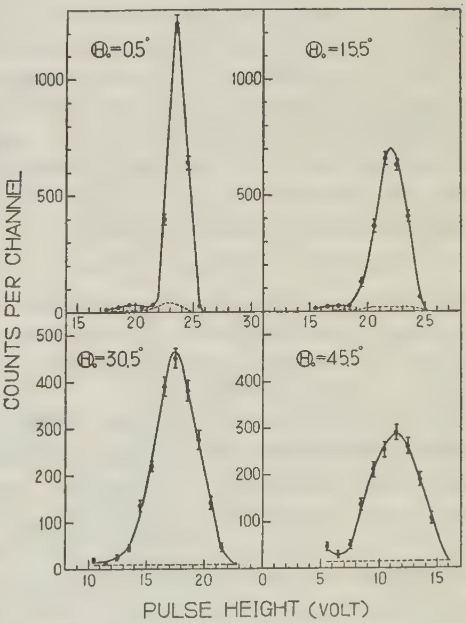

Fig. 6. Typical pulse-height distributions of recoil protons at various angles. Dashed curves represent backgrounds measured by the blank test.

Table I. Total counts of recoil protons at various angles.

Fig. 5) were fed to the coincidence circuit.

Typical data of the pulse-height distributions of recoil protons are shown in Fig. 6 for various setting angles of the telescope axis. Counts per each channel shown in Fig. 6 are total counts of several runs. In a run the data of all angles were taken for about one hour in order to minimize the relative errors of the differential cross sections.

§ 3. Results

Total counts of recoil protons at various angles are shown in Table I. In order to convert the differential cross sections per unit solid angle in the laboratory system to that in the center-of-mass system, they are roughly divided by $4\cos\Theta_0$, where Θ_0 is the setting angle of the counter-telescope axis with respect to the direction of incident neutrons. For exact conversion, however, the correction for the finite size of the polyethylene target and the aperture of the detector is necessary. Then the differential cross sections in the C.M.-system can be calculated from

$$\sigma_{\mathrm{C.M.}}(\theta)=\sigma_{\mathrm{lab}}(\Theta_0)/4\cos\Theta_0\cdot C(\Theta_0)\,, \qquad (1)$$

where $C(\Theta_0)$ is the correction factor for the finite size of the target and the aperture of the detecting system, and is explicitly formulated in Appendix of this paper.

In the first place, the relative differential cross sections in the C.M.-system at various angles were obtained and the angular distribution could be fitted to $1+(0.080\pm0.015)\cos^2\theta$ from a least square analysis to the form $A+B\cos^2\theta$, where the error of anisotropic term (±0.015) was originated only from statistical errors. Although other errors which affected the relative values of the cross section seemed to be negligible at small angles ($\Theta_0=0.5°$ and 15.5°), at large angles ($\Theta_0=30.5°$ and 45.5°) they were as follows:

(1) Correction factor $C(\Theta_0)$ for the finite solid angle of the counter-telescope. Equation (A-5) in the appendix was derived almost exactly, and the uncertainty of the factor $C(\Theta_0)$ was estimated to be less than 0.1%. The relative errors introduced were negligible.

(2) Setting angle Θ_0 of the counter-telescope axis with respect to the direction of the center line of the neutron source and the polyethylene target. The uncertainty of the direction of the center line was 0.1°. The relative errors introduced were 0.1% and 0.2%, respectively.

(3) The deviation of the center of the polyethylene target from the turning axis of the counter-telescope was measured as 0.35 ± 0.3 mm by a cathetometer. The errors were estimated to be about 0.1% at $\Theta_0=45.5°$ and were negligibly small at other angles, after the corrections of about 0.2%.

(4) Degraded neutrons originated by scattering from the target box surrounding the neutron source contributed by about 1% to the counting rate of recoil protons. This value was estimated from the analysis of the low energy tails of the pulse-height distributions at $\Theta_0=0.5°$ and 15.5° (see Fig. 6). The relative errors arising from these degraded neutrons were estimated to be less than 0.3% at $\Theta_0=45.5°$ and 30.5°.

(5) The other degraded neutrons scattered by other matters such as the floor, walls and ceiling of the laboratory could not be evaluated definitely, but the relative errors arising from these may be thought less than 0.5% at $\Theta_0=$ 45.5° and 30.5°.

Thus, the combined rms errors of the relative differential cross sections at $\Theta_0=30.5°$ and 45.5° were estimated to be 1.2% and 1.4%, respectively. The uncertainty of the anisotropic term of the angular distribution was derived to be 1.6% by a least square analysis where the values with errors estimated above were used. Therefore, the ratio of neutrons scattering cross sections at 180° and 90° was calculated to be 1.080 ± 0.016.

Table II. Differential cross sections per unit solid angle of *n-p* scattering at 14.1 MeV (in C.M.-system) obtained by the normalization to 689 mb of total cross section measured by transmission. The errors indicated in this table do not include the uncertainty due to the error of the total cross section 689 ± 5 mb of *n-p* scattering.

θ	165°	146°	118°	89°
$\sigma(\theta)$ (mb/sterad.)	59.1 ± 0.6	58.3 ± 0.6	56.2 ± 0.6	55.0 ± 0.7

Final results of the differential cross sections in the C.M.-system are shown in Table II and Fig. 7. The absolute values of differential cross sections were normalized using the total cross section 689 ± 5 mb measured by transmission[8]. At the normalization the angular distribution of scattered neutrons was assumed to be of the form resulted from the pion theory (see § 4 below) rather than the form $A + B\cos^2\theta$. The errors indicated in Table II and Fig. 7 do not include the uncertainty arising from the error of the total cross section, but they were statistical errors only.

§ 4. Discussion

In Table III, the ratio of the cross sections at 180° and 90° obtained by the present writer was compared with the results obtained by other workers. It will be seen that the present results are in good agreement with the other results within probable errors. It may be concluded that anisotropy is confirmed quite clearly by the precise data obtained in the present experiment.

Table III. Anisotropy of *n-p* scattering at 14.1 MeV obtained by various authors.

Author	$\sigma(180°)/\sigma(90°)$
Barschall *et al.*	1.06 ± 0.06
Allred *et al.*	1.04 ± 0.05
Seagrave	1.06 ± 0.023
Present	1.080 ± 0.016

Now, the present results of the differential cross section will be compared with the results expected from the meson theory. The pion theory of nuclear forces has been verified by analysis of almost all low energy two-nucleon phenomena below about 20 MeV[6], taking properly into account the reliability of the theory in accordance with the Taketani theory[9]. Therefore, let us compare the present results with those calculated from the two-nucleon potential with the "one-pion-exchange tail" proposed by Iwadare *et al.*[6],[10], rather than from phenomenological potential usually used. The potentials proposed by them are as follows:

$$
\begin{aligned}
V(x) &= V^{(1)}(x) \quad \text{(the one-pion-exchange potential)} && \text{for } x \geq x^{(1)} \\
&= V_{0c} + S_{12} V_{0T} && \text{for } x^{(1)} \geq x \geq 0.7 \\
&= V_{0c}' + S_{12} V_{0T}' && \text{for } 0.7 \geq x \geq x_0 \\
&= \infty && \text{for } x_0 \geq x\,,
\end{aligned}
$$

where x is the inter-nucleon distance in the units of the pion compton wavelength and V_{0c}, V_{0T}, V_{0c}' and V_{0T}' are constants. In the triplet even state, the one-pion-exchange potential is written as

$$
V^{(1)}(x) = -(g_e^2/4\pi\hbar c)\mu c^2[1 + S_{12}(1 + 3/x + 3/x^2)]\, e^{-x}/x\,,
$$

and this potential is applied in the outer region of the hard core ($x_0 = 0.34$), and in the triplet odd state

$$
V^{(1)}(x) = (1/3)(g_e^2/4\pi\hbar c)\mu c^2[1 + S_{12}(1 + 3/x + 3/x^2)]\, e^{-x}/x\,,
$$

$$
x^{(1)} = 1.0\,, \qquad x_0 = 0.32\,,
$$

$$
V_{0c} = -20\ \text{MeV}\,, \qquad V_{0c}' = -100\ \text{MeV}\,,
$$

$$V_{0T}=V_T{}^{(1)}(x=1)\,,\qquad V_{0T}'=0\,.$$

In the singlet even state

$$V^{(1)}(x)=-(g_e{}^2/4\pi\hbar c)\mu c^2\,e^{-x}/x\,,$$
$$x^{(1)}=1.6\,,\qquad x_0=0.45\,,$$
$$V_{0c}=-20\text{ MeV}\,,\qquad V_{0c}'=-5\times10^2\text{ MeV}\,,$$

and in the singlet odd state

$$V^{(1)}(x)=3(g_e{}^2/4\pi\hbar c)\mu c^2\,e^{-x}/x\qquad\text{for}\quad x\geq0.34\,,$$

Table IV. Phase shifts at 14.1 MeV.

State		Phase shift and mixing parameter (radian)		
^3E	$^3S_1+{}^3D_1$	$^3\delta_1{}^\alpha=1.670$	$^3\delta_1{}^\gamma=-0.021$	$\varepsilon_1=0.250$

	$^3D_3+{}^3G_3$	$^3\delta_3{}^\alpha=-0.004$	$^3\delta_3{}^\gamma=0.003$	$\varepsilon_3=-0.794$
	$^3G_4$	$^3\delta_4{}^\beta=0.001$		
	$^3G_5+{}^3I_5$	$^3\delta_5{}^\alpha=0.000$	$^3\delta_5{}^\gamma=0.000$	$\varepsilon_5=$——
^3O	$^3P_0$	$^3\delta_0{}^\gamma=0.138$		
	$^3P_1$	$^3\delta_1{}^\beta=-0.056$		
	$^3P_2+{}^3F_2$	$^3\delta_2{}^\alpha=0.013$	$^3\delta_2{}^\gamma=-0.002$	$\varepsilon_2=-0.472$
	$^3F_3$	$^3\delta_3{}^\beta=0.003$		
	$^3F_4+{}^3H_4$	$^3\delta_4{}^\alpha=0.000$	$^3\delta_4{}^\gamma=0.000$	$\varepsilon_4=$——
^1E	$^1S_0$	$^1\delta_0=0.951$		
	$^1D_2$	$^1\delta_2=0.004$		
	$^1G_4$	$^1\delta_4=0.000$		
^1O	$^1P_1$	$^1\delta_1=-0.080$		
	$^1F_3$	$^1\delta_3=-0.001$		
	$^1H_5$	$^1\delta_5=-0.000$		

with $g_e{}^2/4\pi\hbar c=0.08$. Of course the tensor potentials $S_{12}V_{0T}$ and $S_{12}V_{0T}'$ are absent in the singlet states. The various phase shifts[11] at 14.1 MeV derived from the above potentials are listed in Table IV.

For the unpolarized n-p scattering, the differential cross section was given in the appendix of Ref. 6 and the explicit form of the first several terms of that equation was given by Matsumoto[12] or by Rohrlich and Eisenstein[13]. The equations of the differential cross section per unit solid angle are

$$\sigma(\theta)=\frac{3}{4}\,({}^3\sigma(\theta))+\frac{1}{4}\,({}^1\sigma(\theta))$$
$$^3\sigma(\theta)=\frac{1}{k^2}\sum_{n=0}^{4}{}^3C_n\cos^n\theta$$
$$^1\sigma(\theta)=\frac{1}{k^2}\sum_{n=0}^{4}{}^1C_n\cos^n\theta\,,$$

where $k^2=1.21E_{\text{lab}}\times10^{24}\text{ cm}^{-2}$ and ^3C_n is obtained from the table of Matsumoto's paper (but $^3P_2$ and $^3F_2$ must be interchanged in his table).

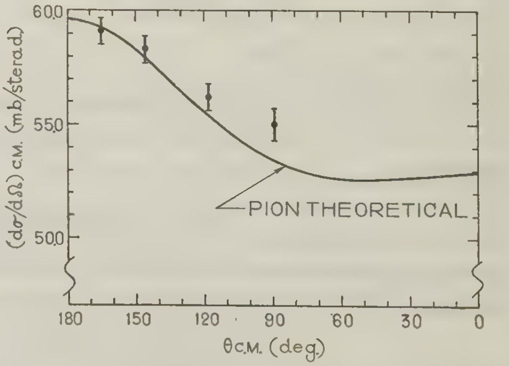

Fig. 7. Differential cross section of n-p scattering at 14.1 MeV. The solid curve represents the cross section calculated from the poin theory.

The numerical equation of the differential cross section at 14.1 MeV is

$$\sigma(\theta)=53.4(1-0.0535\cos\theta+0.0468\cos^2\theta$$
$$-0.0102\cos^3\theta+0.00526\cos^4\theta)\ \text{mb/sterad.},$$

and is shown by a solid-line curve in Fig. 7. The present experimental values are in good agreement with the pion theoretical results. Therefore it can be concluded that these proposed nuclear potentials are verified also for *n-p* scattering at 14.1 MeV.

The author wishes to thank Prof. K. Kimura and Prof. S. Yasumi for their interest and encouragement during the course of this work. He expresses his sincere thanks to Dr. I. Kumabe and Dr. H. Ogata for their valuable suggestions, many discussions and co-operative contributions to this work. His thanks are also due to Dr. W. Watari for valuable theoretical discussions. This work has been supported by the Scientific Research Expenditure of the Ministry of Education.

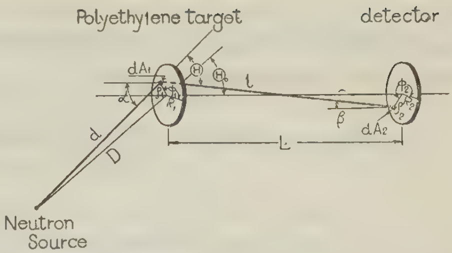

Fig. 8. Geometry of the counter-telescope. R_1 is the radius of the polyethylene target, R_2 is the radius of the aperture of the detector, D is the distance between the neutron source and the polyethylene target, d is the travelling distance of neutrons from the neutron source to the area element dA_1, L is the distance between the target and the aperture of the detector, l is the travelling distance of recoil protons from dA_1 to dA_2, Θ_0 is the setting angle of the counter-telescope axis, Θ is the angle between the travelling lines of the neutron and the recoil proton, α is the angle between d and a line drawn perpendicular to dA_1, and β is the angle between l and a line drawn perpendicular to dA_2.

Appendix

Derivation of the correction factor $C(\Theta_0)$ to the finite solid angle will be described. The geometry and coordinate systems used in the calculation for the derivation of the correction factor $C(\Theta_0)$ are shown in Fig. 8. The number of neutrons which pass through the differential solid angle defined by the area element on the polyethylene target dA_1 is $N_n dA_1\cos\alpha/d^2$ where N_n is the neutron flux per steradian from the source, and α and d are defined in Fig. 8. Hence, the number of proton recoils from dA_1 in the differential solid angle defined by the area element on the detector dA_2 is

$$N_n\left(\frac{dA_1\cos\alpha}{d^2}\right)\left(\frac{P}{\cos\alpha}\right)\sigma_{\text{lab}}(\Theta)\left(\frac{dA_2\cos\beta}{l^2}\right),$$

where P is the number of hydrogen atoms per unit area, $\sigma_{\text{lab}}(\Theta)$ is the differential cross section in the laboratory-system of *n-p* scattering, and β and l are defined in Fig. 8. This equation, when integrated over the planes of the polyethylene target and the aperture of the detector, gives the equation of the counter-telescope counting rate as:

$$n(\Theta_0)=N_n\int^{A_1}\int^{A_2}\frac{dA_1\cos\alpha}{d^2}\,\frac{P}{\cos\alpha}\cdot 4\cos\Theta\cdot\sigma_{\text{C.M.}}(\theta)\,\frac{dA_2\cos\beta}{l^2}, \qquad \text{(A-1)}$$

where $n(\Theta_0)$ is the counting rate at setting angle Θ_0 of the counter-telescope axis, and the differential cross section in the C.M.-system $\sigma_{\text{C.M.}}(\theta)$ is inserted into $\sigma_{\text{lab}}(\Theta)$ using the relation of $\sigma_{\text{lab}}(\Theta)=4\cos\Theta\sigma_{\text{C.M.}}(\theta)$.

In order to evaluate Eq. (A-1), polar coordinate systems (ρ_1, ϕ_1) and (ρ_2, ϕ_2) are taken on the planes of the polyethylene target and the aperture of the detector, respectively. Then, Eq. (A-1) is rewritten as:

$$\begin{aligned} n(\Theta_0)=4N_nP\iiiint &\sigma_{\text{C.M.}}(\theta)\cdot L[(DL\cos\Theta_0-\rho_1{}^2+D\sin\Theta_0\rho_1\ \text{cps}\ \phi_1\\ &+\rho_1\rho_2\cos(\phi_1-\phi_2)-D\sin\Theta_0\rho_2\cos\phi_2)/\\ &(D^2+\rho_1{}^2-2D\sin\Theta_0\rho_1\cos\phi_1)^{3/2}\cdot(L^2+\rho_1{}^2+\rho_2{}^2-2\rho_1\rho_2\cos(\phi_1-\phi_2))^2]\\ &\times\rho_1\rho_2\,d\rho_1\,d\rho_2\,d\phi_1\,d\phi_2, \end{aligned} \qquad \text{(A-2)}$$

where D, L and Θ_0 are constants defined in Fig. 8.

This Eq. (A-2) can be integrated analytically, if $\sigma_{\text{C.M.}}(\theta)$ can be assumed to be constant in the region of the integration, giving

$$n(\Theta_0)=4N_nP\sigma_{\text{C.M.}}(\theta)\frac{\pi^2R_1{}^2R_2{}^2}{D^2L^2}\left[\cos\Theta_0\left\{1-\frac{R_1{}^2+R_2{}^2}{L^2}-\frac{R_1{}^2}{D^2}\left(\frac{3}{4}-2\sin^2\Theta_0\right)\right\}-\frac{R_1{}^2}{2DL}\left(1-\frac{3}{2}\sin^2\Theta_0\right)\right], \tag{A-3}$$

where θ is the mean angle (in the C.M.-system) of scattered neutrons in the region of the integration, and R_1 and R_2 are the radii of the polyethylene target and the aperture of the detector, respectively. (Terms of higher order than $(R_1/D)^4$ or $(R_2/L)^4$ have been neglected, since they are negligibly small in the present experimental geometry.) From the counting rate equation, the differential cross section per unit solid angle in the C.M.-system is rewritten as

$$\sigma_{\text{C.M.}}(\theta)=\frac{n(\Theta_0)}{G}\Big/4\cos\Theta_0\cdot C(\Theta_0)\ , \tag{A-4}$$

where $G\equiv N_nP(\pi^2R_1{}^2R_2{}^2/D^2L^2)$ and $C(\Theta_0)$ is the correction factor to the finite solid angle, which is given by

$$C(\Theta_0)=1-\left[\frac{R_1{}^2+R_2{}^2}{L^2}+\frac{R_1{}^2}{D^2}\left(\frac{3}{4}-2\sin^2\Theta_0\right)+\frac{R_1{}^2}{2DL\cos\Theta_0}\left(1-\frac{3}{2}\sin^2\Theta_0\right)\right]. \tag{A-5}$$

Numerical values of $C(\Theta_0)$ calculated by this Eq. (A-5) are shown in Table V.

Table V. Correction factors to the finite solid angle at various setting angles.

Θ_0	0.5°	15.5°	30.5°	45.5°
$C(\Theta_0)$	0.9893	0.9900	0.9921	0.9950

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 15, No. 8, AUGUST, 1960

On the High Energy Soft Components at 2770 m Altitude

By Tadashi KAMEDA and Toshio MAEDA

Department of Physics, Kobe University, Kobe

(Received Feburary 9, 1960)

An apparatus consisting of GM-counter hodoscopes and an ionization chamber with large area was used to measure cascade showers initiated by electrons and photons at 2770 m altitude (Mt. Norikura). The number of shower particles deduced from the pulse height of the ionization chamber was converted into energy of the electron (or photon) initiating the shower.

The results show that, in the energy range of 2-20 Bev, i) the zenith angle distribution of electrons is represented by $\cos^5\theta$, ii) the differential energy spectra can be represented by a power law of the form $E^{-\gamma}$ with γ of 2.90 ± 0.05 and 2.83 ± 0.05 for electrons and photons respectively, and iii) upper limit of the ratio of the number of electrons to that of photons is 1.1 ± 0.1.

The present results were compared with those obtained near sea level and the origin of the soft component was also discussed.

§ 1. Introduction

To study the origin of the soft component at low altitude, it is desirable to compare the results obtained at different altitude. Hitherto, measurements concerning the soft component of energy higher than 1 Bev have been reported by Schein et al. and by Daion[1]. However, the results reported by Schein et al. can not be compared directly with those obtained by Chou[2] near the sea level, because their apparatus used at sea level and at mountain altitude were different in their arrangement, and the latter did not report the absolute intensities of electrons and photons near sea level. In order to compare the results at different altitude and to deduce some reliable conclusions from them, it is necessary to use the same apparatus and the same arrangement in both measurements.

In the previous paper[3] (hereafter referred to as I) we reported some results concerning the soft component of high energy near sea level. The same apparatus was used at Mt. Norikura (2770 m a.s.l.) to measure the soft component at mountain altitude. In the present paper, the results obtained there and discussions comparing them with those obtained near sea level are reported.

§ 2. Apparatus

The apparatus used to measure the soft component is the same as reported in I, except that GM-counters composing tray B and C have effective length of 18.5 cm and diameter of 2.8 cm (instead of diameter of 2.0 cm and of the same length), and the lead absorber between tray F and G has thickness of 15 cm (instead of 10 cm in I). Centers of the tray AS_1 and AS_2 are apart from the center of the tray A by 170 cm and 240 cm respectively, and are placed immediately under the roof whose thickness is 1.5 g/cm² wood and 0.2 g/cm² copper. Experiments were carried out in the wooden hut at Mt. Norikura in the autumn of 1955.

The hodoscopes are triggered by the master pulse of $C^{\geq 1}D^{\geq 3}I^{\geq x}$, where x is the pulse height in terms of unit of Po$-\alpha$, and the pulse height is indicated by the neon lamps connected to 12 channel discriminator.

§ 3. Analysis of the Data and Results

Method of analysing the data is quite similar to that described in I § 3, that is, by inspecting the photographs of the hodoscopes, and by following the criteria mentioned in I § 3A, we select, a) single incident electrons and photons which do not associate with the extensive air shower (EAS) of density $\Delta\geq 4/\text{m}^2$, b) multiple incident electrons and photons, and c) electrons and photons which associate with EAS of density $\Delta\geq 4/\text{m}^2$. The ionization chamber was filled with argon of 99.9% purity and of 4.0 atm. pressure (at 0°C), alike in the sea level experiments. Therefore, the number of shower particles

N_1 corresponding to the pulse height of unit Po$-\alpha$ is 24.0, if the primary electrons (or photons) are incident vertically to the absorber.

(I) *Single incident electrons and photons*

a) Energy spectra of the electrons and photons

Integral number spectra obtained by changing the pulse height to the number of shower particles initiated by the vertically incident primaries, are shown in Fig. 1a and 1b, the former is those of electrons and the latter those of photons for various thickness of absorber.

These spectra are well represented by the form of

$$F(\geq N_x) \propto N_x^{-\nu} \qquad (1)$$

and the values of ν's are listed in Table I.

	photon	2.90±0.25	2.28±0.14	2.10±0.10	2.07±0.12	3.08±0.30	2.24±0.15
γ	electron	2.82±0.17	2.95±0.12	2.90±0.10	2.94±0.12	2.57±0.16 (2.86±0·19)*	2.78±0.13 (2.91±0.14)*
	photon	2.81±0.16	2.80±0.11	2.81±0.09	2.85±0.11	2.31±0.13 (2.85±0.18)*	2.84±0.12 (2.87±0.13)*

* These values were calculated by α's obtained from the recent paper of Ivanenko.[13]

As stated in I, assuming that the differential energy spectrum has the form of $E^{-\gamma}dE$, ν is related with γ by the relation

$$\nu = \alpha(\gamma - 1) \qquad (2)$$

where α is a constant appearing in the relation I (7).

For the values of α's for lead, we cited those obtained from the calculated results given by Ivanenko,[4] and for iron those given be Snei der and Serber.[5] The results thus obtained are listed in Table I.

From these figures, the following values of γ are obtained

$$\left.\begin{array}{ll} \gamma_e = 2.90 \pm 0.05 & \text{for electrons,} \\ \gamma_p = 2.83 \pm 0.05 & \text{for photons.} \end{array}\right\} \qquad (3)$$

where the suffix e and p represent the quantity for electron and photon respectively.

(b) Zenith angle distribution of electrons

An example of the projected zenith angle distribution, which is obtained by the discharged GM-counters in tray A and tray B, is illustrated in Fig. 2, which shows the distribution of electrons which initiate the cascade showers giving pulse height of 0.7 Po$-\alpha$ under 2 cm thickness of lead.

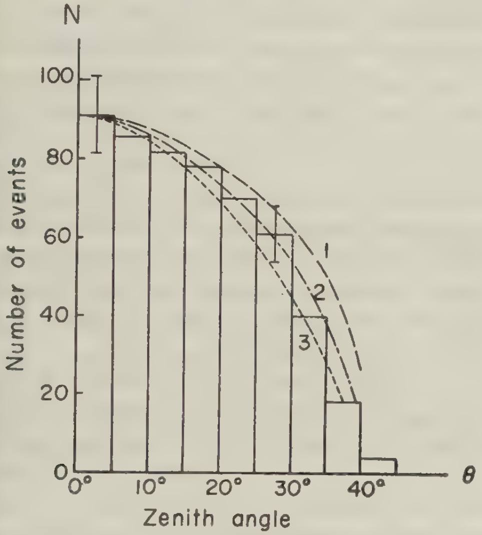

Fig. 2. Zenith angle distribution.
1: m=2,
2: m=3,
3: m=4.

As mentioned in I § 3, if the primary electrons have the zenith angle distribution of the form $\cos^n\theta$, that of the electrons giving rise to pulse heigher than a certain pulse height is represented by the form of $\cos^m\theta$ in our apparatus, where

$$m=n-\alpha(\gamma-1) \qquad (4)$$

The curves in Fig. 2 are the projected zenith angle distribution calculated for the geometry of our apparatus, assuming m=2, 3, and 4. The curve for m=3 appears to fit well with the measured distribution. Therefore, in this case we obtain by (4) n=5, putting $\alpha=1.15$ and $\gamma=2.90$.

Other examples of projected zenith angle distributions obtained for several thicknesses of lead and for 8 cm thickness of iron give the similar results, and from them we conclude that n=5±1.

(c) Absolute intensity of electrons

Absolute intensity of single incident electrons, is obtained by the relation I (9). Assuming the differential energy spectrum of

$$G(E)dE=cE^{-\gamma}dE \qquad (5)$$

and calculating numerically the integral in I (9) for our geometry, we obtained the following value for c_e;

$$c_e \begin{cases} =1.50\times10^{-4}/\text{cm}^2\cdot\text{sec. sterad. BeV for 1 cm and 2 cm thickness of lead} \\ =1.55\times10^{-4}/\text{cm}^2\cdot\text{sec. sterad. BeV for 3 cm thickness of lead} \\ =1.60\times10^{-4}/\text{cm}^2\cdot\text{sec. sterad. BeV for 4 cm thickness of lead} \end{cases} \qquad (6)$$

$$c_e \begin{cases} =1.62\times10^{-4}/\text{cm}^2\cdot\text{sec. sterad. BeV for 4 cm thickness of iron}^{*)} \\ =1.89\times10^{-4}/\text{cm}^2\cdot\text{sec. sterad. BeV for 8 cm thickness of iron}^{*)} \end{cases}$$

The increasing values of c_e for increasing thickness of lead, and the larger value for iron can be consistently explained assuming that the events classified as single incident electron by the criteria I § 3 contain some nuclear events (§ 4 (i)). Correcting these, we obtain

$$c_e=(1.45\pm0.10)\times10^{-4}/\text{cm}^2\cdot\text{sterad. sec. BeV}. \qquad (7)$$

(d) Ratio of the number of electrons and photons

If we assume that the angular distribution for photons is the same as that for electrons, and that the rate of containing the nuclear events is quite similar to the case of electrons, we obtain for various thickness of lead and iron

$$c_e/c_p=1.10\pm0.10\,. \qquad (8)$$

It will be noted that this value is the upper limit of the ratio, because we can not separate individually the particles which are incident close together. Moreover, taking into consideration of the conversion of photons by the roof and upper walls of GM-counters in tray A, the above mentioned value may be lowered to 1.0.

(II) *Multiple incident electrons and photons, and high energy electrons and photons associated with EAS*

---

*) This is calculated by Ivanenko's results.

Table II. No. of Events≥ 0.7 Po-α (/hr).

Absorber material	Pb					
Absorber thickness	1 cm	2 cm	3 cm	4 cm	4 cm	8 cm
Electron shower	5.80±0.40	9.87±0.43	8.58±0.35	6.85±0.55	4.35±0.49	6.02±0.49
Photon shower	4.88±0.37	8.04±0.39	8.80±0.36	5.80±0.50	3.85±0.46	5.37±0.45
Multiple soft shower	4.76±0.44	6.65±0.35	3.15±0.21	2.23±0.31	0.32±0.13	0.54±0.15
E.A.S. associated shower	4.50±0.42	6.07±0.33	2.62±0.22	1.79±0.28	0.32±0.13	0.44±0.12
Penetrating shower	0.82±0.16	1.04±0.08	2.18±0.32	2.67±0.28	1.12±0.25	2.48±0.32
〃 (E.A.S. associated)	2.21±0.30	1.37±0.10	2.73±0.45	3.82±0.33	2.43±0.37	2.25±0.30
Uncertain events	1.92±0.28	2.48±0.21	2.25±0.18	2.05±0.30	1.44±0.28	1.85±0.27

Counting rates of single incident electrons and photons, of multiple incident electrons and photons, and of high energy soft components associated with EAS ($\Delta \geq 4/\mathrm{m}^2$) are listed in Table II. and the number spectrum of multiple incident electrons and photons for 2 cm thickness of lead is illustrated in Fig. 3, as an example. From the table and the figure, the followings are found;

(a) Ratio of the multiple incident electrons and photons to the single incident electrons (or photons) decreases rapidly for 3 cm thickness of lead comparing with that for 2 cm thickness of lead. This fact shows that most of the particles contained in the multiple events are not of high energy but only a few part are of high energy.

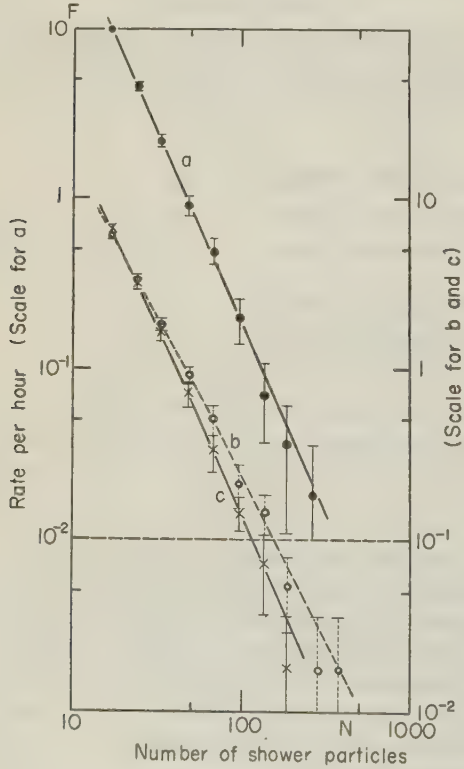

Fig. 3. Number spectra of shower particles.
a: single incident electron
b: EAS associated electrons and photons
c: multiple incident electrons

(b) The number spectrum, as shown in Fig. 3, is less steep than those of single incident electron (or photons) at $N \leq 60$, but approaches to $\nu = 2.25$ for large N. The difference of the values of exponent at $N \leq 60$ is 0.15. The same facts are observed for various thickness of absorber material.

(c) High energy electrons and photons are scarcely found in EAS of small density, and the rate of existence increases slightly in EAS of large density. The same result as stated in (a) is also found in them. The value of ν is less steep than that of multiple events, and at large N (≥ 60) it tends to 1.95 ±0.15.

§ 4. Discussion

i) *Errors involved in the data*

The rate of occurrence of nuclear interactions involved in the data, which is classified as single incident electron (or photon), will be known by comparing the results obtained near sea level with those at mountain altitude. c_e at mountain altitude (c_{em}) to c_e near sea level (c_{es}) is 3.7 for 2 cm thickness of lead (1/8 nuclear interactian length), and is 4.6 for 8 cm thickness of iron (1/2 nuclear interaction length). From these figures, neglecting the nuclear interaction at sea level, we may conclude that the data at mountain altitude classified as the single incident electrons (or photons) contain nuclear interaction of 20% of them for 8 cm iron, and those of 5% for 2cm thickness of lead. This will reasonably explain the difference of the values of c_e for different thickness of lead. Thus, correcting for the nuclear interaction, we obtain for c_{em}/c_{es},

$$c_{em}/c_{es}=3.52\pm0.10\ .$$

ii) *Penetrating showers*

The same facts as mentioned in I (§4, E (b)) are also observed in this measurements. Referring to the discussion stated there, we may conclude that the power law with constant exponent holds for the energy range measured and the electron and photon intensities should be increased by 5% (as the upper limit) taking into account the parallel events, in which the electronic components and penetrating components are incident on the apparatus simultaneously.

The integral energy spectra of soft components, including the events stated in §3 (II) and the above mentioned, are illustrated in Fig. 4. The errors of the total intensity in the figure may be nearly 15%, because of the inaccuracy of the energy of electrons and photons contained in the multiple events and in EAS.

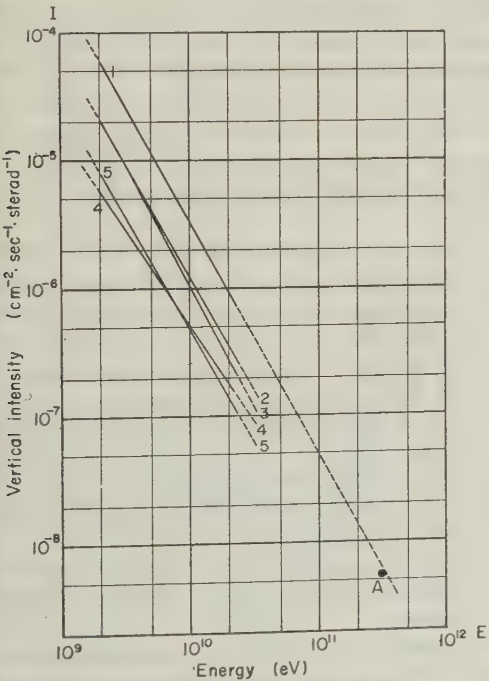

Fig. 4. Integral energy spectra of soft component.

1: total electronic component
2: single incident
3: single incident electron
4: EAS associated electrons and photons
5: Multiple incident electrons and photons
A: I.N.S. emulsion group

iii) *Origin of electrons and photons*

Assuming that the absorption mean free path of nucleons is 120 g/cm² in air, we conclude from the value of ratio c_m/c_s that 70% of the soft components of energy ≥ 2 BeV originate from μ-mesons and 30% from N-components at sea level, and these figures are altered to 20% and 80% at mountain altitude. This explains also the difference of the zenith angle distribution between the two altitudes. The zenith angle distribution of μ-mesons which are the primaries of the soft component of the measured energy interval at sea level and at mountain altitude is expressed by $\cos^{0.5}\theta$, referring to the intensities and zenith angle distribution underground[6] and the momentum spectrum of μ-mesons of vertical and inclined direction.[7] Thus, the zenith angle distributions of the soft components at sea level and at mountain altitude are expressed by $0.3\cos^{8}\theta+0.7\cos^{0.5}\theta$ and $0.8\cdot\cos^{6}\theta+0.2\cos^{0.5}\theta$ respectively, and they may be represented roughly by $\cos^{2}\theta$ and $\cos^{5}\theta$ in the interval of measured zenith angle (0°–40°).

iv) *Comparison with other measurement*

According to Daion,[1] electrons and photons of energy 0.4–2 BeV have the integral energy spectra of the form $E^{-(\gamma+1)}$, where $\gamma=2.5\pm0.2$, and at higher energies the value of γ increases at 3200 m altitude. We believe that the value of γ increases gradually between 1 BeV–3 BeV and reaches to 2.9. Schein and Chou[1] reported that $\gamma=2.6$ between 1 and 30 BeV for the single incident electrons and photons, and $\gamma=2.4$ for the electrons and photons corresponding to the multiple incident ones in our classification. Though their values seem to be less than ours by 0.2–0.3, one of the causes of the difference lies in taking account of the angular spread of the shower particles and the zenith angle distribution of primary particles in our case. We confirmed that the energy spectra obtained neglecting the above accounts had the nearly same form as reported by them. As another reason, the difference of height of the places where the measurements were performed may be also considered.

Recently, the intensity of the electronic component of $\geq$300 BeV is measured at Mt. Norikura by I.N.S. emulsion group.[8] According to their preliminary results, intensity at 300 BeV is $5.4 \times 10^{-9}/\mathrm{cm}^2 \cdot$sec. sterad., and it lies on the line extraporated to 300 BeV in Fig. 4. Thus, the energy spectrum obtained by us seems to hold up to ~300 BeV.

v) *Comparison with the calculated results*

Intensities of electronic components are calculated by Hayakawa[9] and by Tachibana,[10] who calculated the contribution from the μ-meson decay, the collision process of μ-mesons, and π°-meson decay to the electronic component. Contribution from the μ-meson decay and collision, and that from the π°-meson decay are also calculated by Stroffolini[11] and by Cadorin,[12] respectively.

Comparing our results to the calculated ones, the followings are clarified qualitatively:

a) Values of exponents in the energy spectra coincide with the calculated ones within the experimental errors at both altitude.

(b) The calculated ratio of the electronic components from μ-mesons to those from π°-mesons fits well with ours.

c) The calculated absolute intensities fit well with ours in Ref. (9), but in Ref. (10) the difference amounts to factor 3 in both altitudes.

d) The ratio c_e/c_p agrees with ours at sea level but it departs from ours at mountain altitude (calculated $c_e/c_p=0.7$, ours 1.1 ± 0.1).

Though there are some discrepancies between the observed results and the calculated ones, it appears to be verified that the origin of the soft component at the low altitude is explained by the well known processes qualitatively, but there remains some ambiguities quantitatively.

§ 5. Concluding Remarks

The results obtained by the present experiments show that in 2–20 BeV,

i) the zenith angle distribution of single incident electrons is represented by $\cos^5\theta$ at mountain altitude,

ii) vertical flux of single incident electrons and photons is represented by

$$G_e(E)dE = (1.45 \pm 0.10) \times 10^{-4} E^{-2.90} dE/\mathrm{cm}^2 \cdot \mathrm{sec.\ sterad.\ BeV} \text{ for electron}$$

$$G_\nu(E)dE = (1.32 \pm 0.10) \times 10^{-4} E^{-2.83} dE/\mathrm{cm}^2 \cdot \mathrm{sec.\ sterad.\ BeV} \text{ for photon}$$

iii) vertical flux of the total electronic component is obtained taking into consideration the electronic component accompanied by multiple events and EAS, and is represented by

$$G(E)dE = (3.8 \pm 0.5) \times 10^{-4} E^{-(2.82 \pm 0.05)} dE/\mathrm{cm}^2 \cdot \mathrm{sec.\ sterad.\ BeV}$$

iv) ratio of electrons to photons, c_e/c_p, is 1.1 ± 0.1,

v) at mountain altitude, 20% of the electrons and photons originate from μ-mesons and 80% from π°-meson decay, and near sea level their rates are 70% and 30% respectively,

vi) origin of the electronic component at the low altitude appears to be explained by the well known processes.

The authors want to express their deep gratitude to Prof. O. Minakawa for his advice and encouragement for this work. They also wish to thank Mr. Watanabe for his assistance in carring out the experiment. The authors are greatly indebted to Prof. S. Kikuchi, Director of the Cosmic Ray Observatory of Mt. Norikura, and to Prof. Hirata, the former Director of it, for their permission to use the facilities of the observatory.

Graphitization Stress in Polycrystalline Carbon as An Origin of Dislocations

By Takuro TSUZUKU

College of Science and Engineering, Nihon University
Kanda-Surugadai, Chiyoda-ku, Tokyo, Japan

(Received January 23, 1960)

When a polycrystalline carbon is heat-treated for graphitization, large thermal stress is produced owing to the interference of the extremely anisotropic expansion of each crystallite. The stress of this kind is expected to promote the rearrangement of the crystallites, directly or indirectly, from the so-called turbostratic structure to the tri-dimensional graphite lattice, and so it may be adequately called "graphitization stress". The stress analysis has been made on each of the spherical and the cylindrical (filamentarily textured) polycrystals in which the carbon crystallites are aligned with the basal planes parallel to the external surface. These two models accommodate to the structure of pyrolytic carbon particle and to that of fibrous soft coke respectively. It is shown that in either of these two cases about 3×10^{10} dynes/cm^2 tension in a-direction and about 0.9×10^{10} dynes/cm^2 compression in c-direction can be produced by heat treatment at 2500°C, which are enough to buckle the crystal lattice at the stress concentrations of 5～20 times and may lead to the generation of dislocations. From the corresponding strain distribution curves, the criterion on the stress relaxation by these dislocations has been determined in connection with the crystallite size, which may give a measure of distinction between the so-called soft and hard carbons.

§ 1. Introduction

Previously, by means of electron microscope and diffraction, this author[1] has revealed some structural aspects of graphite connected with the dislocations; *e.g.*, pyramidal layer growth, conicla crystal habit, laminar cleavage, polygonization, net work of etch pits *et al.* Using modern high-resolution electron microscopes (operated at large magnification above ×10,000), Grenall[2] and Fujita-Izui[3] have independently succeeded in direct observation of individual dislocations, alignment and motion consistent with theoretical prediction, lying inside of some natural and artificial graphite flakes. These experimental results are accepted to corroborate the presence of dislocations in the graphite structure. Now, it may be significant to investigate how the initial dislocations are introduced, during the so-called graphitization process of pyrolytic carbons. On the origin of dislocations in crystals, though the definitive analysis is not established at present, some probable mechanisms have been suggested hitherto by several authors[4]; *e.g.*, (*a*) misfit of adjacent nuclei generated at local high super-saturation, (*b*) one-dimensional dislocations in the edge row of the growing terrace, (*c*) curvature of the growing crystal which has met with impurities, (*d*) collapse of flat-condensed vacancies, (*e*) mechanical buckling of crystal lattice caused by stress concentration *et al.* Among these proposals, the mechanisms (*d*) and (*e*) attract our attention in the respect that they are considered to accommodate especially to graphite as to be described in the following paragraphs.

In the most cases, graphite crystals are prepared by the heat treatment of polycrystalline carbons at extremely elevated temperature up to 2500～3000°C. Hence, the interference of extremely anisotropic thermal expansion of each crystallite may arise large internal stresses enough to buckle the crystal lattice at the stress concentrations of really possible magnitude, and may lead to the spontaneous formation of dislocations. On the other hand, as pointed out by Mrozowski[5], the stress of this kind is expected to promote the rearrangement of the crystallites from the so-called turbostratic structure to the tridimensional graphite lattice, *i.e.* the growth of the crystallite, and so may be called "graphitization stress" hereafter. This may suggest that the mechanism of graphitization is in close connection with the presence of dislocations.

The collapse of condensed vacancies which may develop to the dislocation ring is presumed to easily take place in graphite because of the characteristic stacking layer structure and of the high temperature treatment, and will be discussed in detail separately.

§ 2. Basic Models and Equations

2A. *Carbon Spherulite*

Firstly, let suppose a spherical carbon particle as schematically illustrated in Fig. 1, in which the turbostratic carbon crystallite are aligned with the basal planes tangential to the external surface, so that the c-axes are radially oriented arround the centre. By means of electron shadow-microscope and diffraction, Grisdale[6] has shown that the structure of black carbons resulting from the pyrolysis of gaseous hydrocarbons is well represented by such a model, which is caused by the intermediate formation of droplets of complex hydrocarbons prior to the solidification. According to him, moreover, the morphology of carbon products obtained from highly cross-linked organic polymers is wholly analogous to those for the pyrolytic black carbons. Therefore, this model is taken to be appropriate, in general, for the structure of hard (non-graphitizing) components which are left over the organic solvent extraction as the so-called free carbons. Hereafter, the structure of this kind may be called "*carbon spherulite*".

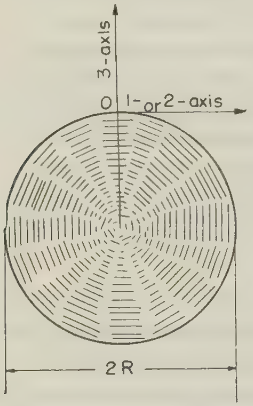

Fig. 1. Structure model of carbon spherulite.

It has been widely accepted that, in polycrystalline carbons, especially the so-called hard one, peripheries of the turbostratic crystallites are tightly hooked by the complicated system of criss-cross valence bonds with one another. Therefore, in discussing the graphitization stresses in a carbon spherulite, we can regard the the aromatic net planes surrounding the centre as to be two-dimensionally continuous and isotropic in approximation. Besides, the strength of the interlayer van der Waals bonds oriented along the radius is supposed to be nearly even all over the particle. Then, if such a spherical elastic continuum is heated uniformly, symmetrical stress distribution with respect to the centre may be obtained, owing to the anisotropy in thermal expansion, and so, the condition of stress equilibrium of a volume element as shown in Fig. 2 is given by the following expression

$$\frac{d\sigma_r}{dr}+\frac{2}{r}(\sigma_r-\sigma_\theta)=0\ , \tag{1}$$

where σ_r and σ_θ denote the normal stresses in radial and tangential directions respectively (shearing components=0). Next, using a rectangular coordinate, 1-, 2-axes in tangential and 3-axis in radial, we obtain the following stress-strain relations;

$$\varepsilon_r-\alpha_r T=s_{33}\sigma_r+2s_{13}\sigma_\theta \tag{2}$$

$$\varepsilon_\theta-\alpha_\theta T=(s_{11}+s_{12})\sigma_\theta+s_{13}\sigma_r\ , \tag{3}$$

where T denotes the temperature variation from the unstressed state, and ε_r, ε_θ, α_r, α_θ and s_{ij} ($i, j=1, 2, 3$) severally represent the strains, the thermal expansivities and the elastic coefficients in the directions indicated by the suffixes.

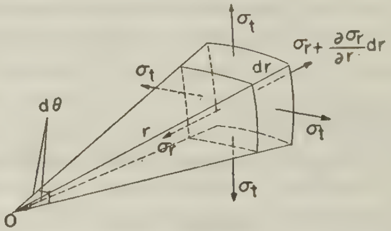

Fig. 2. Volume element in carbon spherulite.

According to Nelson and Riley[7], the thermal expansivity of graphite unit-cell in a-direction has been known very small, even negative below 400°C, as expected for the valence bonding. Since the co-planar bond of ungraphitized carbon is rather stronger than that of graphite, this result may be applicable in the present case; *i.e.*, the second term on the left-hand side of Eq. (3), $\alpha_\theta T$, is neglected in approximation. On the other hand, representing the displacement in the radial direction by u, the strain components are expressed by $\varepsilon_r = du/dr$ and $\varepsilon_\theta = u/r$.

Thus, substituting these relations into the equilibrium equation (1), we can obtain an Euler's differential equation as follows;

$$r^2\frac{d^2u}{dr^2} + 2r\frac{du}{dr} - \frac{2(s_{33}+s_{13})}{s_{11}+s_{12}}u = \frac{2(s_{11}+s_{12}+s_{13})}{s_{11}+s_{12}}\alpha_r T\cdot r\,. \tag{4}$$

According to the present model, α_r is taken to be the expansivity of graphite unit-cell in the *c*-direction determined by Nelson and Riley[7], 28.3×10^{-6}°C^{-1} at room temperature. Similarly, the elastic coefficients of graphite lattice evaluated by Riley[8] are used; *i.e.*,

$$\begin{aligned} s_{11}+s_{12} &= 1.8\times10^{-13}\ \text{cm}^2/\text{dyne}\,,\\ s_{13} &= -4.3\times10^{-13}\quad \text{〃}\,,\\ s_{33} &= 58.5\times10^{-13}\quad \text{〃}\,. \end{aligned}$$

By solving Eq. (4) under the boundary conditions $u=0$ at the centre $(r=0)$ and $\sigma_r(u)=0$ at the external surface $(r=R)$, the stresses and the strains are expressed as the functions of r/R in the following forms;

$$\sigma_r = \left\{5.4\left(\frac{r}{R}\right)^{6.3} - 5.4\right\}T\times10^6\ \text{dynes/cm}^2\,, \tag{5}$$

$$\sigma_\theta = \left\{22.6\left(\frac{r}{R}\right)^{6.3} - 5.4\right\}T\times10^6\quad \text{〃}\,, \tag{6}$$

and

$$\varepsilon_r = \left\{12.5\left(\frac{r}{R}\right)^{6.3} - 1.34\right\}T\times10^{-6}\,, \tag{7}$$

$$\varepsilon_\theta = \left\{1.72\left(\frac{r}{R}\right)^{6.3} - 1.34\right\}T\times10^{-6}\,. \tag{8}$$

2B. *Filamentarily Textured Polycrystal*

The second model is cylindrical one in which the basal planes of the crystallites are parallel to the external surface, surrounding the central axis. In this case, Fig. 1 may be taken to represent the cross section perpendicular to the central axis. This model is appropriate for the filamentary texture of the so-called soft (graphitizing) cokes which is caused by a frozen-in flow pattern, as pointed out by Mrozowski[5], in the viscous fluid at the time of solidification.

The stress analysis may be proceeded in nearly the same way as that for the carbon spherulite, taking into account the contributions of the axial (z) components. The equation of stress equilibrium is given by

$$\frac{d\sigma_r}{dr} + \frac{1}{r}(\sigma_r - \sigma_\theta) = 0\,, \tag{9}$$

similar to the condition in two-dimensional problem. The stress-strain relations are

$$\varepsilon_r - \alpha_r T = s_{33}\sigma_r + s_{13}(\sigma_\theta + \sigma_z) \tag{10}$$

$$\varepsilon_\theta = s_{11}\sigma_\theta + s_{13}\sigma_r + s_{12}\sigma_z\,, \tag{11}$$

$$\varepsilon_z = s_{11}\sigma_z + s_{13}\sigma_r + s_{12}\sigma_\theta\,, \tag{12}$$

where the expansivity of aromatic net-plane surrounding the central axis is neglected (; $\alpha_\theta=0$, $\alpha_z=0$).

Supposing a infinitely long filament, the axial strain ε_z is taken to be zero, and, the radial displacement u is again used as a stress function. Thus, we can obtain another Euler's equation as follows,

$$r^2\frac{d^2u}{dr^2} + r\frac{du}{dr} - \frac{s_{11}s_{33}-s_{12}^2}{s_{11}^2-s_{12}^2}u = \left(1 - \frac{s_{13}}{s_{11}+s_{12}}\right)\alpha_r T\cdot r\,. \tag{13}$$

In the present case, however, the elastic coefficients s_{11} and s_{12} should be separately evaluated for the numerical expression. The aforesaid Riley's treatise[8] on the thermal anisotropy of graphite gives only $s_{11}+s_{12}=1.8\times10^{-13}$ cm²/dyne. Hereupon, by assuming the Poisson ratio of the aromatic plane s_{12}/s_{11} to be 0.3, which is proper value for most isotropic solids, they are computed at $s_{11}=2.57\times10^{-13}$ and $s_{12}=-0.77\times10^{-13}$cm²/dyne.

Thus, the final expressions are as follows;

$$\sigma_r = \left\{5.85\left(\frac{r}{R}\right)^{3.7} - 5.85\right\}T\times10^6\ \text{dynes/cm}^2\,, \tag{14}$$

$$\sigma_\theta = \left\{27.4\left(\frac{r}{R}\right)^{3.7} - 5.85\right\}T\times10^6\quad \text{〃}\,, \tag{15}$$

$$\sigma_z = \left\{18.0\left(\frac{r}{R}\right)^{3.7} - 11.5\right\}T\times10^6\quad \text{〃}\,, \tag{16}$$

and

$$\varepsilon_r = \left\{ 14.6 \left(\frac{r}{R} \right)^{3.7} + 1.87 \right\} T \times 10^{-6} , \qquad (17)$$

$$\varepsilon_\theta = \left\{ 3.13 \left(\frac{r}{R} \right)^{3.7} + 1.87 \right\} T \times 10^{-6} . \qquad (18)$$

§ 3. Numerical Results and Discussions

3A. *Evaluation of Stress*

In order to numerate the graphitization stresses, the temperature variation T should be measured from the point at which the solidifications of carbon material just completes and the stresses are about to arsie. Because of the complex composition of the raw materials, such a point can not be uniquely determined in general, but it would be safe to roughly estimate that at about 1000°C (temperature of industrial baking furnace) the volatilization of the organic components mostly treminates and the high-polymeric plasticity may be replaced by the brittleness of the coke structure. In other words, the constraint on the expansion of each carbon platelets is abruptly strengthened by the increase of the peripheral criss-cross valence bonds, which is coincidently related with the transition from the so-called organic semi-conductor to the carbon semi-conductor in the electron band structure. This estimation is in fairly good agreement with the experimental results concerning the dependence of dimensional change[9], thermal expansion[10] and electronic properties[11] on the heat treatment.

The stresses in the carbon spherulite and the filamentarily textured polycrystal at 2500°C (lowest graphitization temperature) computed by putting $T = 2500 - 1000 = 1500$(°C) are plotted against r/R in Fig. 3. As seen there, the crystallites lying nearby the external surfaces are severally subject to the maximum tension in a-direction, and those in the central parts to the compression in all directions. The maximum values and the ratios to the corresponding Young's modulei of graphite lattice, $1/s_{11} = 39 \times 10^{11}$ dynes/cm^2 in a-direction and $1/s_{33} = 1.7 \times 10^{11}$ dynes/cm^2 in c-direction (see § 2), are tabulated as follows:

(1) Spherulite

Surface $\sigma_\theta = 2.6 \times 10^{10}$ dynes/cm$^2 \approx (150 s_{11})^{-1}$

Centre $\sigma_r = 0.81 \times 10^{10}$ dynes/cm$^2 \approx (21 s_{33})^{-1}$

(2) Filament

Surface $\sigma_\theta = 3.2 \times 10^{10}$ dynes/cm$^2 \approx (120 s_{11})^{-1}$

$\sigma_z = 0.98 \times 10^{10}$ dynes/cm$^2 \approx (395 s_{11})^{-1}$

Centre $\sigma_r = (= \sigma_\theta) = -0.88 \times 10^{10}$ dynes/cm$^2 \approx (19 s_{33})^{-1}$

$\sigma_z = -1.7 \times 10^{10}$ dynes/cm$^2 \approx (230 s_{11})^{-1}$.

In the actual cases, owing to the inevitable assymmetry and heterogenity in the configuration of crystallites, the graphitization stresses may be accompanied by some shearing components other than the normals itemized above. Basing on the assumption that the shearing stress is a sinusoidal function of the displacement with period of the interatomic spacing along the slip plane, the theoretical shearing stress τ_m is expressed by

$$\tau_m = \frac{b}{c} \frac{G}{2\pi} , \qquad (19)$$

where G, b and c denote the seear modulus, the lattice periods parallel and perpendicular

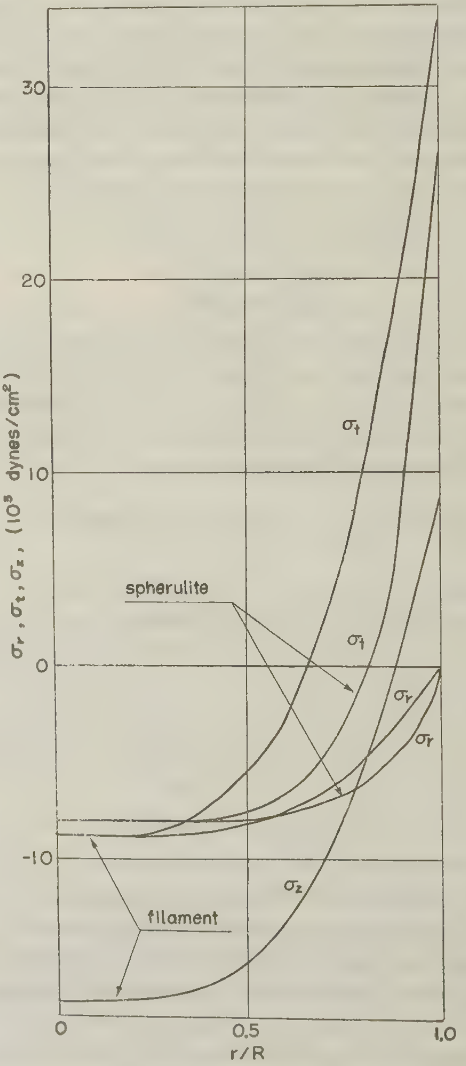

Fig. 3. Stress distribution curves.

to the slip plane respectively[12]. Then, supposing that the abovemensioned ratios in the case of normal stresses are crudely equal to those of the shearing components against the corresponding moduli, one can expect that the graphitization stresses give rise to the local slip at the stress concentrations of about 5∼20 times, breaking the crystal lattice; *i.e.* the spontaneous formation of dislocations. These concentrations may be attained by the presence of the microscopic deffects lying in the graphite structure *a'priori*; *e.g.*, cavities produced by the evaporation of impurities, irregularities nearby the intercrystallite boundaries *et al.*

3B. *Stress Relaxation by Dislocations*

The strain distribution curves at 2500°C are plotted in Fig. 4, corresponding to the stress distribution curves in Fig. 3.

Now, let suppose a crystallite of tangential length x and of thickness δr, lying nearby the external surface. It is easily understood that the crystallite is strained as if a bending deformation is given, and the corresponding curvature is expressed by $1/\rho=(1/x)(\delta x/\delta r)=d\mathcal{E}_\theta/dr$, where ρ and δx represent the curvature radius and the tangential elongation severally. Since the stress is expected to buckle the crystal lattice, as mentioned in the last sub-section, the bending may be taken by plastic flow, and a number of edge dislocations of same sign which have the extra half-planes on the outer side are produced in the way as schematically illustrated in Fig. 5. That is to say, the graphitization stress is released by the formation of dislocations. As well known, the density of such dislocations (n) is determined by the curvature, *i.e.*

$$n=\frac{1}{\rho b}=\frac{1}{b}\,\frac{d\mathcal{E}_\theta}{dr}\,, \tag{20}$$

where b is the magnitude of the Burgers vector.

At the same time, these edge dislocations are expected to cause the so-called polygonization of crystals, through the migration from dispersed distribution to vertical alignment. The polyhedral form of graphitized particles of carbon black *Thermax*, which has been observed by Kmetko[13] and Kuroda-Akamatsu[14], would be explained by this mechanism. While, it is worthy to note that the polygonization has been observed only for the large-particle grade black above 3000 A in diameter. Kuroda ond Akamatsu have shown, in the same experiment, that small-particle grade blacks of 300∼500 A diameter belonging to the typical hard carbon are not polygonized by heat treatment, and some of them ultimately break up into finer fragment at 3000°C. In a ward, the graphitization stress in small particles can not be relaxed by the introduction of dislocations but leads directly to the brittle fracture.

In order to explain this anomaly, our attention should be focussed on the distribution of dislocations. In Fig. 4, one can see that

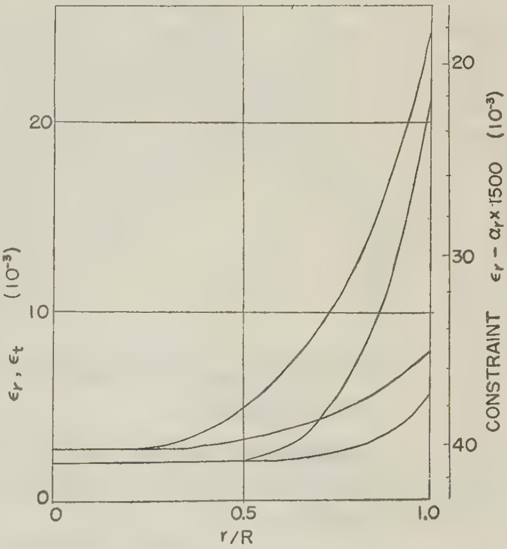

Fig. 4. Strain distribution curves.

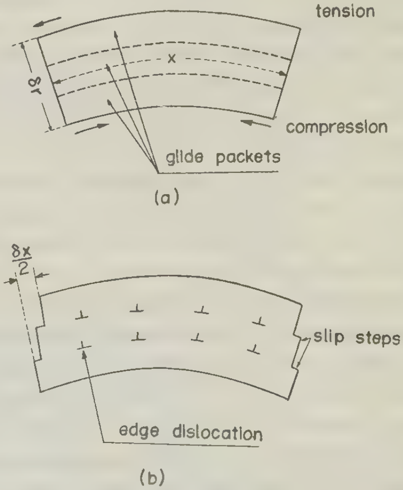

Fig. 5. Formation of edge dislocations by plastic bending of crystal lattice.

the radial gradient of $\mathcal{E}_\theta$ steeply increases toward the external surface, especially in the part between $r/R=0.8\sim1.0$. Therefore, most of the dislocations which contribute to the stress relaxation are concentrated nearby the external surface. Substituting $b=1.42$ A and $\mathcal{E}_\theta$ between $r=0.8R\sim R$ into Eq. (20), the local density n of dislocations in the carbon spherulite and the corresponding average spacing $1/\sqrt{n}$ are plotted against R in Fig. 6 (curves (1) and (2)).

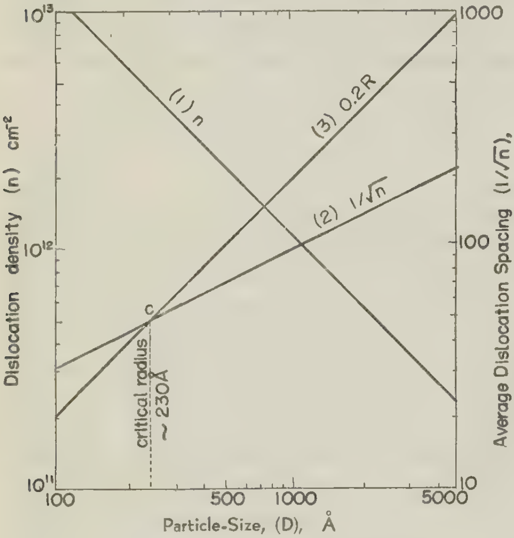

Fig. 6. Dedendence of dislocation density (n) and average dislocation spacing ($1/n$) on particle-size for carbon spherulite.

On the other hand, it is known that on the graphitization of carbon black the limiting size to which the crystallites can grow up is roughly proportional to the particle size; *i.e.* about $1/5\sim1/10$ of the diameter from the X-ray data[15]. Then, it may be appropriate to assume that $0.2R$ $(=R-0.8R)$ just gives the crystallite size itself consisting the spherulite, which is also plotted in Fig. 6 (curve (3)). Now, in the small particles ($R<230$ A) found on the left-hand side of point C in Fig. 6, the crystallite size is smaller than the dislocation spacing, so that some crystallites can not contain the dislocations by which the graphitization stress is released and are inevitably led to fracture by the residual stress.

This explanation implies an assumption that the intercrystallite boundary dividing the spherulite let pass the thermal stress but intercept the stress field arround the dislocations. Such an expectation is seen somewhat arbitrary at the present stage. However, it is possible to say that the stress field of dislocation is less transmissive to the adjacent crystallite as compared with that of thermal stress, since stretching the bond at the boundary is supposed to be fairly anisotropic. In large particles, dislocations are so uniformly dispersed as to form one kind of self-consistent stress field in each crystallite, by which the graphitization stress may be relaxed independently. Conclusively, the basic model assuming the elastic continium can be generally used in the calculation of the graphitization stress, but, in discussing the stress relaxation process it is not applicable for the small particles.

The dependence of n and $1/\sqrt{n}$ on R for the filamentarily textured polycrystal can be similarly computed, and the criterion on the stress relaxation may be formally determined. However, as mensioned before, the filamentary carbons which have been frequently observed in soft cokes are caused by the macroscopic flow pattern in the viscous hydrocarbon fluid, and hence the diameters are by far larger than those of pyrolytic black carbons, ranging from several microns upto about 1/10 mm. Accordingly, the aforesaid criterion is no meaning, and the graphitization stress is easily released by the formation of dislocations and the following motion for redistribution in each crystallite.

§ 4. Concluding Remarks

The principal conclusions obtained in the preceding theoretical investigation are summerized as follows: (1) Heat treatment of polycrystalline carbon for graphitization gives rise to large thermal stress, due to the interference of extremely anisotropic thermal expansion of each crystallite. (2) Evaluation of this so-called graphitization stress made on two representative models (spherical and cylindrical ones) suggests that the stress is enough to produce the dislocations through the direct mechanical buckling of crystal lattice. (3) Stress relaxation process in connection with the formation of dislocation has been discussed, and a criterion is given in order to distinguish the soft and hard carbons. (4) Consequently, the graphitization process of polycrystalline carbon can be thought of a process in which the aforesaid internal stress and the corresponding elastic strain is gradually released, and the generation of dislocations followed by the movement for redistribution may surely play a most important role in it.

In the next stage of the theory, it is required to establish more general treatment of the graphitization mechanism, taking into account the behaviors of the boundary dislocations and other imperfections connected with the crystallite growth.

Kinematic Theory of Ferroelectric Domain Growth

By Terutaro NAKAMURA

Department of Physics, Faculty of Science,
Ochanomizu University, Otsuka, Tokyo

(Received February 6, 1960)

Sidewise motion of 180° wall in ferroelectric barium titanate is described, applying the kinematic wave theory developed by Lighthill-Witham. The rather peculiar shapes of the domain in growing and in shrinking processes, observed by Miller and Husimi, can be derived purely kinematically.

180° wall is described as an assembly of steps. Orientation of the wall is described by step density. There is a part of constant orientation that moves with a constant velocity, which is shown to be identical to the kinematic wave velocity.

Round squares observed in the growing process and straight domain fronts in the shrinking process are fairly well explained as a result of propagation of kinematic waves, assuming a suitable functional relationship between the velocity and the density of the progressing steps. Discontinuity of wall orientation is interpreted as " kinematic shock wave."

§ 1. Introduction

Recently it has been found by Miller[1),2),3)] that the polarization reversal in $BaTiO_3$ single crystal with electrolyte electrodes[9)] is brought about by sidewise motion of 180° wall under application of lower and higher electric fields, in contrast to Merz's[4)] observation that the polarization reversal of crystal with electrodes of evaporated noble metal takes place by nucleation of a good many domains, which appear to grow only in the forward direction under application of higher pulse fields. Very recently, Husimi[5] also observed the sidewise motion of domain walls in crystals with silver-plated electrodes prepared by a chemical process, obtaining essentially similar results as Miller. These authors observed that the smallest switched domains are probably circular in cross sections but grow through sidewide motion of 180° walls into large ones approximately square in cross sections, with sides at 45° to *a*-axis under lower fields, but with sides parallel to *a*-axis under higher fields.

In this paper we discuss the growth and shrinkage of domains in a $BaTiO_3$ single crystal from kinematical point of view, applying the kinematic wave theory developed by Lighthill-Witham[6]. We consider principally the growth and not the nucleation of the domains. The treatment is on the same line as the theory of growth and dissolution of crystals by Cabrera-Vermilyea[7] and Frank[8].

Our treatment indicates that the transient shape of growing domains can be derived by assuming that the rate of motion of steps, that may exist on the domain boundary surface, is a function of the orientation of the surface. Under this assumption, the experimental results by Miller and Husimi will give informations on the progression of steps on the domain boundary surface during domain growth.

§ 2. Kinematic Wave Theory

Consider a one-dimensional flow of a compressible substance in x-direction. Let the particle velocity be $s(x, t)$ and the linear density of the particle be k. The particles must conserve, or we have the equation of continuity:

$$\frac{\partial(ks)}{\partial x}+\frac{\partial k}{\partial t}=\frac{\partial q}{\partial x}+\frac{\partial k}{\partial t}=0 \tag{2.1}$$

where $q=ks$ is the flux, that is, the number of particles passing a particular point in unit time.

Now we shall postulate that the particle velocity s, with which the particles move, is completely determined by proximity of other particles, that is, that the particle velocity s is a function of the linear density:

$$s=s(k) \tag{2.2}$$

and accordingly

$$q=q(k)\ . \tag{2.3}$$

Under this postulate the equation of continuity (2.1) can be rewritten as

$$\frac{dq}{dk}\frac{\partial k}{\partial x}+\frac{\partial k}{\partial t}=0\ . \tag{2.4}$$

If we put

$$dk=\frac{\partial k}{\partial x}dx+\frac{\partial k}{\partial t}dt=0$$

we obtain

$$\frac{dq}{dk}=c(k)=\frac{dx}{dt}\ . \tag{2.5}$$

This means that, if we identify the parts of the substance by the value of k and accordingly of q, then there is a part which moves with a constant velocity $c(x)=dx/dt$. The velocity $c(k)$ is what is called by Lighthill-Witham[6] the "kinematic wave velocity". In $x-t$ space, k and accordingly q are constant along a straight line of slope $c(k)$. This is what is called "characteristic" in the theory of partial differential equations.

Hence we have two important velocities:

$$\left.\begin{array}{l}\text{(1) particle velocity } s(k)=q/k\ ,\\ \text{(2) kinematic wave velocity } c(k)=dq/dk\ .\end{array}\right\} \tag{2.6}$$

If the relation $q=q(k)$ is non-linear, kinematic wave velocity $c(k)$ depends on k, and overtaking of slower waves by faster ones may occur. This is what is called "kinematic shock wave". The shock wave is always accompanied by a discontinuity of k and q. The velocity of the shock wave is given by

$$U=(q_2-q_1)/(k_2-k_1) \tag{2.7}$$

where q_1 and k_1 are the flux and the density on the one side of the shock wave, and q_2 and k_2 are those on the other side.

§ 3. Application of Kinematic Wave Theory to Ferroelectric Domain Growth

The analysis in the foregoing section will be adapted to the two-dimensional growth of domains of barium titanate crystal in $x-y$ plane or the plane perpendicular to c-axis.

For this purpose the domain growth or shrinkage process is conceived of as a progression of steps of lattice planes, as shown in Fig. 1. Let the x-direction be [100] crystallographic axis. The linear density of steps along x-direction is denoted as k, and the height of each step is denoted as h, which is supposed to be an atomic lattice spacing.

It seems not unreasonable to adopt this model, since the domain will have no thickness, change of polarization at the boundary being abrupt, and since the ferroelectric domain boundary is identical to crystallographic twin boundary.

We shall assume that the velocity s of the progression of each step is only the linear density k in x-direction,

$$s=s(k)\,, \tag{3.1}$$

and hence the "step flux" q, that is, the number of steps passing a particular line $x=x_0$ in unit time, is dependent on the step density k alone:

$$q=q(k)\,. \tag{3.2}$$

Then, the method described in § 2 will be applied to a two-dimensional growth of 180° domains in barium titanate.

The density k is taken to be positive for the case shown in Fig. 1a, negative for Fig. 1b. The flux q is taken to be positive, if the steps move in the positive direction of x in Fig. 1a, and positive, if they move in the negative direction of x in Fig. 1b.

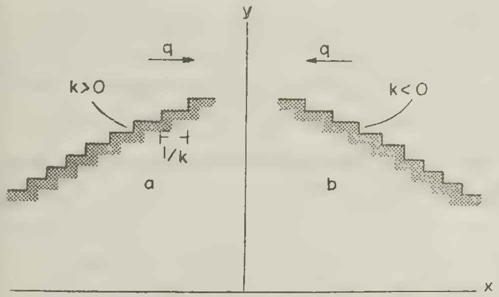

Fig. 1. Description of domain boundary movement by progression of steps.

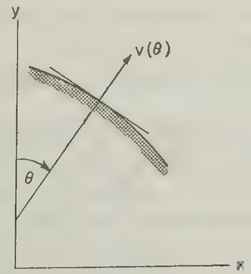

Fig. 2. Orientation of domain boundary surface. θ is the parameter in the couple of Eq. (3.6).

According to our step model, a domain boundary making an angle θ with the (100) plane will be characterised by the density k expressed by:

$$\frac{1}{kh}=\frac{\partial x}{\partial y}=-\frac{1}{\tan\theta}\,. \tag{3.3}$$

The velocity of domain boundary motion along the y-axis is

$$\left(\frac{dy}{dt}\right)_{x=\mathrm{const}}=-\frac{\partial x/\partial t}{\partial x/\partial y}=-qh\,. \tag{3.4}$$

The normal velocity of domain wall is given by

$$v=-qh\cos\theta\,. \tag{3.5}$$

Owing to the functional relationship between q and k on the one hand, and between k and θ on the other hand, we can find a definite functional dependence of v on the angle θ:

$$v=v(\theta)\,.$$

Conversely, if we know the functional form of $v(\theta)$, we have

$$\begin{cases} v(\theta)=-qh\cos\theta\,, \\ \tan\theta=-kh\,, \end{cases} \tag{3.6}$$

which is considered to be an expression of the relation $q=q(k)$ using a parameter θ.

The kinematic wave velocity dq/dk can be brought to a form using $v(\theta)$ as

$$\begin{aligned} c_x(\theta)=\frac{dq}{dk}&=\frac{(d/d\theta)(v(\theta)/\cos\theta)}{(d/d\theta)\tan\theta} \\ &=v(\theta)\sin\theta+v'(\theta)\cos\theta\,. \end{aligned} \tag{3.7}$$

The kinematic wave velocity, $c_x(\theta)$, which is constant for a constant value of θ, is physically interpreted as the x-component of the velocity, with which a point of constant orientation θ on the domain boundary surface moves.

The velocity with which steps actually move in the x-direction (Fig. 1) is

$$s(k)=q/k$$

or

$$s(\theta)=v(\theta)/\sin\theta\,. \tag{3.8}$$

The kinematic shock wave corresponds, in our model, to a discontinuous change of surface orientation and the velocity of the shock wave in x-direction is

$$\begin{aligned} U_x=\frac{q_2-q_1}{k_2-k_1}&=\frac{(v(\theta_1)/\cos\theta_1)-(v(\theta_2)/\cos\theta_2)}{\tan\theta_1-\tan\theta_2} \\ &=\frac{v(\theta_1)\cos\theta_2-v(\theta_2)\cos\theta_1}{\sin\theta_1\cos\theta_2-\cos\theta_1\sin\theta_2}\,. \end{aligned} \tag{3.9}$$

§ 4. Alternative Expression of the Theory

The physical meaning of the kinematic wave will be more intuitively understood as follows. It will be assumed that every point on the domain boundary surface at $t=t_0$ sends out "elementary plane wave," with normal velocity (velocity normal to the boundary surface) $v(\theta)$ which is dependent on the orientation of the boundary surface. After a time interval δt, each "plane wave" will reach a certain position. An envelope of these "elementary plane waves" should give the transient shape of domain boundary at the time $t_0+\delta t$. This procedure may be similar to that used to obtain the wave front of light using Huygens' principle. (Fig. 3)

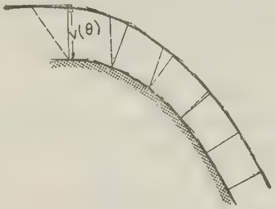

Fig. 3. Movement of a curved domain wall. Note the relation between the normal of domain wall and the trajectory of faces with constant orientation.

Let us take an initial shape of domain boundary given by $F(x, y)=0$. The equation of the tangent to this curve at a point (x, y) on the wall is expressed as

$$x \cdot \sin\theta + y \cdot \cos\theta = p\ , \tag{4.1}$$

where

$$\sin\theta = \frac{F_x(x_0, y_0)}{\pm\sqrt{F_x^2(x_0, y_0)+F_y^2(x_0, y_0)}}\ ,$$

$$\cos\theta = \frac{F_y(x_0, y_0)}{\pm\sqrt{F_x^2(x_0, y_0)+F_y^2(x_0, y_0)}}\ ,$$

$$p = \frac{F_x(x_0, y_0)x_0+F_y(x_0, y_0)y_0}{\pm\sqrt{F_x^2(x_0, y_0)+F_y^2(x_0, y_0)}}\ . \tag{4.2}$$

Note that the envelope of planes (4.1) for various values of θ is identical to the boundary $F(x, y)=0$. The equation of the envelope of the "plane waves" at $t_0+\delta t$ is obtained by eliminating θ from a pair of equations

$$\left\{\begin{array}{l} x \cdot \sin\theta + y \cdot \cos\theta = p + v(\theta)\delta t\ , \\ x \cdot \cos\theta - y \cdot \sin\theta = \qquad v'(\theta)\delta t\ , \end{array}\right. \tag{4.3}$$

and is represented by parameter θ as

$$\left\{\begin{array}{l} x = p \cdot \sin\theta + (v(\theta)\sin\theta + v'(\theta)\cos\theta)\delta t\ , \\ y = p\cos\theta + (v(\theta)\cos\theta - v'(\theta)\sin\theta)\delta t\ . \end{array}\right. \tag{4.4}$$

From the couple of Eq. (4.4) it is obvious that a point of constant orientation θ on the boundary moves with a constant velocity, whose x- and y-components are

$$c_x(\theta) = v(\theta)\sin\theta + v'(\theta)\cos\theta \tag{4.5}$$

and

$$c_y(\theta) = v(\theta)\cos\theta - v'(\theta)\sin\theta \tag{4.6}$$

along a straight line. Note here that $c_x(\theta)$ of (4.5) is the kinematic wave velocity that propagates in the x-direction,

$$c_x(\theta) = dq/dk\ ,$$

and similarly $c_y(\theta)$ of (4.6) is that in the y-direction.

Now, let us consider a functional form, for example,

$$v(\theta) = v_0(1 + A\cos 4\theta) \tag{4.7}$$

which is a continuous function of θ. In Fig. 4 this functional form is represented as a curve

$$r = 1/v(\theta)\ , \tag{4.8}$$

which may be called the polar diagram of reciprocal rate of domain growth.*

First, we consider domain growth from a

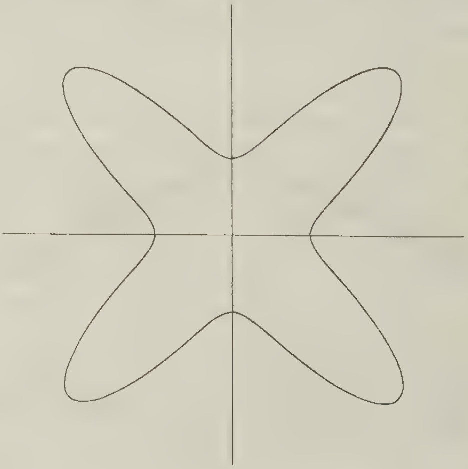

Fig. 4. Polar diagram of reciprocal rate of domain growth

$$r = 1/v_0(1 + A\cos 4\theta). \qquad [A=0.5]$$

---

* Advantage of adopting this curve, instead of $r=v(\theta)$, consists in that the direction of the normal to the curve (4.8) at the point (r, θ) gives the direction of the trajectory of the point of orientation θ on the domain boundary surface. This is easily seen, because the normal to (4.8) has the orientation

$$\frac{c_y(\theta)}{c_x(\theta)} = \frac{v(\theta)\cos\theta - v'(\theta)\sin\theta}{v(\theta)\sin\theta + v'(\theta)\cos\theta}\ .$$

nucleus of circular form. In Fig. 5 are shown trajectories of points with various orientations. For θ smaller than γ, which corresponds to the inflection point of the curve (4.8), trajectories are convergent. In general, however, these trajectories do not focus sharply upon one point, but form an envelope shown in Fig. 5. This situation may be similar to the formation of caustic surface in optical systems.

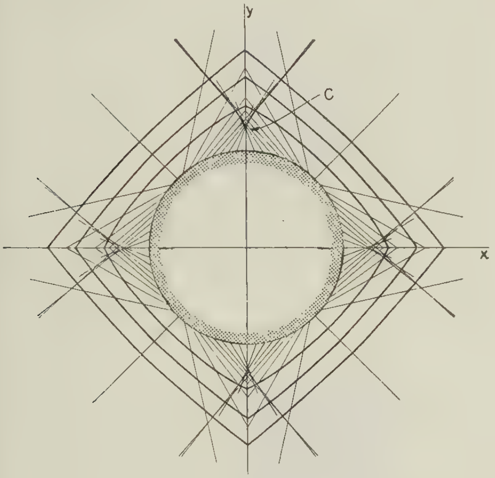

Fig. 5. Theoretical shapes of growing domain, derived from (4.7), trajectories of points with various orientations, and "caustic surface".

Since the equation of a trajectory starting from a point (x, y) on the boundary surface of the circular nucleus domain $x^2+y^2=a^2$ is

$$(x-a\cdot\sin\theta)c_y(\theta)=(y-a\cdot\cos\theta)c_x(\theta)\ , \qquad (4.9)$$

the equation of the envelope of the "caustic surface" is obtained by eliminating θ from (4.9) and

$$-a\cdot\cos\theta c_y(\theta)+(x-a\cdot\sin\theta)c_y'(\theta)$$
$$=a\cdot\sin\theta c_x(\theta)+(y-a\cdot\cos\theta)c_x'(\theta)\ . \qquad (4.9')$$

The equation of the "caustic surface" is

$$\left\{\begin{aligned} x&=-a\frac{v'(\theta)\cos\theta-v''(\theta)\sin\theta}{v(\theta)+v''(\theta)}\ ,\\ y&=a\frac{v'(\theta)\sin\theta+v''(\theta)\cos\theta}{v(\theta)+v''(\theta)}\ , \end{aligned}\right. \qquad (4.10)$$

being represented by parameter θ. The "caustic surface", as shown in Fig. 5, exhibits a cusp at the point C on ⟨010⟩ axis.

Starting from the circular nucleus, the shape of the domain in each stage of its growth will be given by the envelope of the "elementary plane waves", that is, by Eq. (4.4). Since the growth is faster in the direction of the coordinate axis, the shape becomes more and more like a round-sided square. Until the domain boundary reaches the cusp of the "caustic surface", however, the corner is rounded with a finite curuature.

If the domain boundary moves beyond the point C, the discontinuity of the surface orientation of the boundary takes place along ⟨010⟩ axis. That is, trajectories of the point of orientation θ_1 and $-\theta_1$, that statisfy $0<\theta_1<\alpha$, encounter each other on the (100) plane, where α denotes "critical orientation", whose trajectory is parallel to [010] axis, or for which $c_x(\alpha)=0$.* It will be emphasized here that this discontinuity takes place even when we take a continuous function $v=v(\theta)$ as (4.7). This discontinuity or "bunching" corresponds to the kinematic shock wave in the model of the progressing steps. The amount of the discontinuity increases with growing domain, until it reaches an asymptotic value 2α. In the progressing step model the velocity of the kinematic shock wave along x-direction is given by

$$U_x=\frac{v(\alpha)\cos(-\alpha)-v(-\alpha)\cos\alpha}{\sin\alpha\cos\alpha-\sin(-\alpha)\cos\alpha}$$
$$=\frac{v(\alpha)(\cos\alpha-\cos\alpha)}{\sin 2\alpha}=0 \qquad (4.11)$$

in accordance with the fact that the discontinuity moves on the y-axis.

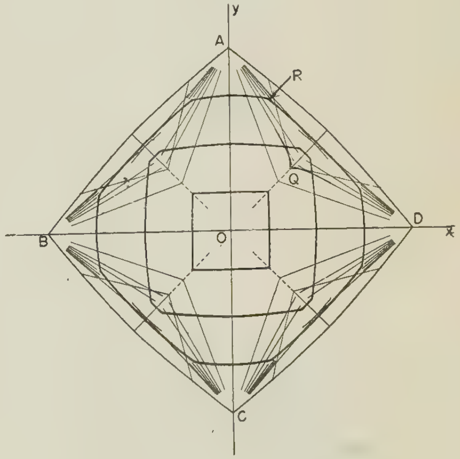

Fig. 6. Theoretical shapes of shrinking domain, derived from (4.7), trajectories of points with various orientations, and "caustic surface".

---

* In the polar diagram representation, ±α correspond to the points at which the outside common tangent contacts with the curve.

Secondly, we consider the process of domain shrinkage that takes place when the field is reversed at a stage in which the domain has grown sufficiently large, as shown by ABCD in Fig. 6. It may be supposed that, in a very narrow region near A, faces of orientations between α and $-\alpha$ are potentially present, and send out the "elementary plane waves". Trajectories for the faces $\theta<\gamma$ starting from the corner are divergent, while ones for faces $\theta>\gamma$ are convergent. In a quite similar manner as in the growing process we may have "caustic surface" formed by the rays of kinematic waves for the faces $\theta>\alpha$, which has a cusp as shown in Fig. 6. Accordingly, when the domain wall reaches the cusp Q while shrinking, a discontinuity of orientation occurs and will move on the line Q_0 in Fig. 6, which is parallel to [110] axis. It must be noted here that, in the shrinking process, another discontinuity R takes place. The latter discontinuity occurs only when the trajectory of the point of orientation $\theta=\gamma$ starts from the corner of the initial domain.

§ 5. Comparison with Experimental Results

From the experimental results obtained by Miller[1], Miller-Savage[2] and Husimi[5], we can summarize the following characteristic aspects of domain growth under lower fields:

(1) On photographs including sequence of domain boundary in a crystal which has been partially switched and successively etched (Photos. 2 and 4) points of given orientation are on a straight line, that is, the trajectory of a point of a given orientation is a straight line.

(2) The normal velocity $v(\pi/4)$ for a surface of $\theta=\pi/4$ is independent of time t.

(3) In the process of domain growth, discontinuity of orientation of domain boundary surface is formed along ⟨100⟩ direction (Photos. 1, 2, 3 and 4), that is, regions of orientation θ which satisfy

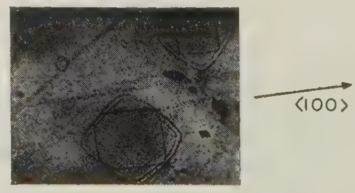

Photo. 5. Photomicrograph showing shape of shrinking domains. Note that the wave front in shrinking process is sharply straight. By courtesy of Dr. K. Husimi.

$$-\alpha \leq \theta \leq \alpha$$

are not realized, where α is found to be about 33°.

(4) In the process of domain shrinkage, a discontinuity is formed along ⟨110⟩ direction. Walls are in this case scarcely curved. There occurs another discontinuity, where the straight wall front meets the round wall that has started from the edge. (Photo. 5)

It will be seen that all the above features are what we have expected from our theory. That is, the domain wall motion can be described as the propagation of kinematic waves. From the observed angle of discontinuity in the growing process, we obtain the polar diagram of reciprocal domain growth rate as shown in Fig. 8, where the normal becomes parallel to [010] axis at $\theta \fallingdotseq \pm 33°$. To interpret the form of the domain wall with the nearly straight sides observed in the shrinking process, the part near P of polar diagram in Fig. 8 would be rather sharp. The velocity $v(0)$ for $\theta=0$ may be about ten times as large as $v(\pi/4)$. (after Husimi[5])

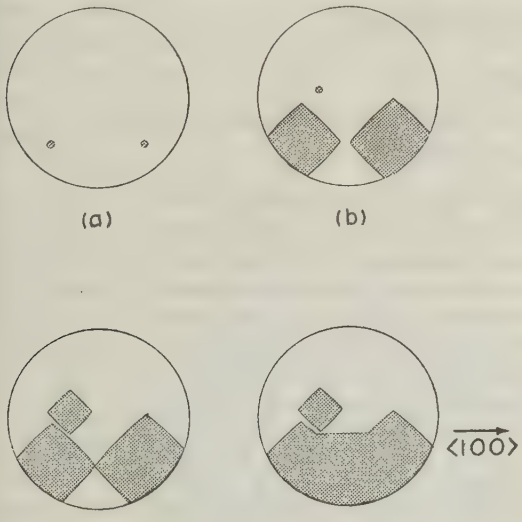

Fig. 7. Successive stages of growth process of the domains shown in Photo. 3.

It is interesting to note that, by applying our theory, we can tell to a certain extent the history that a domain configuration has gone through. For example, let us look at Photo. 3. This domain configuration will be supposed to have been realized by a process as follows. 1) Two nuclei are first formed (Fig. 7a). 2) They grow in a form as shown in Fig. 7b, while a third nucleus is born. 3) Previous two domains coalesce (Fig. 7c). 4) From the concave part of the boundary starts the propagation of a straight wall, which is quite similar as that in the shrinking domain (Fig. 7d).

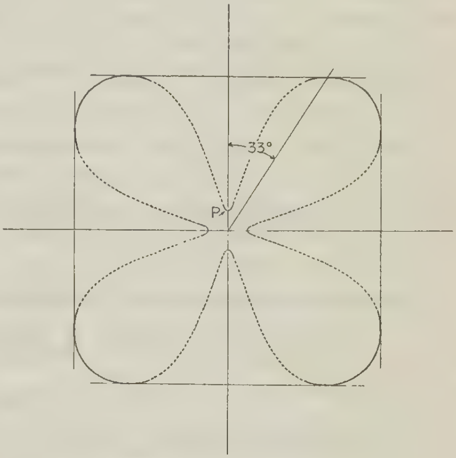

Fig. 8. Polar diagram of reciprocal rate of domain growth, which explains experimental results.

§ 6. Concluding Remark

Present theory indicates that the rather peculiar behavior of domain shape can be derived purely kinematically, only by assuming a suitable functional relation between the velocity and the density of the moving steps in the growing as well as in the shrinking process.

It must be admitted that the present theory is purely phenomenological and the mechanism of step nucleation as well as the factors that determine the elementary processes of step progression under applied fields remain unanswered.

The author wishes to express his sincere gratitude to Professor H. Takahasi of University of Tokyo for his invaluable discussions and encouragement. He is also thankful to Dr. R. C. Miller of Bell Telephone Laboratories and the Physical Review and to Dr. K. Husimi of Electrical Communication Laboratory and the Journal of Physical Society of Japan, for their kind permissions to reproduce photographs. This work was finantially supported by the Grant in Aid for Scientific Research from the Ministry of Education.

Change in Modulus of Rigidity of Brass Wires by Cold-Working and Subsequent Annealing

By Jun KUROYANAGI

Department of Physics, Faculty of Liberal Arts and Science, Yamagata University

(Received March 29, 1960)

The change in the modulus of rigidity caused by cold-working and subsequent annealing was measured on brass wires containing 10.14, 30.15 and 40.24 per cent zinc and a commercial brass wire (32.66 per cent zinc), and compared with that of pure copper wire. The results showed that; (1) in well annealed state, the modulus of rigidity of brass wires decreases quasi linearly with the increase of zinc content, (2) the modulus of rigidity of a brass wire always decreases with the increase of the degree of cold-working, but the relative decrease of the modulus of rigidity compared with the decrease of a pure copper wire equally cold-worked different according to the zinc content and (3) the variations in the temperature coefficient of the modulus of rigidity with the method of cold-working and with the degree of cold-working have a characteristics according to the zinc content.

§ 1. Introduction

Previously[1], the present author measured the change in the rigidities of wires of pure copper and also of 70/30 brass which had been subjected to a cold-working and subsequent annealing, and found that the existence of 30 per cent zinc gives a conspicuous influence on the effect of the above mentioned treating. Now, as it seems to him interesting to elucidate this phenomenon in detail, this investigation was undertaken.

§ 2. Specimens and method of measurement

The materials used were the three kinds of alloys containing 10.14, 30.15 and 40.24 per cent zinc in copper, and also a commercial brass was added. The X-ray diffraction patterns obtained in a Debye-Scherrer camera from these alloys were essentially the same as that of copper. The existence of β phase could not be found even in the brass containing 40.24 per cent zinc. Nevertheless, according to the phase diagram, β phase should coexist with α phase in this brass which may exert some influence on the rigidity of this specimen. The chemical composition of these materials are shown in Table 1. They were drawn into wires, about 1 mm in diameter, from which proper lengths were taken for the specimens. The specimens were first annealed at 600°C for 2 hours in nitrogen atmosphere, and then subjected to cold-working in the manner of

Table 1. Composition of materials used (wt. %)

Materials	Zn	Fe	As	Sb	Bi	Pb
Copper		0.0007	0.00003	0.00001	0.0004	0.0002
Brass 1	10.14	0.004	0.00006	0.00003	0.0004	0.0096
Brass 2	30.15	0.0037	0.00006	0.00003	0.0004	0.0046
Brass 3	40.24	0.0028	0.00006	0.00003	0.0006	0.0024
Brass 4 (Commercial)	32.66	0.0039	0.010	0.001	0.0004	0.15

rolling and twisting. As the degree of rolling was defined by the reduction of area $(A-a)/A$, where A and a denote the cross-sectional area of a wire before and after the rolling, respectively. As the degree of twisting was defined by nd/l, where n is the number of turns, d is the diameter and l is the gauge length. The used technique of the measurement and apparatus were the same as that have been described in the previous paper. The measurements were always made after the specimens had been aged at room temperature for one month.

The specimen set in the apparatus was heated at the constant rate of 1.7°C/min from room temperature to 400°C and the time of 100 rotating oscillations of the pendulum was measured with a stopwatch at every temperatures of 20°C interval during heating.

In addition, the behaviour of the hardness was traced for varying degree of cold-working in correspondence to the rigidity, by means of a micro Vickers hardness tester. To eliminate the error due to the influence of the amount of the loads applied to the indentor on the hardness number, the load was fixed to 500 g and the time of indentation to 1 min.

§ 3. Results

The relations between the square of the frequency f of torsional oscillation, which is approximately proportional to the modulus of rigidity, and the degree of cold-working or temperature of measurement were obtained but not the absolute value of the modulus of rigidity, because the present purpose was to see the relative change in modulus of rigidity.

(1) *Influence of the change of zinc content*

To see the variation of the modulus of rigidity of brass wires with the change of zinc content, the relations between $(f^2_{\mathrm{Brass}}-f^2_{\mathrm{Cu}})/f^2_{\mathrm{Cu}}$ and zinc content were obtained for annealed and cold-rolled specimens at room temperature, where f_{Brass} and f_{Cu} are the frequencies of torsional oscillation, respectively, of brass wire and copper wire equally cold-rolled. Figs. 1 and 2 show the above relations which were obtained for cold-rolled specimens, the degree of cold-rolling of which were 10.5 and 57.5 per cent, before and after they were heated at 400°C for 1 hour and then cooled slowly to room temperature, respectively.

From Fig. 1 it can be seen that the modulus of rigidity of brass wire containing 10 per cent zinc is higher than that of pure copper wire, but that of brass wires containing more than 10 per cent zinc decreases quasi linearly in proportion to the increase of zinc content in the case of 10.5 per cent cold-rolled specimens.

In the case of annealed specimens, before they were heated at 400°C for 1 hour, the modulus of rigidity of pure copper wire is lower than the value which was obtained by the method of extrapolation from the quasi linear relationship, which holds to the modulus of rigidity of brass wires containing more than 10 per cent zinc, as can be seen from Fig. 1. On the other hand, after the specimens were heated at 400°C for I hour, as can be seen

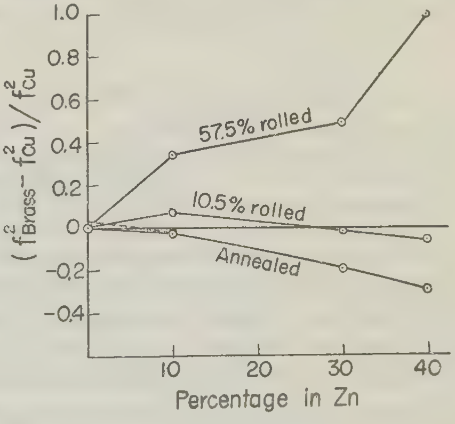

Fig. 1. Modulus of rigidity *vs* percentage of zinc content for cold-rolled brass wires.

from Fig. 2, the modulus of rigidity of the specimens which were either annealed or cold-rolled 10.5 per cent decreases quasi linearly through the whole extent of zinc content.

In the case of the specimens which were cold-rolled 57.5 per cent, regardless of the heating at 400°C for 1 hour, the modulus of rigidity does not change quasi linearly with the increase of zinc content and the specific ratio of the modulus against to that of pure copper increases with the increase of zinc content on the contrary to the case of the specimens which were cold-rolled 10.5 per cent.

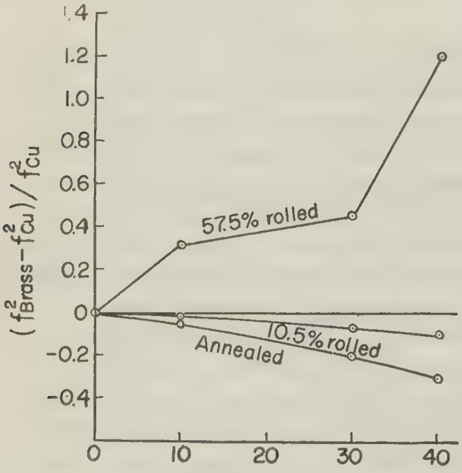

Fig. 2. Modulus of rigidity *vs* percentage of zinc content for cold-rolled brass wires, after annealed400$_0$C, 1 hr.

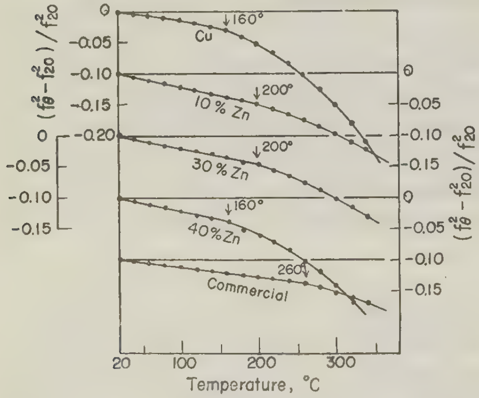

Fig. 3. Change in modulus of rigidity for annealed specimens due to the rising temperature of annealing with constant rate of 1.7°C/min.

(2) *Influence of the rise of temperature at annealed state*

The variation of the rigidity with the rise of temperature was measured with annealed specimens, results being obtained as shown in Fig. 3. In this figure f_θ and f_{20} represents the frequencies of torsional oscillation at a temperature θ and at room temperature (20°C), respectively. Through a set of measurement the observed values in the heating stage almost coincided with that in the following cooling stage at the corresponding temperature respectively. From this figure it can be seen that the rigidity of the normalised specimen decreases slowly in an approximately way with rising temperature, and then remarkably decreases, especially in pure copper and in brass wire containing 40.24 per cent zinc, but in the case of commercial brass wire the temperature range of linearity extends up to a higher point than pure copper and other brass wires.

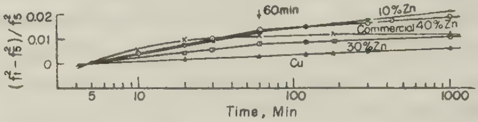

Fig. 4. Relations between $(f_t^2-f_5^2)/f_5^2$ and logarithm of time t at room temperature for cold-rolled specimens, where f_t and f_5 are the frequencies of torsional oscillation at time t and 5 minutes after deformation. Degree of cold-rolling$=$30.5 per cent.

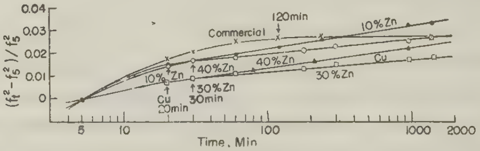

Fig. 5. Relations between $(f_t^2-f_5^2)/f_5^2$ and logarithm of time t at room temperature for cold-twisted specimens, where f_t and f_5 are the frequencies of torsional oscillation at time t and 5 minutes after deformation. Degree of cold-twisting $nd/l=0.10$.

(3) *Recovery of rigidity at room temperature*

The early recovery of the rigidity of a cold-worked specimen is clearly seen from isothermal data. Figs. 4 and 5 show the relations between $(f_t^2-f_5^2)/f_5^2$ and logarithm of the time at room temperature after the cold-work, where f_t and f_5 are the frequencies of torsional oscillation at a time t and 5 minutes after deformation, respectively. From these figures it can be seen that a freshly deformed metal has a relatively low value rigidity, which increases very rapidly in a short time with deformation and then increases almost exponentially from about one hour after deformation, even at room temperature.

(4) *Recovery of rigidity with the rise of temperature in cold-rolling specimens*

Figs. 6–8 show the observed values of $(f^2_{A,\theta}-f^2_{A,20})/f^2_{A,20}$ with relations to temperature for brass wires of various compositions as well as for pure copper wire at various cold-rolled states, where $f_{A,\theta}$ and $f_{A,20}$ are the frequencies of torsional oscillation of the cold-rolled specimens at a temperature θ and 20°C, respectively. It is interesting that the change in the temperature coefficient of the modulus of rigidity with the temperature and with the degree of cold-rolling have a characteristic aspects according to the amount of zinc and impurities contained. Although a definite information cannot be given of the relation between the temperature coefficient of the modulus of rigidity and zinc content, the temperature coefficient in the brass wires containing 10.14 and 30.15 per cent zinc show a great difference from that of the brass wires containing 40.24 per cent zinc and from that of the commercial brass wire. From these figures it can also be seen that the variation of the rigidity with the rise of temperature in copper wire and brass wire subjected to low degree of cold-rolling (10.5 and 30.5 per cent reduction) differs substantially from that subjected to high degree of cold-rolling (57.5 per cent reduction) with an exception of commercial brass wire.

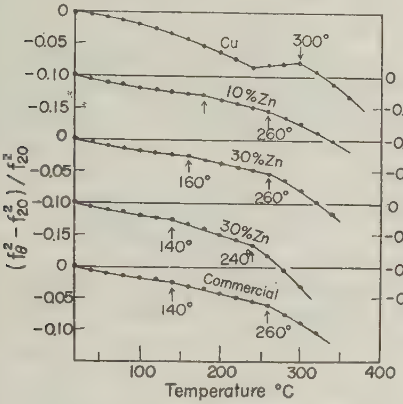

Fig. 6. Relations between $(f_\theta^2-f_{20}^2)/f_{20}^2$ and temperature for cold-rolled various brass wires, where f_θ and f_{20} are the frequencies of torsional oscillation at a certain temperature θ and room temperature, respectively. Degree of cold-rolling was 10.5 per cent for all specimens.

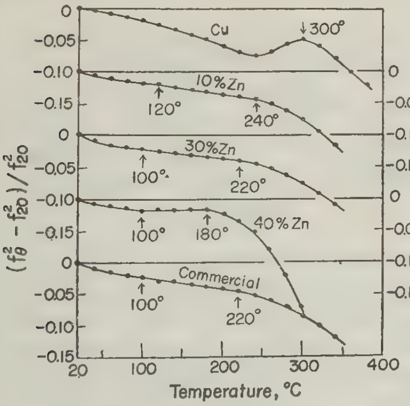

Fig. 7. Relations between $(f_\theta^2-f_{20}^2)/f_{20}^2$ and temperature for cold-rolled various brass wires, where f_θ and f_{20} are the frequencies of torsional oscillation at a certain temperature θ and room temperature, respectively. Degree of cold-rolling was 30.5 per cent for all specimens.

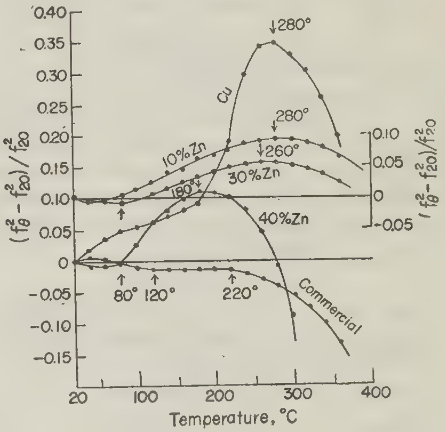

Fig. 8. Relations between $(f_\theta^2-f_{20}^2)/f_{20}^2$ and temperature for cold-rolled various brass wires, where f_θ and f_{20} are the frequencies of torsional oscillation at a certain temperature θ and room temperature, respectively. Degree of cold-rolling was 57.5 per cent for all specimens.

(5) *Recovery of rigidity with the rise of temperature in cold-twisted specimens*

The same observations as above were carried out with cold-twisted wires, the results obtained being shown in Fig. 9. In this case, the temperature coefficient of the modulus of rigidity also varied with temperature and with degree of cold-twisting, showing a characteristic aspect according to the amount of zinc and impurities contained in brass wires. But, this characteristic is not so obvious as that in cold-rolled specimens.

(6) *Change in rigidity due to the removal of internal stress*

Fig. 10 shows the variation of rigidity with the rise of temperature in the brass wire, containing 40.24 per cent zinc, subjected to the cold-rolling of 57.5 per cent. Curve *A* was obtained during first heating, and curve *B* during reheating this specimen after the first heating. Curve *B* was almost reproducible; hence, it may be considered to show the variation of the rigidity with rising temperature of the well annealed specimen. Accordingly, the variation of $(f^2_{A,\theta}-f^2_{B,\theta})/f^2_{B,\theta}$ with temperature θ, where $f_{A,\theta}$ and $f_{B,\theta}$ are the values respectively of the curve A and B at a temperature θ, may be said to show the recovery of the modulus of rigidity by the removal of internal stress due to the rise of temperature.

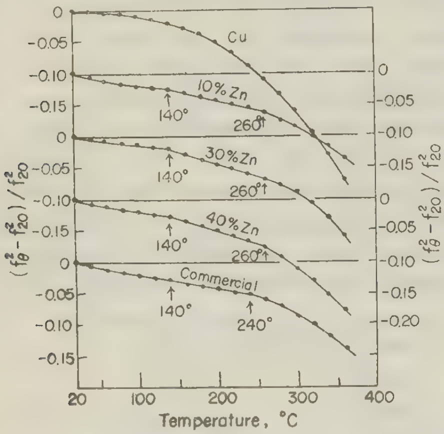

Fig. 9. Relations between $(f_\theta{}^2-f_{20}{}^2)/f_{20}{}^2$ and temperature for cold-twisted various brass wires, where f_θ and f_{20} are the frequencies of torsional oscillation at a certain temperature θ and room temperature, respectively. Degree of cold-twisting was 0.10 for all specimens.

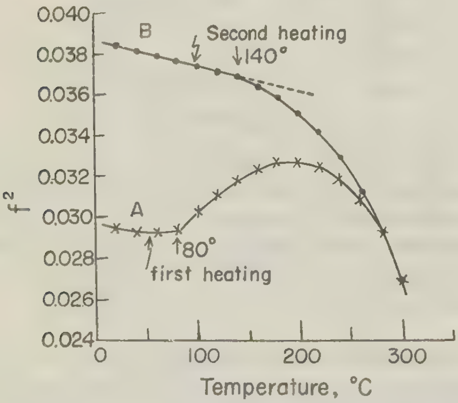

Fig. 10. Change in the modulus of rigidity of the cold-rolled brass wire containing 40.24 per cent zinc, degree of cold-rolling of which was 57.5 per cent, due to the rising temperature of annealing with constant rate of 1.7°C/min.

(a) *Cold-rolled specimens*

To see the effect of zinc on the recovery of rigidity due to the removal of internal stress in cold-rolled specimens, the variation of $(f^2_{A,\theta}-f^2_{B,\theta})/f^2_{B,\theta}$ with temperature θ was measured for various brass wires cold-rolled at almost the same degree (57.5 per cent). The results are shown in Fig. 11. In copper wire the recovery occurs mainly in one stage of the temperature range 180°–320°C as shown in the previous paper[1]. In brass wires containing 10.14 and 30.15 per cent zinc the recovery occurs gradually over the wide range of temperature 80°–360°C, which can be divided into three stages, i. e. 80°–200°C, 200°–

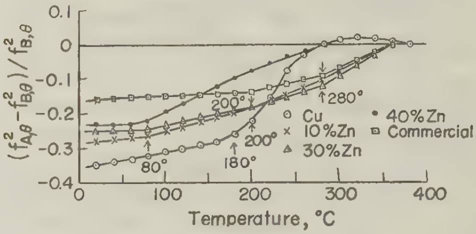

Fig. 11. Relations between $(f^2_{A,\theta}-f^2_{B,\theta})/f^2_{B,\theta}$ and temperature for cold-rolled various brass wires, where $f_{A,\theta}$ and $f_{B,\theta}$ are the frequencies of torsional oscillation at a certain temperature θ for cold-rolled and annealed specimens, respectively. The degree of cold-rolling was 57.5 per cent for all specimens.

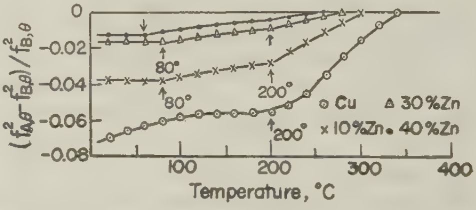

Fig. 12. Relations between $(f^2_{A,\theta}-f^2_{B,\theta})/f^2_{B,\theta}$ and temperature for cold-twisted various brass wires, where $f_{A,\theta}$ and $f_{B,\theta}$ are the frequencies of torsional oscillation at a certain temperature θ for cold-twisted and annealed specimens, respectively. The degree of cold-twisting was 0.10 for all specimens.

280°C and 280°–360°C. In commercial brass wire the recovery occurs mainly in the range of temperature 200°–360°C, which can be divided into the two stages, i. e. 200°–280°C and 280°–360°C. In all cases the recovery takes the greatest rate at the last stage. In brass wire containing 40.24 per cent zinc the recovery occurs rapidly in one stage of the temperature range 80°–280°C.

(b) *Cold-twisted specimens*

Fig. 12 shows the relations between $(f^2_{A,\theta}-f^2_{B,\theta})/f^2_{B,\theta}$ and temperature θ for various brass wires cold-twisted at almost the same degree $(nd/l=0.125)$. In this case, the rigidity of all brass wires recovers over the temperature ranges 80°–200°C and 200°–300°C, and the rate of recovery at latter srage is greater than that at the former stage. These two stages of recovery may by correspond to the former two stages of recovery in the cold-rolled specimens as mentioned in the previous paper¹⁾.

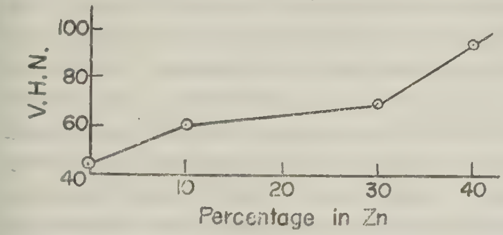

Fig. 13. Relation between Vickers hardness and percentage in zinc content for annealed various brass wires.

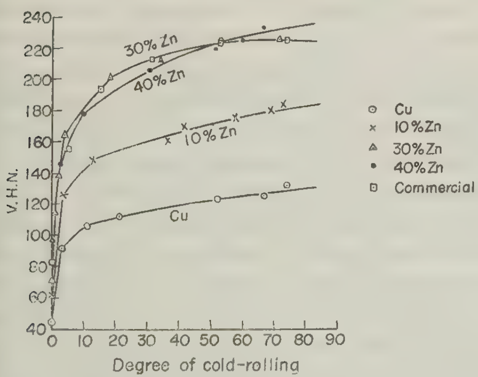

Fig. 14. Relations between Vickers hardness and degree of cold-rolling for cold-rolled various brass wires.

(7) *Change in hardness caused by cold-working*

In Fig. 13 the variation of the Vickers hardness of the annealed brass wires is plotted against the change of zinc content. From this figure it can be seen that the hardness of the annealed brass increases quasi linearly with the increase of zinc content on the contrary to the change of the modulus of rigidity. The change in hardness with the increasing degree of cold-rolling is plotted in Fig. 14. From this figure it can be seen that the curves showing the change in hardness with the increasing degree of cold-rolling are similar to the stress-strain curves which obtained by many workers with brass. It can also be seen that the slopes of these curves increase in proportion to the increase of zinc content.

§ 4. Discussion

(1) *Variation of rigidity of brass wires with the change of zinc content*

The relation between the rigidity and composition in metal alloy is very complicated and it has not yet been satisfactory established.

(a) *Well annealed specimens*

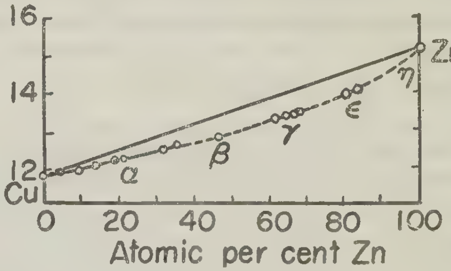

Fig. 15. Volume per atom in Cu-Zn alloy. (Westgren and Almin).

The variation of rigidity of thoroughly annealed and then slowly cooled solid solution alloys of copper can be described in terms of three effects.

(i) *Lattice strain caused by the difference in the atomic radii of the copper and zinc atoms.* It was thought at one time that the variation of lattice parameter in a single phase alloy was an exact linear function of the composition, which is known as Vergard's law. Generally speaking, however, all systems show a greater or less deviation from this law and, when intermediate phases are formed, they are often accompanied by a marked contraction in atomic volume. It appears to be desirable, therefore, to determine the change in lattice constant for the alloys under investigation, in order to measure the lattice strains which they induce. The volume per atom in Cu–Zn alloy is illustrated in Fig. 15, the results being taken from the work of Westgren and Almin[2]. From this figure, it can be seen that the lattice parameter in Cu–Zn alloy increases quasi linearly in the range of α-phase. Zener[3] has studied this problem and found a good correlation between the lowering of the rigidity upon solute addition and the residual strain energy resulting from atomic size disparity.

(ii) *Difference in valence between the solute and solvent metals.* Rigidity of solid solution alloys should be varied with the change in the average number of electrons per atom upon the addition of solute elements. Elliot and Axon[4] showed that the rigidity decreases as the valence of the solute element increase in the case of copper base alloys.

(iii) *Difference in rigidity between the solute and solvent metals.* The fact that the rigidity of pure copper is greater than that of pure zinc should be considered as one of the cause of the decrease of the rigidity of brass wire with the increase of zinc content. Swalinin[5] showed theoretically that the rigidity vary linearly with mole fraction of solute metal for germanium-silicon alloys from this point of view.

(b) *Specimens cold-rolled 10.5 per cent*

In this case, the rigidity of pure copper wire is less than that of brass wire containing 10.14 per cent zinc and deviates from the quasi linear relationship which holds for the modulus of rigidity of the brass wires containing more than 10 per cent zinc. Moreover, the slope of this quasi linear curve is slower than that of well annealed specimens. These facts indicate that the decrease of rigidity in pure copper wire due to the small amount of cold-rolling is very large as compared with that of the brass wire containing 10 per cent zinc and the decrease of rigidity in brass wires containing more than 10 per cent zinc dwindles as the zinc content increase.

The decrease of the modulus of rigidity in the strained pure metal and the associate deviation from the quasi linear relationship in very dilute solution alloys has been observed by Bradfield and Pursey[6] for copper alloys, who observed that after the initial rise of modulus at low concentrations the modulus/concentration curve becomes quasi linear and fall with a slope which may be related to the solidus variations of the particular system, or, perhaps more profitably, to such conventionally accepted alloying factor as atomic size and valence[7]. Furthermore, these phenomena have been discussed by Friedel[8] and by Elliot and Axon[4] in detail, who visualized the effects as being due to the generation of mobile dislocations by small amount of plastic strain and as due to the progressive locking of mobile dislocations with the increase of solute elements. In the present experiment, studied by means of X-ray and metallographic examination, any significant change in structure that account for the change in modulus of rigidity was observed neither before nor after cold-rolling in 10.5 per cent cold-rolled specimens. Consequently, the decrease of rigidity of pure copper wire produced by 10.5 per cent cold-rolling should be due entirely to the lattice distortion and structural defects, without the complicating influence of preferred orientation. In other words, we can visualize this effect as being due to the generation of mobile dislocations by cold-rolling. Mobile dislocations in the crystal tend to decrease the rigidity from the value it would reach in their absence. Any alternation in the number of mobile dislocations, which may arise from cold-working (or the annealing out of cold-working effects), or in the mobility of mobile dislocations, which may result from the locking of dislocations at impurity atoms, will produce an additional contribution to the alternation of rigidity over and above any changes to be expected of conventional alloy theory. In the dilute solid-solution range, increasing concentration of solute atoms will increase the probability of locking, and hence, will increase the rigidity even without special annealing treatment, but on the other hand, at high solute concentration the dislocations are saturated with solute atoms, and the dislocation contribution to the rigidity swamped. The fact that the rigidity of brass wire containing 10.14 per cent zinc is larger than that of pure copper wire can be explained by locking of dislocations at solute atoms.

(c) *Specimens cold-rolled 57.5 per cent*

The fact that the rigidity of brass wires is greater than that of pure copper wire and increases with the increase of zinc content may be correlated with the preferred orientations which were developed by the heavily cold-rolling.

Cook and Richards[9] found the following facts from X-ray studies; (1) when polycrystalline copper and brass strips are cold-rolled, the deformation proceeds by a slip mechanism up to about 33 per cent reduction in thickness for copper and slightly more for brass, and beyond this stage it proceeds by a breakdown of the crystals into minute blocks with glide over flow layer, (2) marked preferred orientation develops during this second stage of deformation and the degree of preferred orientation increases progressively with the increase of cold-rolling.

Merlini and Beck[10] showed that three preferred orientations of the following types are present in rolled copper and brass strips; $(011)[2\bar{1}1]$, $(112)[11\bar{1}]$ and $(011)[100]$. The orientation represented by $(011)[2\bar{1}1]$ is present in large amount for any zinc content between 0 and 30 per cent. The orientation represented by $(112)[11\bar{1}]$ is typical of copper and decreases in intensity with increasing zinc content[11]. The orientation represented by $(011)[100]$ is typical of 70–30 brass and decreases in intensity with decreasing zinc content.

It is well known that the rigidity G depends on the orientation according to the formula[12]

$$\frac{1}{G}=\frac{1}{G_{\max}}+3\left(\frac{1}{G_{\min}}-\frac{1}{G_{\max}}\right)\cdot F \qquad (1)$$

$$F=\gamma_1^2\gamma_2^2+\gamma_2^2\gamma_3^2+\gamma_3^2\gamma_1^2=\frac{h^2k^2+k^2l^2+l^2h^2}{(h^2+k^2+l^2)^2} \qquad (2)$$

where γ_1, γ_2, γ_3 are the direction cosine of the direction under consideration with respect to the cubic axis and h, k, l are the Miller indices. As $F_{\min}=0$ for $[100]$ and $F_{\max}=1/3$ for $[111]$, it follows that the rigidity is largest in the direction $[100]$ and smallest in the direction $[111]$.

Consequently, if the Merlini and Beck's results are tentatively accepted, the increase of the modulus of rigidity with the increase of zinc content of the 57.5 per cent cold-rolled specimens may by explained by the increase of the intensity of preferred orientation represented by $(011)[100]$, for which the value of the modulus of rigidity is largest, and the decrease of the intensity of preferred orientation represented by $(112)[111]$, for which the value of the modulus of rigidity is smallest, with the increase of zinc content.

(2) *Variation of hardness with the change of zinc content*

The hardening of an metal by the addition of solute metal has been explained by Mott and Nabarro[13] and by Cottrell[14] on the basis of interaction between dislocations and solute atoms. In addition, Dorn, Pietrokowsky and Tietz[15] found on some aluminium alloys that part of the solid solution hardening should be attributed to (1) the difference in valence between the solute and solvent metals, (2) lattice strain caused by the difference in the atomic radii of the host and solute atoms. The experimental results mentioned above seems to be due to the combined effect of these factors.

(a) *In the case of annealed specimens*, the increase of hardness with the increase of zinc content may be due to the effect of the lattice strain and the change in the number of electrons per atom with the addition of zinc. The fact that the hardness of the specimen containing 40 per cent zinc is especially large can be explained by the coexistence of β phase.

(b) *The rapid increase in hardness at early stage of cold-rolling* should be due to the rapid increase of the density of free dislocations, and the gradual increase in hardness at high stage of cold-rolling seems to show the density of dislocations is getting near to a saturated state as the degree of cold-rolling steadily increases.

(c) *The fact that the variation in hardness with zinc content of the cold-rolled specimens, the degree of cold-rolling of which being the same in all cases, is larger than that of annealed specimens* can be explained as the additional effect of the interaction between dislocations and solute atoms to the lattice strain and change in valence. This interaction may increase with increasing concentration of solute atoms when the degree of cold-rolling being the same.

(3) *Room temperature recovery of rigidity*

It is well known that a crystal contains a three dimensional network of dislocation loops or segments and that the presence of such a dislocation network will act to reduce the rigidity of the material. If N is the dislocation density, viz, the total length of dislocation lines per cm³ and L is the effective loop length of the dislocation segments, the decrease in modulus of rigidity G is represented by[16]

$$\Delta G/G\sim N\cdot L^2 \qquad (3)$$

It is suggested that the modulus defect which recovers rapidly even at room temperature is attributed to the existence of relatively free dislocations within the subgrain structure, and is regarded as not influenced by dislocations that form the subgrain boundaries. In view of this model, the question next arises: what is happening to the interior dislocations in the early stage of recovery, i. e., when the rigidity are changing so rapidly? Two general mechanism have been suggested as to this problem.

(a) *The first theory*(17) assums that point defects created by the deformation pin the dislocation segments to produce recovery. According to this theory, the modulus defect can be eliminated through the shortening of the dislocation loops due to defect pinning, before any dislocation migration or rearrangement takes place. Dislocations may be pinned by point defects, impurities and solute atoms along the straight portions. If the concentration of the solute element is large enough, a dislocation segment (L) meets solute atoms on the average at a distance (L_0) which decreases when the concentration of solute atoms increases, so that the rate of recovery of the rigidity should increase with the increase of the concentration of solute atoms. The rigidity of the cold-worked commercial brass wire, in which large amount of impurities are contained than in the other specimens, recovers much faster than the other specimens in a short time after deformation and thereafter it recovers with a slower rate than the other specimens in both cases of rolling and twisting, as was expected. But, in regard to the other specimens this fact is not obvious. In the case of cold-rolled specimens, the rate of recovery in a short time after deformation is slowest in pure copper wire and increases with the increase of zinc content, except the brass wire containing 10.14 per cent. Nevertheless, in the case of cold-twisted specimens the relation between the rate of recovery and zinc content is complicated and can not be explained with the above theory.

(b) *The second theory*(17) considers that dislocation rearrangement is responsible for the recovery of this stage. According to this theory, it is assumed that dislocations in the interior of the subgrains undergo rearrangement which serves to reduce either their effective length or their loop length L. The concept that the rapid rearrangement is taking place immediately after plastic deformation to produce the recovery of rigidity was suggested by Nowick(17). According to this theory, the rate of rearrangement of dislocations, or consequently, the rate of recovery should decrease rapidly by the pinning of dislocations with solute atoms, viz, be the formation of Cottrell atmosphere and the time necessary to cease the recovery practically should become shorter with the increase of the concentration of solute atoms and impurities. Our experimental results show that the rate of recovery decreases with the increase of zinc and impurity content at a certain time after deformation on the whole as can be seen from Figs. 5 and 6.

It is impossible to conclude which one of these two theories is correct only by these experimental results.

(4) *Recovery of rigidity at the elevated temperature*

The recovery occurring between room temperature and recrystallization temperature is concerned with both point defects and dislocations, and their combination varies with the method and degree of cold-working, kind of metal and alloy, and impurities content, etc. as mentioned in the previous paper(1).

For the pure copper wire used in this experiment practically no recovery of rigidity occurs before recrystallization, suggesting that almost all recovery processes occur during the deformation and during the period of aging at room temperature. However, for the brass wires the manner of the recovery of rigidity differs from that of pure copper wire and begins to occur at about 80°C as shown in Figs. 12 and 13. This may be due to the formation of atomosphers of zinc atoms around the dislocations during and after deformation at room temperature. Thus the movement of the dislocations involved in recovery would occur either by the breaking away of dislocations from their atmosphers of solute atoms or by the disappearance of atmosphers moving with the dislocations. Both of these processes would require higher temperature than would be necessary in pure copper.

The author wishes to express his sincere thanks to Professor Tokutaro Hirone of Tohoku University for the kind guidance and to Mr. Toyojiro Isano for his assistance.

Study on Some Tl Base Alloys, with Reference to their Electronic Structure

By Ryōji SUGANUMA

Physical Institute, Kyoto Prefectural University of Medicine

(Received February 27, 1960)

Kinds and boundaries of phases at room temperature in Tl-rich sides of the alloy systems of Tl-Cd, Tl-Sn and Tl-Sb were determined by X-ray and electron diffraction. From the consideration of experimental results obtained in the present work as well as in previous works by other workers, it was deduced that phase boundaries of a particular structure in some Tl base alloys appeared to correspond to the same electron atom ratio and to be affected mainly by the electronic factor. The results obtained from the lattice constant and density measurements in the f.c.c. region of Tl-Sn system, which was confirmed to be stable, were interpreted in terms of the Brillouin zone concept. Considering Matyas' result for trivalent Al, a suggestion for the high energy portion of $N(E)$ curve for the f.c.c. structure was proposed.

1. Introduction

The electronic structures of the metals and lloys which involve the overlap of electrons rom the first Brillouin zone are complicated nd still uncertain. The first calculation of $V(E)$ curve for the f.c.c. structure was made y Mott and Jones[1] in 1937, but its high nergy portion was highly speculative and the se of this curve was a very approximate rocedure for the cases where the electron oncentration was nearly 3 and involved the overlaps. Recent results for trivalent Al calculated by Matyas[2,3] differ from that of Mott and Jones, and the overlap across the {200} planes from the first Brillouin zone into the second one does not occur. His explanations are supported to some extent by the shape of the soft X-ray emission bands of Al obtained by Skinner,[4] and also by the magnetic susceptibility measurement for Al made by Lingelbach *et al.*[5] There is, however, evidence that the electronic structure of Al is somewhat different from that of Matyas. Leigh,[6] in a discussion on the elastic constants of Al, has shown that it is necessary also to take account of a small overlap across the {200} faces of the first zone.

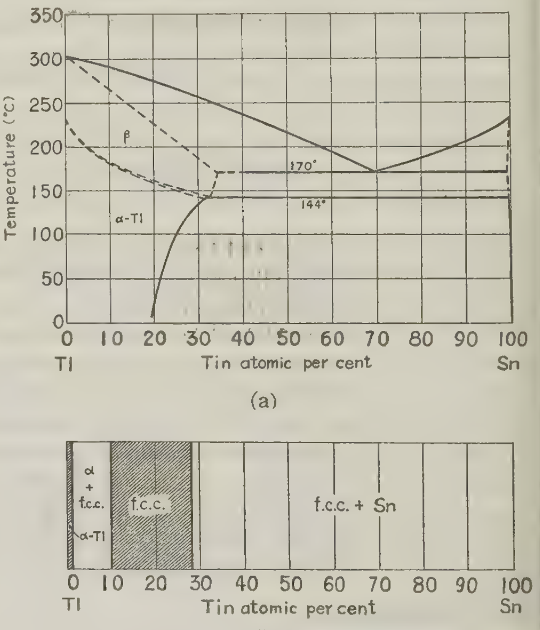
On the other hand, the experimental informations have not yet been obtained sufficiently, especially for the cases in which the electron concentration is considerably higher than 3, because the f.c.c. phases having such an electron concentration seem to be restricted to the solid solutions of Al and some Tl base alloys. However, the elements of higher or lower valency than Al have not appreciable solubilities in Al. For example, Si and Ge have the solubilities of only one or two atomic percentages in Al. Whereas, the Tl base alloys have not yet been investigated. From these points of view, the f.c.c. phases in Tl base alloys are particularly of interest.

According to Hansen,[7] the Tl base alloys seem to be restricted to the case where the solute elements are situated in the vicinity of Tl in the Periodic Table. Tl forms a simple eutectic with Ag or Au (Group I_B) and the solid solubility ranges exist in Ag- or Au-rich side but not in Tl-rich side. Tl-Cd (Group II_B) and Tl-Hg (Group II_B) are also eutectic*, and contrary to the case where Ag or Au is a solute, the terminal solid solutions exist in Tl-rich sides, although it has not yet been determined in the Tl-Cd case. Tl and In which have the same group valencies tend to form a continuous series of solid solutions. Tl-Pb (Group IV_B) resembles Tl-Bi (Group V_B) in its Tl-rich side and has the f.c.c. phase following a small range of α terminal solid solution, and in addition, the latter has another compound in Bi-rich side. However, Tl-Sn (Group IV_B) and Tl-Sb (Group V_B) seem to be quite different from Tl-Pb and Tl-Bi, respectively, and are reported to have the wide ranges of α solid solutions but not the f.c.c. phases. As to the systems of Tl-Cd, Tl-Sn and Tl-Sb, however, there is some uncertainty in their phase diagrams which will be discussed briefly in the next paragraph, and hence the reexaminations are necessary. If the systematic changes in the homogeneity ranges of the terminal solid solutions in α-Tl or the f.c.c. phases with solute valency were observed, some information concerning the electronic effect upon the phase boundaries in Tl base alloys would be available. Therefore, the writer intended to investigate the three Tl-rich alloys mentioned above by X-ray and electron diffraction methods. Kinds and boundaries of phases at room temperature were determined in connection with the effect of their electron concentrations, and then some detailed investigations for the f.c.c. phase in Tl-Sn system, which was confirmed to be stable by the present investigations, were performed in relation to its electronic structure and a possible high energy portion of $N(E)$ curve consistent with the experimental observations was proposed.

§ 2. Previous Work on the Pase Diagrams

2-1. *Case of Tl-Sn*

The phase diagram due to Hansen[7] is shown in Fig. 1(a). The liquidus curve was drawn on the basis of thermal analysis. The solid solubility of Sn in Tl up to 140°C was determined by measuring the electrical resistivity. Fuchs[8] showed by thermal analysis that the phase transformation temperature of Tl was lowered by addition of Sn, as shown in Fig.



(a)

(b)

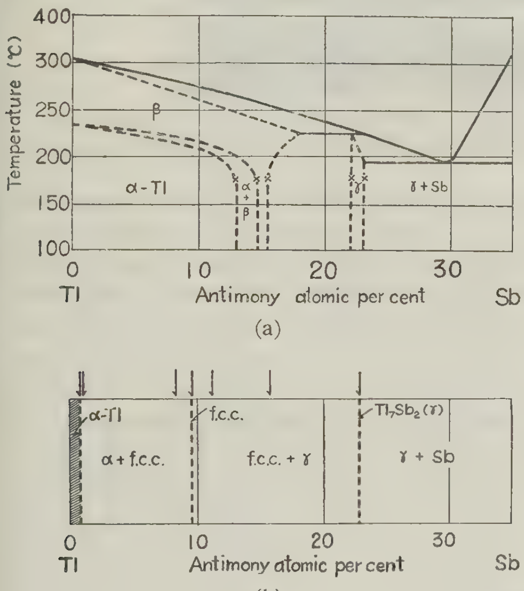
Fig. 1. (a) Phase diagram of Tl-Sn after Hansen.
(b) Kinds of phases at room temperature after the present work.

---

* The system of Tl-Hg has a f.c.c. phase at about 25 at. % Hg below 14.5°C, but not in Tl-rich side.

1(a). Sekito[9)] reported that the alloys containing 16 and 30 at. % Sn which were quenched into ice water from the melt possess the f.c.c. lattice. The result of this X-ray work, however, seems to be curious, because it has been established afterwards that β-Tl has a b.c.c. structure.[10)] Therefore, Sekito's f.c.c. structure has been considered to be a metastable one resulting from the β → α transformation of the solid solution in β-Tl. No other reliable X-ray work has yet been carried out.

2–2. *Case of Tl-Sb*



(a)

(b)

Fig. 2. (a) Phase diagram of Tl-Sb after Hanson.
(b) Kinds of phases at room temperature after the present work.

The phase diagram appearing in Hansen[7)] is shown in Fig. 2(a). The liquidus and solidus curves indicated by solid line were based on the thermal data. The existence of intermediate phase γ was confirmed by Barth[11)] and Persson[12)] *et al.* by the metallographic and X-ray studies. The phase boundaries of α-Tl, β-Tl and γ-phase at 180°C as indicated by crosses in Fig. 2(a). were fixed by Kurzyniec[13)] on the basis of resistivity measurements. While, it was reported by Persson *et al.* that β-Tl was apparently stabilized down to room temperature at about 10∼11 at. % Sb, although the composition of γ-phase agreed closely with the result of Kurzyniec. It should be noted, however, that β-Tl is believed to be f.c.c. rather than b.c.c.. Therefore, the kinds of phases in the Tl-rich alloys are not yet fully established and should be examined.

2–3. *Case of Tl-Cd*

Tl and Cd form a eutectic and no intermediate phases are known.[7)] The solubility of Cd in Tl was estimated to be about 4.3 at. % Cd at 203°C from the thermal data,[14)] but not determined at room temperature. No X-ray work on this system can be found in existing literatures.

§ 3. Determinations of Kinds and Boundaries of Phases in Tl Base Alloys

3-1. *Case of Tl-Sn*

(a) *Kinds and boundaries of phases at room temperature*

Accurately weighed quantities of the component metals (99.9+% Tl and 99.999% Sn), whose total amount was approximately 2 g, were melted in sealed Pyrex tube of about 8 mm in diameter. After air-cooling to room temperature, needle-like specimens of about 0.3 mm in diameter were cut from the ingots and then annealed for 30∼50 hours at about 100°C in glycerin, and after the room temperature aging for 2∼3 days they were examined by X-rays. Cu K_α radiation was used with Ni filter. The applied voltage was about 40kV and the tube current for the rotating target X-ray tube was about 50 mA. The exposure time required was 40∼50 minutes. Among the specimens listed in Table I, those designated by symbol A in the last column were prepared and heat-treated as mentioned above. Another kind of specimens containing 8∼30 at. % Sn was prepared in quantity of approximately 10 g using the same conditions of preparation and heat-treatments. These specimens, designated by symbol B in Table I, were subjected to density measurements at first and then examined by X-rays.

Kinds of phases at room temperature obtained by X-ray diffraction method with the annealed specimens is shown in Fig. 3 and Table I. The lattice constant measured for each specimen attained a constant value within the limit of experimental error after the annealing for about 20 hours at about 100°C, and the lattice constants for two specimens of the same composition prepared by different two methods (see the last column of Table I)

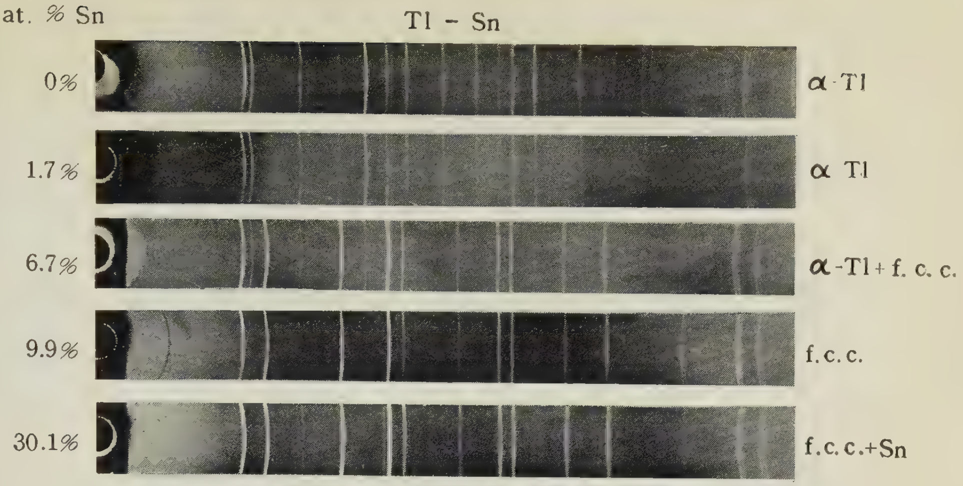

Fig. 3. Kinds of phases at room temperature obtained by X-ray diffraction.

also agreed with each other after the same heat-treatment. As seen from Fig. 3 and Table I, the Tl-rich side of Tl-Sn system differs considerably from that of Fig. 1. The solid solubility of Sn in α-Tl at room temperature was reduced to about 1.7 at. % Sn and the disordered f.c.c. lattice was observed between about 9 and about 28 at. % Sn. No changes in diffraction pattern were detected after the annealing for more than about 50 hours at 100°C. For comparison with Sekito's results obtained by quenching from the melt, specimens prepared in quantity of about 2 g were melted in Pyrex tube and poured into ice water or diffusion pump oil of about −30°C cooled by dry ice. The X-ray examination of these specimens were finished within about one hour after quenching, but showed the same kinds of phases as the annealed ones. These specimens are designated by symbol C in Table I.

The lattice constants of pure Tl are also shown in Table I. For comparison, the results of other workers are summarized as follows:

a	*c*	*c/a*	ref.
3.456 ±5Å	5.530 ±6Å	1.60	(**10**)
3.4566±2	5.5248±4	1.5983	(**15**)

(b) *Kinds and boundaries of phases at high temperature*

Kinds of phases at high temperature was investigated by electron diffraction with thin films containing about 78, 23 and 7 at. % Sn, which were prepared in vacuum (about 10^{-5} mmHg) by successive evaporation of Sn and Tl on Formver films at room temperature. Film thickness was of the order of 35 mμ. Specimens were set in camera with heating device and diffraction pattern were taken at various temperatures. The composition of the film was estimated approximately from the evaporated quantities of component metals.

The alloy formation by successive deposition of constituent metals was observed as seen in some other systems.[16] The kinds of phases at room temperature after suitable heat-treatment was in accordance with the results obtained by X-ray diffraction.

The alloys containing about 78 at. % Sn (Fig. 4(a)), which show the mixed patterns of disordered f.c.c. and Sn at room temperature, exhibit halos superposed on the crystalline pattern of Sn at about 164∼170°C and, after cooling to room temperature, show the same patterns as those obtained before heating. These alloys were annealed for about 2 hours at about 130°C and for about 1.5 hours at about 156°C respectively, but no changes in the diffraction patterns were observed. Therefore, the thermal effect at 144°C shown in Hansen's diagram (Fig. 1(a)) could not be confirmed in the present examination.

The films containing about 23 at. % Sn (Fig. 4(b)) gave the pattern of disordered f.c.c. phase only. By heating these specimens, the pattern completely changes to halos at about 256°C without any other change during heating. After subsequent cooling to room

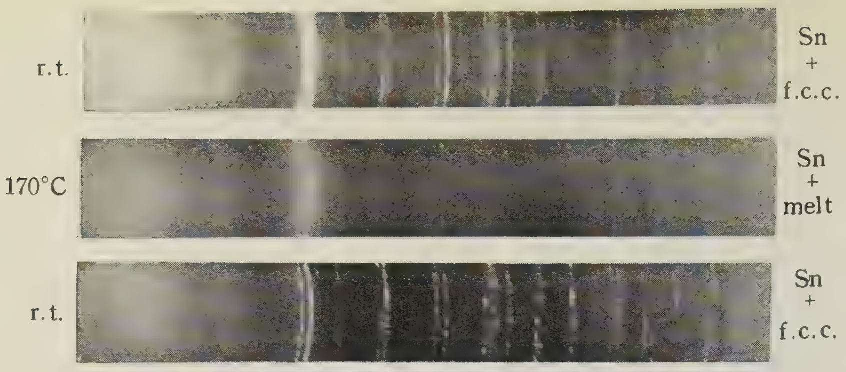

Fig. 4 (a). Electron diffraction pattern from thin film of Tl-Sn containing about 78 at. % Sn.

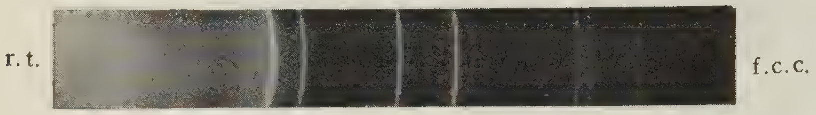

Fig. 4 (b). Electron diffraction pattern from thin film of Tl-Sn containing about 23 at. % Sn.

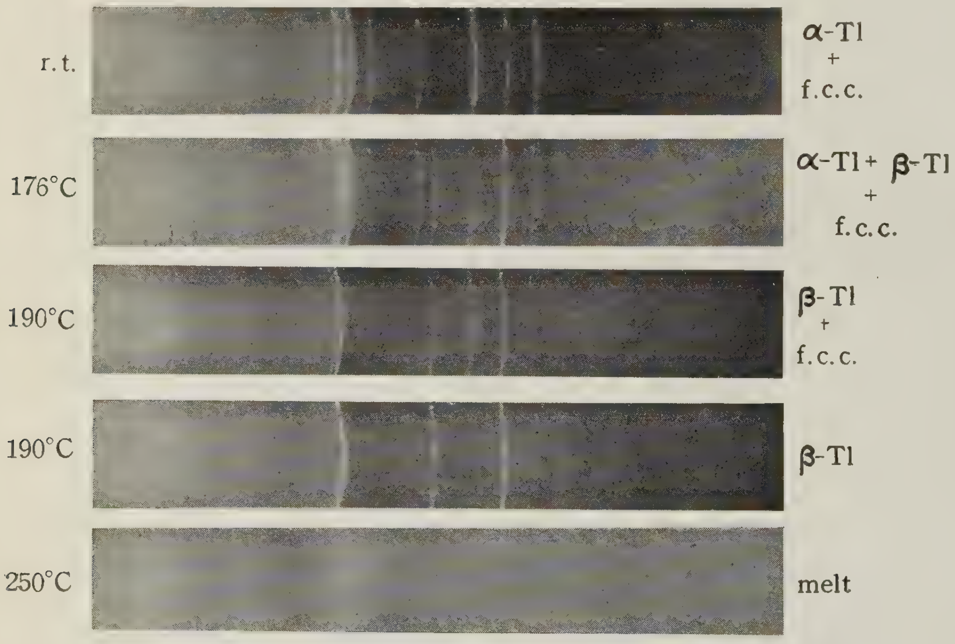

Fig. 4 (c). Electron diffraction pattern from thin film of Tl-Sn containing about 7 at. % Sn.

temperature, these films show again the pattern of f.c.c. phase only. With the specimens of this composition various heat-treatments were carried out: They were (i) aged for about a week at room temperature, (ii) annealed for about one day at about 100°C, (iii) after homogenizing for one hour at 160~170°C, cooled to 86°C at the rate of about 0.3°C per minute and then annealed for 5 hours at 86~80°C. In all cases, no extra lines and no changes in the relative intensities of the disordered f.c.c. lines were observed. The diffraction pattern at room temperature after the heat-treatment (iii) is given in Fig. 4(b). Deducing from their lattice constant measurements, Tang and Pauling[17] reported that an ordered structure exists in f.c.c. region of Pb-Tl system, but the direct evidences could not be obtained, because the scattering power of Tl is close to that of Pb.

If any superlattice were formed in f.c.c. region of Tl-Sn system, it should be detected, since the scattering powers of component elements are considerably different.

The specimens containing about 7 at. % Sn (Fig. 4 (c)) show the diffraction rings of α-Tl and f.c.c. between room temperature and about 150°C. No changes were observed after annealing for about one hour at about 155°C, but the rings of β-Tl began to be superposed on those of α-Tl and f.c.c. phase after annealing for about 30 minutes at about 176°C. After annealing for one hour at about 190°C, these specimens exhibited the rings of β-Tl and f.c.c. only, and these two phases changed into the halo pattern at 245~250°C by further heating. In some cases, a part of the film which showed α-Tl and f.c.c. below 170°C indicated β-Tl only at about 190°C. The transformation from (α-Tl+f.c.c.) to (β-Tl+f.c.c.) is supposed to be very drastic and the accurate transformation temperature cannot be determined from the present experiment, but it is estimated to lie between 155 and 176°C.

The experimental informations about the phase diagram of Tl-Sn system obtained by the present investigation may be summarized

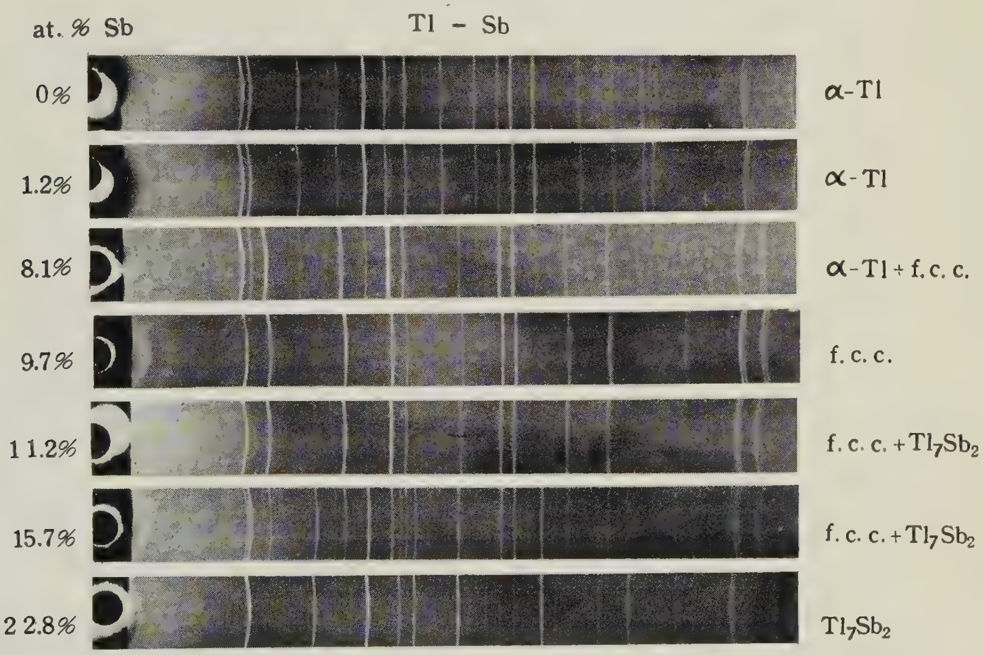

Fig. 5. Kinds of phases at room temperature obtained by X-ray diffraction.

Table II.

15.7	Tl_7Sb_2+f.c.c.				
22.8	Tl_7Sb_2				

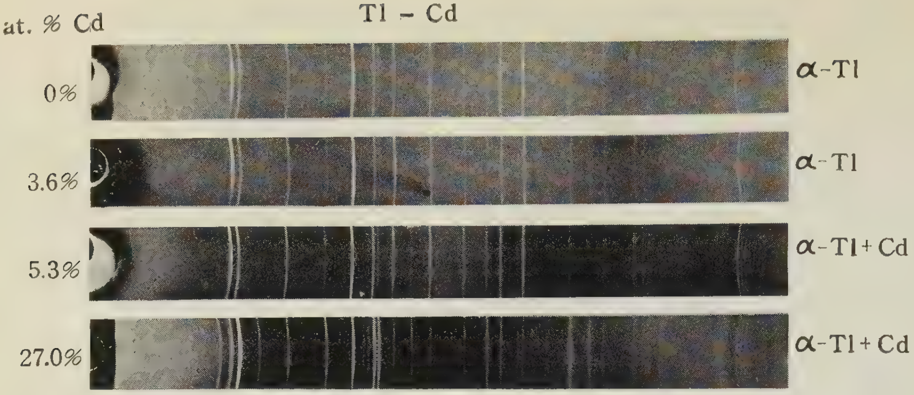

Fig. 6. Kinds of phases at room temperature obtained by X-ray diffraction.

Table III.

At. % Cd	Phases	a (Å)	c (Å)	c/a	Number of electrons per atom
1.8	α	3.4591	5.5230	1.5966	2.98_2
3.6	α	3.4672	5.5343	1.5962	2.96_4
5.3	α+Cd	3.4730	5.5449	1.5966	2.94_7
7.0	α+Cd				
27.0	α+Cd				

as follows. The kinds and boundaries of phases at room temperature may be confirmative, and is shown in Fig. 1(b) diagramatically. Although further extensive evidences will be required for the accurate determination of phase boundaries, the solid solubility of Sn in α-Tl at room temperature was determined to be about 2 at. % Sn and the f.c.c. phase was found to be stable between about 10 and 28 at. % Sn. The high temperature portion of this system, deduced mainly from the results obtained by electron diffraction with thin films, may be somewhat speculative. From the consideration of the facts mentioned above, however, the Tl-rich side of the present system seems to be quite different from that which appeared in Hansen's diagram, but it is suggested that the high temperature portion of Tl-rich side of the present system is quite analogous to those of Tl-Pb and Tl-Bi systems. As for the region of f.c.c. phase, the lattice constants and density will be described in detail in the next paragraph.

3-2. *Case of Tl-Sb*

Materials used were 99.9+% Tl and 99.999% Sb. The specimens were prepared and heat-treated under the same conditions as those described in Tl-Sn system (total amount was about 2 g). All measurements were made by X-ray diffraction at room temperature. The experimental results are shown in Fig. 5 and Table II. The diagramatical expression is made in Fig. 2(b), in which the arrows indicate the compositions at which the X-ray diffractions were carried out.

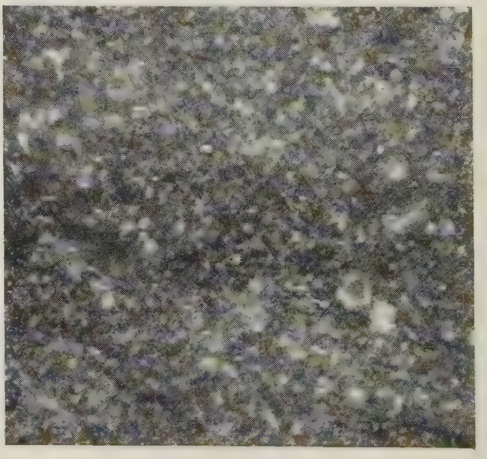

Fig. 7. Micrograph of the f.c.c. phase in Tl-Sn containing 20.5 at. % Sn.

The solid solubility of Sb in α-Tl at room temperature is of the order of one at. % Sb and the f.c.c. phase is stable as in the case of Tl-Sn system at about 10 at. % Sb. Whether this phase possesses a small homogeneity range or not could not be decided from the present experiment. Tl_7Sb_2 was also observed at about 22 at. % Sb which agreed well with that of Fig. 2(a). The kinds and boundaries of other phases at room temperature differ from those of Fig. 2(a), but show practical agreement with the results reported by Persson and Westgren.[12] They detected the f.c.c. lattice at about 10 at. % Sb, and considered it to be β-Tl stabilized down to room temperature, because it was believed in those days that β-Tl had the f.c.c. structure. They also reported that alloys containing 8.1 at. % Sb consisted of α-Tl and f.c.c. at room temperature, and again this agrees well with the present results. Although they did not say anything about the solubility limit of Sb in α-Tl, this limit is estimated to be of the order of one at. % Sb in the present work. If the phase boundaries of α-Tl and f.c.c. at room temperature obtained from the present study are compared with those at 180°C reported by Kurzyniec[13] (indicated by crosses in Fig. 2 (a)), the solid solubility of Sb in α-Tl at high temperatures should be considerably increased and marked curvature of α-Tl/(α-Tl+f.c.c.) boundary should be observed. A systematic study at high temperature will be required.

3–3. *Case of Tl-Cd*

Materials used were 99.9+% Tl and Merk's Cd. The specimen preparation and heat-treatments were the same as those in Tl-Sb system. The experimental results obtained by X-ray diffraction at room temperature are shown in Fig. 6 and Table III. It was confirmed that Tl and Cd form the simple eutectic and no intermediate phases exist at room temperature, as shown in Hansen's diagram. The solid solubility of Cd in α-Tl obtained at room temperature was of the order of 4 at. % Cd which seems to be reasonable as compared with diCapua's value,[14] 4.3 at. % Cd, at the eutectic temperature.

§4. The f.c.c. Phase in Tl-Sn Alloy

As mentioned in §1, the f.c.c. phase in Tl base alloys is of interest in connection with its electronic structure. Therefore, the lattice constant and density of the f.c.c. phase in Tl-Sn system were measured for the same specimens, which were prepared as mentioned in §3–1, in relation to the electronic structure of the f.c.c. phase.

The X-ray diffraction patterns were photographed by Debye-Scherrer camera of the usual type whose diameter was 9 cm, calibrated against the lattice constant of 99.99% Al. The calculated lattice spacings were corrected for systematic errors by the extrapolation method of Nelson and Riley.[18] The effect of film shrinkage was considered, but no correction for refractivity was made. The experimental error was estimated to be about 0.02% and all measurements were performed at 32±2°C.

The displacement liquid was glycerin which was a very good protective liquid for the Tl base alloys and whose density was determined to be $1.254_5\ \mathrm{g\,cm^{-3}}$ at 32°C. Specimens were microscopically examined and confirmed to be free from porosities (Fig. 7). The accuracy of about 0.1% could easily be obtained for the specimens of about 10 g in the present case. All measurements were carried out at 32°C.

The lattice constant a and density ρ_m measured in the present experiment are summarized in Table I and plotted in Fig. 8. Table I also includes the calculated density ρ_c, which was calculated from the measured lattice constant using the expression $\rho_c = mMN/a^3$, where M was the mean atomic weight, N the number of atoms in the unit cell, m the atomic unit of mass (1.66035×10^{-24} g), and a the lattice constant in cm. The percentage of filled sites for each composition calculated from ρ_m and ρ_c is listed in Table I, and using these values, the number of electrons per lattice site was calculated. These values are also shown in Table I with those of the number of electrons per atom, calculated on the basis that each unit cell contains four atoms. These results of lattice constant and density measurements will be discussed in §5–2.

§5. Discussions

5–1. *Kinds of phases at room temperature of some Tl base alloys*

From the considerations of the present results with the systems of Tl-Cd, Tl-Sn and

Tl-Sb, and of the previous results with those of Tl-Ag, Tl-Au, Tl-Hg, Tl-In, Tl-Pb and Tl-Bi obtained by other workers, some regularity in the constitutional diagrams of these systems may be deduced. Remarks on these diagrams and the solute percentage at phase boundaries are summarized in Table IV. Except the elements of Group I_B as solutes, all other elements can be dissolved in α-Tl, and solid solubility is most marked for the system of Tl-In, both components of which belong to the same group, and becomes less marked for other systems with increasing solute valency. The f.c.c. phase is found in the systems of Tl-Sn, Tl-Pb, Tl-Sb and Tl-Bi in which the solute elements have higher valen-

Table IV.

Group	Solute	Remarks on phase diagram	At. % of solute at the solubility limit		Ref.
			Solid solution in α-Tl	Tl rich side of f.c.c. phase	
I_B	Ag	eutectic	—	—	(7)
I_B	Au	eutectic	—	—	(7)
II_B	Cd	eutectic	~ 4	—	—
II_B	Hg	eutectic*	~ 4	—	(7)
III_B	In	cont. solid solution**	~10	~40	(7), (25)
IV_B	Sn	f.c.c.	~ 2	~10	—
IV_B	Pb	f.c.c.	~ 3	~12	(7), (17)
V_B	Sb	f.c.c., Tl_7Sb_2	~ 1	~10	—
V_B	Bi	f.c.c., $TlBi_2$	~ 1	~ 5***	(7), (26)***

* A f.c.c. phase exists at about 25 at. % Hg below 14.5°C, but not in Tl rich side.

** Component metals have a tendency to form a continuous solid solution like the systems of Mg-Cd etc., but are prevented from doing so because their crystal structures are different.

*** In Ölander's paper, the specimen containing about 4 at. % Bi is reported to be two phases of α solid solution and f.c.c.. Therefore, the specimen containing about 5.2 at. % Bi was prepared by the present author and confirmed to be a single phase of f.c.c..

cy than Tl, and another intermediate compound ($TlBi_2$ or Tl_7Sb_2) appears in Tl-Bi or Tl-Sb.

The phase boundary of α solid solution and Tl-rich side of the f.c.c. phase for each system are shown diagramatically in Fig. 9, taking the electron atom ratio as abscissa. It was assumed here that Tl, Sn and Pb exhibit their group valencies, although it was often claimed[19] that these metals were incompletely ionized in the state of element. The solute-rich side of the f.c.c. phase will be different in the electron concentration from system to system and is not discussed at present. It is apparent that the phase boundary for each system is closely related to almost the same electron concentration except the case of Sb as a solute. That is, the Tl-rich side of the f.c.c. phase corresponds approximately to 3.10 electrons per atom, and for the hexagonal solid solution, the phase boundary which is rich in the solutes of higher valency than Tl corresponds to about 3.02 electrons per atom, while that which is rich in the solutes of lower valency than Tl corresponds to about 2.96 electrons per atom.

According to Hume-Rothery[3] and Raynor *et al.*,[20] various factors other than valency are responsible for the stabilities of alloy phases. Atomic size factor of the solute elements concerned with the systems shown in Fig. 9 is about 10% and within the favorable zone. That of Ag or Au exceeds 20% and is apparently unfavorable, which may be the reason why these metals cannot be dissolved in α-Tl. Electrochemical difference between Tl and each solute element is small, but in Tl-Sb and probably in Tl-Bi some contribution from this factor may be considered. The effect of ionic radius may be marked only when a relatively large ion of solute is forced into the relatively small ions of solvent and the electron cloud of the former begins to overlap that of the latter, but except the case of Hg as a solute, the ionic radius of solutes is smaller than that of solvent in the present case. As a result, it appears that the phase boundaries of some Tl base alloys concerned in Fig. 9 are affected mainly by electron concentration, suggesting that in every case the homogeneity of a particular structure may be restricted by the appropriate Brillouin zone.

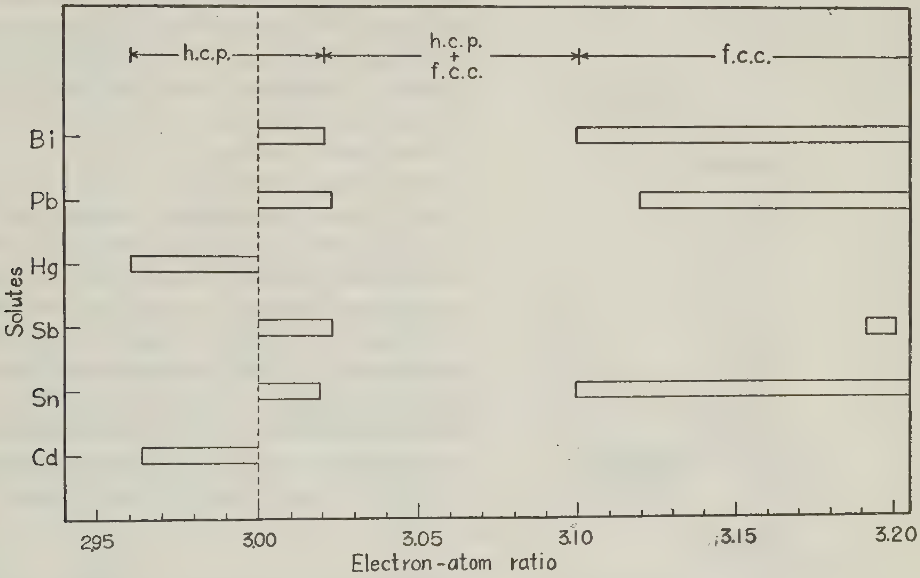

Fig. 9. The ranges of homogeneity in terms of electron concentration.

5-2. *N(E) curve for the f.c.c. phase in Tl-Sn*

As described briefly in § 1, experimental informations about the high energy portion of *N*(*E*) curve for the f.c.c. structure have not completely been obtained. Since the first Billouin zone for f.c.c. can contain only two electrons per atom, it is clear that considerably overlap into the second zone must occur across the {111} faces or across both {111} and {200} faces in the present case. Calculating the $N(E)$ curve for the f.c.c. structure, Mott and Jones[1] assumed that the energy gaps at the surface of the first Brillouin zone were equal to those for copper deduced from its optical properties. Consequently the high energy portion of this curve is highly speculative and seems to be inadequate for the discussion with trivalent metals (Fig. 10(a)). Recent results for Al calculated by Matyas,[2] whose curve[3] is shown in Fig. 10(b), indicate that the first zone is nearly filled with slightly less than two electrons per atom but contains unoccupied states in the form of thin slabs parallel to the {200} faces of the first zone and that slightly more than one electron per atom passes into the second zone. Consequently the overlap into the second zone occurs across the {111} faces but not across the {200} faces at three electrons per atom.

(a) After H. Jones.
(b) After Z. Matyas. The portion of total $N(E)$ curve in broken line is hypothetical, and drawn by the present author.

So far as the Brillouin zone effect is concerned, the lattice expansion may be expected with the increasing electron concentration, and if the change in composition results in the occurrence of the overlap across the faces of an appropriate Brillouin zone, a kink in lattice constant *versus* composition curve will be produced. It may also be supposed that the lattice expansion should be much increased if the {200} overlap is superposed on {111} overlap, compared with the case of {111} overlap only, for the f.c.c. phase concerned in the present work.

The lattice expansion is considered to be due to the simultaneous effects of solute valency and atomic size difference between solute and solvent atoms. In the present experiment, volume per atom was taken as a measure of atomic size, because Tl and Sn have not a cubic symmetry and there may be some uncertainty in the concept of usual atomic diameter. The change of lattice constants due to atomic size difference can be calculated from Vegard's law expressed as

$$a_{\mathrm{S}} = x a_{\mathrm{Sn}} + (1-x) a_{\mathrm{Tl}} ,$$

where a_{Tl} and a_{Sn} are the lattice constants of hypothetical f.c.c. lattices having the same volumes per atom as pure Tl and Sn, respectively, and x is the atomic fraction of Sn. In the present case a_{Sn} is smaller than a_{Tl}, and therefore, linear decrease in a_{S} with increasing atomic percentage of Sn should be expected. The difference Δa between observed lattice constants a and calculated ones a_{S} may be considered as the measure of valency effect only to the first approximation, and is shown in Fig. 11.

The large positive deviation from Vegard's law and a kink at about 16 at. % Sn are evidently observed. A kink of such kind has been detected in c-spacings for Mg-rich alloys and has been explained as a result of the internal stress present in the lattice due to the zone overlap in the direction parallel to the hexagonal axis. Detailed discussions and theoretical treatments were made by Raynor[21] and Jones,[22] respectively.

From Matyas' results and the above discussions, it will be suggested that the kink observed in Fig. 11 (the corresponding electron concentration is 3.16 electrons per atom) may be associated with the onset of overlap across the {200} faces of the first Brillouin zone, although the form of total *N*(*E*) curve for electron concentration higher than three electrons per atom was not given by Matyas. There will also be some ambiguity in discussing the present results from Tl base alloys in relation to the *N*(*E*) curve derived for Al.

Matyas' results suggest the existence of a sharp fall in *N*(*E*) curve before the onset of {200} overlap. The density measurement made in the present work also suggests this

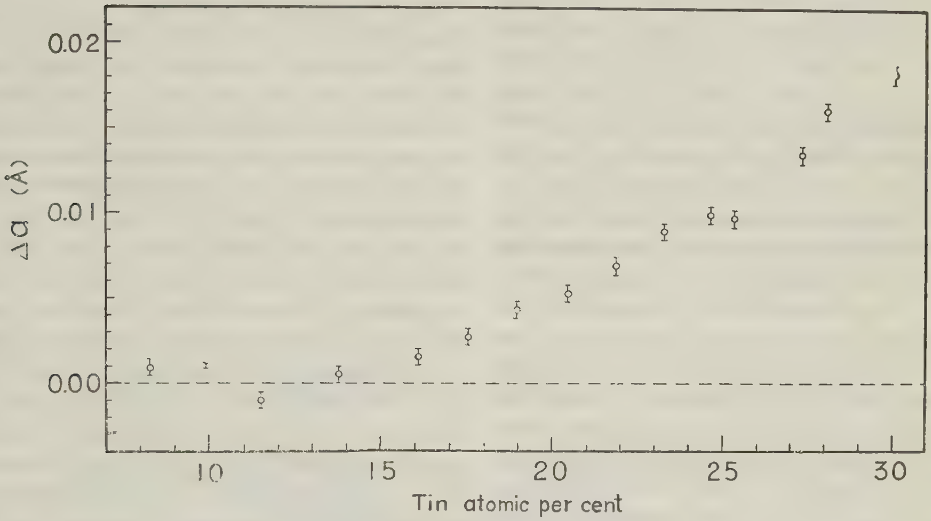

Fig. 11. The change of Δa with atomic percentage of Sn.

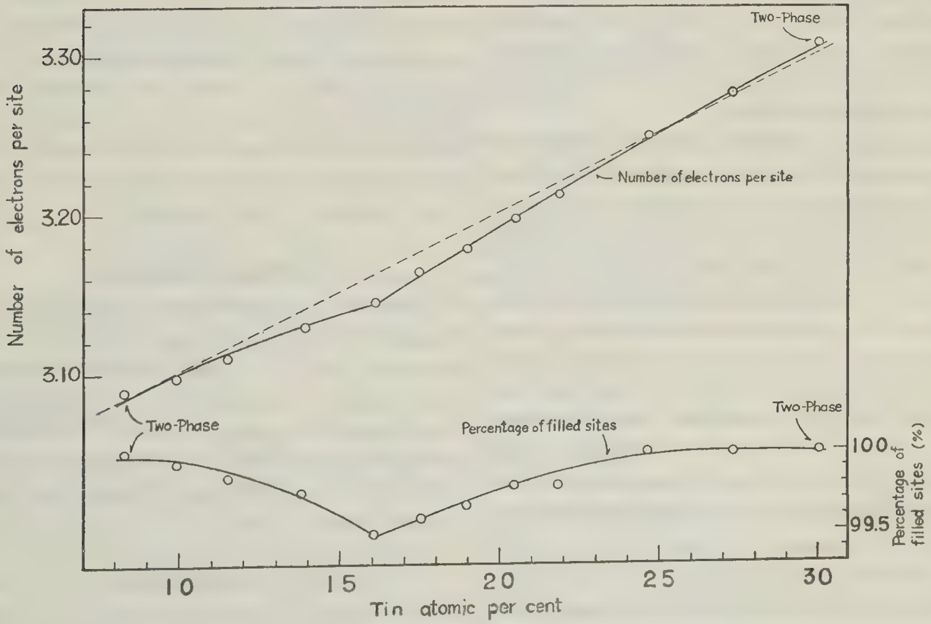

Fig. 12. The changes of the percentage of filled sites and the number of electrons per lattice at site with atomic percentage of Sn.

as follows. Since the discrepancies between the measured and calculated densities (Fig. 8) are much larger than the limit of experimental error and the specimens used for density measurement seem to be free from porosities, these discrepancies may be attributed to the formation of vacant sites. The percentage of filled sites and the corresponding number of electrons per site are shown in Fig. 12.

The vacant sites gradually increase with increasing solute concentration and a maximum is reached at about 16 at. % Sn which agrees with the atomic percentage at which the kink in the lattice constant versus composition curve occurs. After this maximum gradual decrease is observed until lattice sites are completely filled. The number of valence electrons per site (solid line in Fig. 12), therefore, shows less increase with increasing solute concentration than that corresponding to the complete filling of sites (broken line in Fig. 12). The introduction of vacancies into the structure to avoid rapid increase in the number of electrons per site is typical for the case where the $N(E)$ curve has a sharp fall which causes more rapid increase in the total energy of valence electrons with increasing number of electron per site. It is probable, therefore, that the rising portion of $N(E)$ curve corresponds to the range where vacancies are disappearing. Therefore, it may be said that the portion at which the vacancy concentration is maximum would be a trough of $N(E)$ curve and consequently this portion is comparatively unstable.

The occurrence of vacancy with increasing electron concentration, for example, was observed in solute-rich side of γ-phase in Cu-Al or Cu-Ga and is closely related to the sharp fall of $N(E)$ curve for the structure of γ-brass type.[23] Both the occurrence and the disappearance of vacancy were found in some Sn base alloys and interpreted to some extent by the Brillouin zone structure suggested for Sn.[24] In this case, however, the disappearance occurs in the range of falling in the suggested $N(E)$ curve and hence seems to be somewhat different from the present results.

Now, the existence of the rise in $N(E)$ curve, which suggests the onset of {200} overlap, following the sharp fall at about 3.16 electrons per atom is proposed as the result of consistent explanation for both changes of lattice constant and density with composition, and this is to be expected when Matyas' results are taken into account.

§ 6. Summary

Kinds and boundaries of phases in Tl-rich sides of the systems of Tl-Cd, Tl-Sn and Tl-Sb were determined by X-ray and electron diffraction. Considering the experimental results obtained in the present work as well as those obtained by previous workers, it was deduced that phase boundary of a particular structure in Tl base alloys corresponds to the same electron concentration, namely, 3.10 electrons per atom for the Tl-rich side of f.c.c. phase, and in the case of the hexagonal α solid solution, 3.02 electrons per atom for the side which is rich in the solute of higher valency than Tl and 2.96 electrons per atom for the case of lower valency than Tl. The phase boundaries of α solid solution and f.c.c. phase of Tl base alloys, therefore, seem to be mainly affected by the electronic factor.

The changes of lattice constant and density with composition in the f.c.c. region of Tl-Sn system, which was confirmed to be stable, were also measured. The kink observed in Δa, and the formation of vacant sites deduced from the discrepancies between the measured and calculated density were interpreted in terms of the Brillouin zone concept. Considering Matyas' results for trivalent Al, a suggestion for the high enery portion of $N(E)$ curve for the f.c.c. structure, namely, the existence of the sharp fall in $N(E)$ curve at about 3.16 electrons per atom followed by the rising portion, which suggests the onset of {200} overlap, was proposed.

Observations of Dislocation Networks in an Alloy of Body-Centered Cubic Lattice by Electron Microscopy

By Soji NENNO, Toshio SABURI and Masayoshi TAGAYA
Department of Metallurgy, Faculty of Engineering, Osaka University
Zenji NISHIYAMA
Institute of Scientific and Industrial Research, Osaka University

(Received May 6, 1960)

Electron microscopic observations were made on dislocation networks in thin foils of 55%Cr–Fe alloy annealed at 720°C after cold working. Dislocation cross-grids, hexagonal networks and networks of irregular shape are observed. From the presence of three-fold nodes, it is suggested that Burgers vectors of type [100] may be stable as well as those of type ½[111].

§1. Introduction

Direct observation of dislocation networks in body-centered cubic metal by electron microscopy has not yet been made except the one on α-Fe reported briefly by Hirsch[1]. The present writers have found dislocation networks in 55%Cr–Fe alloy during their studies on the sigma phase formation in body-centered cubic matrix. Some of the experimental results will be described in the following section.

§2. Experimental Procedure and Results

The material used is a forged bar of the alloy with the following compositions: Cr: 55%, C: 0.007%, N: 0.007%, H: 0.00023%, O: 0.078% and Fe: balance. It was again forged to a plate of 0.3 mm thick and pieces taken out from the plate were beaten until crack began to occur, followed by annealing at 720°C for 24 hrs. From these pieces thin foils for the electron microscopic observation were obtained by electro-polishing under the following conditions:

electrolyte perchloric acid 200 cc/l
glacial acetic acid 800 cc/l
current 0.6 amp., voltage 12 volt, 8°C.

The electron microscope was operated at 60 kV, unless otherwise mentioned.

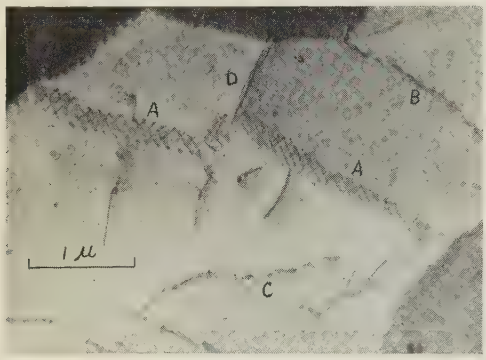

Fig. 1. Dislocation cross-grids constituting slightly misoriented subgrains.

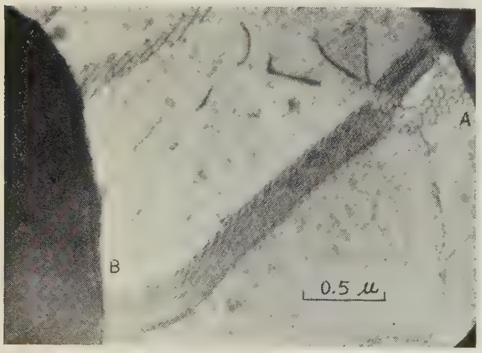

Fig. 2. Hexagonal network of dislocations between two subboundaries A and B.

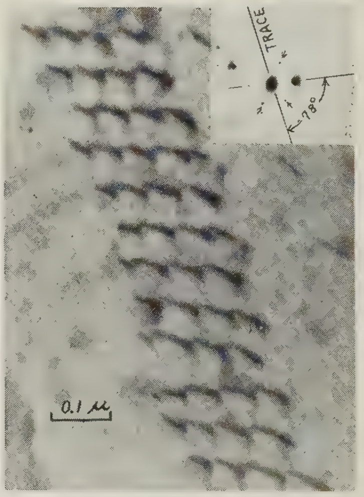

Fig. 3. Network with possibly extended dislocation ribbons and its selected-area diffraction pattern.

Some examples of electron micrographs are given in Fig. 1 to 6. Fig. 1 represents an example of dislocation cross-grids, at A, which constitute the boundaries of slightly misoriented subgrains. In view of the treatment given to the specimen, such a cross-grid seems to be fairly stable in this alloy. At subboundaries B and C, dislocations display double images. Subboundary at D is considered as consisting of dislocations rather than of incoherent precipitates. Fig. 2 indicates a hexagonal network in which segments of the network with a particular direction are absent, probably because Bragg condition is not fulfilled. The network stretches over between two adjacent subboundaries, with two kinks near subboundaries A and B. The size of each net is smaller at the middle region than near subboundaries A and B. In body-centered cubic crystals, it was proposed[2] that the diamond structure of dislocation network is stable. Only when two layers of diamond network are viewed at a particular direction, they look like a hexagonal network. Since, in the present case, hexagonal networks were found in many photographs, it is unlikely to attribute all of them to the two layers of diamond network. Fig. 3 shows a cross-grid or a hexagonal array of dislocations in which one component of dislocation segments is much shorter than the other two. At the nodes the dislocations are broadened to some extent and they may be interpreted as the extended dislocations. In the corner of this figure is inserted the selected-area diffraction pattern* of the dislocation network, in which the trace of the plane of the network is also shown corrected for rotation of the image. The index of the foil plane as derived is (1.31, 1.59, 1.00) and the direction of the trace of the network [−1.16, 0.327, 1.00] or [−5.63, 4.00, 1.00]. Hence the possible index of the plane of the network is (101) or (112). (112) appears more likely if we consider the projected width of the network plane and its inclination to the foil plane, although it is not yet conclusive, at present, which is more probable.

---

* The spots indicated by arrows have been retouched in order to make reproduction possible.

In Fig. 4, dislocations in the direction marked with the arrow look consisting of spots. This may be attributed to the Pendellösung effect. The extinction distance estimated from the photograph is about 300 Å which is of the same order of magnitude as those already calculated for Ni and Cu[3]. In Fig. 5, subboundary A seems to consist of dislocations perpendicular to the foil, and terminates at B where an irregular dislocation network is found. In region C where subboundaries are not yet completed, many of dislocations are distributed in rather random fashion. Dislocation nodes at D are thought to be formed by a reaction of the following type as a result of intersection of dislocations in two families.

$$\tfrac{1}{2}[111]+\tfrac{1}{2}[1\bar{1}\bar{1}]\rightarrow[100]\ .$$

The presence of this type of nodes and hexagonal networks suggests that in body-centered cubic crystal Burgers vectors of [100] type may be stable as well as those of ½[111] type, as pointed out by Hirsch[1].

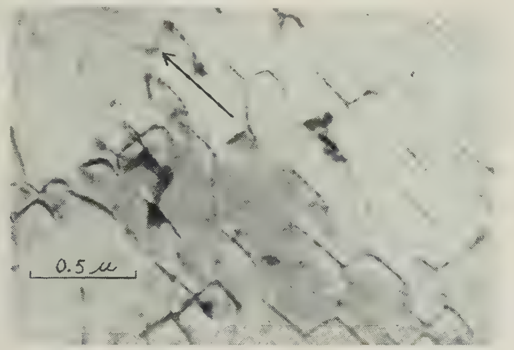

Fig. 4. Dislocation images consisting of spots lined in the direction of arrow.

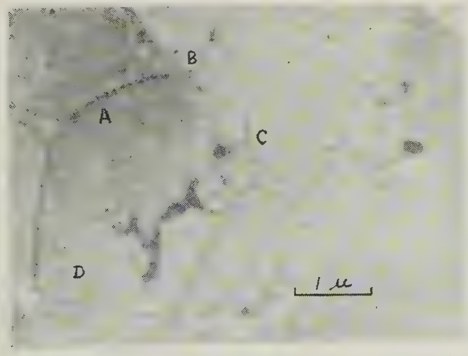

Fig. 5. Irregular dislocation networks and three-fold nodes.

Fig. 6(a)* appears to show a process[4] in which dislocations in two families intersect and form network. This region corresponds to area A in Fig. 6(b)*. In this figure the black broad band running obliquly is a Neumann band formed by hammering at room temperature. The bright area might correspond to the original single grain before hammering. In areas B and C some of subgrains are found. At D, a subboundary is being formed.

An X-ray Study on the Structure of Cobalt Dichloride Hexahydrate

By Jōji MIZUNO

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai Japan

(Received February 27, 1960)

The crystal structure of $CoCl_2 \cdot 6H_2O$ has been determined by the X-ray single crystal method. The unit cell is monoclinic with $a=10.34$ Å, $b=7.06$ Å, $c=6.67$ Å and $\beta=122°20'$. The space group is C_{2h}^3-C2/m and the unit cell contains two molecules. Two Cl^- ions and four water molecules are octahedrally coordinated to Co^{2+} ion to form the group $[CoCl_2 \cdot 4H_2O]$. These groups are held together parallel to the b axis by O···H-O type hydrogen bonds. The other two water molecules of the formula unit are far from Co^{2+} ion. The crystal has the layer structure parallel to (001), and this causes the perfect cleavage. The structure proposed for this salt by Stroganov *et al.* seems to be incorrect.

§1. Introduction

There has been no report on the crystal structure of cobalt dichloride hexahydrate, $CoCl_2 \cdot 6H_2O$, until 1958. Since several years ago, the structural information has been keenly required in relation with the magnetic behavior of this salt at the liquid helium temperature. Haseda and Kanda[1] measured the magnetic susceptibilities of powdered samples of this salt and found an anomaly at about 3°K. Haseda[2] also found the same magnetic behavior on the single crystal samples. These authors considered this behavior to be caused by the anti-ferromagnetic transition. Since the above transition temperature is higher than that expected when each metallic ion was octahedrally surrounded by six water molecules as in alums or Tutton salts, they inferred that one or two chlorine atoms in $CoCl_2 \cdot 6H_2O$ would occupy the positions of the octahedral coordination around a cobalt atom in the place of water molecules and these octahedrons would be adjacent to one another without insertion of any atom or any molecule. It was considered desirable, therefore, to examine whether Cl^- ions in $CoCl_2 \cdot 6H_2O$ were directly coordinated to Co^{2+} ion or not.

The present work was thus undertaken. Rotation, oscillation and multiple-film equi-inclination Weissenberg photographs have been taken about the a and the b axes with Fe$K\alpha$ and Mo$K\alpha$ radiations. The structure has been determined in the usual way by the Patterson and the Fourier syntheses and has been refined by both the difference Fourier syntheses and the method of least squares.

From the intensities of ($h1l$) and ($1kl$) reflections, the proposed model has been confirmed to be correct. A part of the present work was preliminarily reported[3].

Before the present work was not finished, Stroganov, Kozhina and Andreev[4] proposed in 1958 the crystal structure of this salt, but their structure model reported is entirely different from the result in the present paper. The differences will be discussed in § 6 and it will be concluded that the present structure model is reasonable.

§ 2. Data from the Literature on $CoCl_2 \cdot 6H_2O$

In "*Chemische Kristallographie*, **I** Teil" (Groth, 1906)[5] the following data are given: the crystal is monoclinic prismatic, the axial ratios $a:b:c$ are 1.4788:1:0.9452, β being 122°19′. The crystal shows a perfect cleavage parallel to (001), an imperfect cleavage parallel to (110) and well-developed faces parallel to (100). It is dark red in colour and hygroscopic. The density is 1.924 gr./cm³.

§ 3. Experimental

Dark red single crystals were grown from saturated aqueous solution. They were similar in habit, especially in well-developed faces parallel to (100), as described by Groth. Samples used for the X-ray study were cut out of these crystals and enclosed in thin-walled glass capillaries. They were about $0.3 \times 0.3 \times 2.5\ \mathrm{mm}^3$ in dimension. The rod axis was the a or the b axis.

At first, rotation and oscillation photographs were taken about the a and the b axes using Mn-filtered Fe$K\alpha$ and Zr-filtered Mo$K\alpha$ radiations. Next, multiple-film equi-inclination Weissenberg photographs of zero-, the first-, the second- and the third-layer were taken about the a and the b axes using Zr-filtered Mo$K\alpha$ radiation. These photographs gave the unit cell with the following constants:

$$a = 10.34\ \text{Å}, \quad b = 7.06\ \text{Å}, \quad c = 6.67\ \text{Å}$$

$$a:b:c = 1.47:1:0.945$$

$$\beta = 122°20′\ .$$

The number of molecules contained in the unit cell was calculated, from these lattice constants and the density value, 1.924 gr/cm³, to be 2.02, which means the existence of two molecules per unit cell. From the indexed oscillation and Weissenberg photographs, it was ascertained that general reflections (hkl) are present only if $h+k=2n$ and reflections ($h0l$) and ($0kl$) are present only if $h=2n$ and $k=2n$, respectively. Thus the space group was determined as $C_{2h}^3 - C2/m$.

The diffracted intensities on photographs were estimated by visual comparison with the time-exposure calibrated strips, and also by microphotometry, and were corrected in the usual way for Lorentz and polarization factors. The linear absorption coefficients were calculated to be 174.2 cm⁻¹ and 27.76 cm⁻¹ for Fe$K\alpha$ and Mo$K\alpha$ radiations, respectively. Using these coefficients, the rough absorption correction was made by assuming cylindrical shape of the sample.

§ 4. Determination of the Structure

As a first step, a Patterson projection on the (010) plane of the unit cell was made using ($h0l$) data obtained from oscillation photographs taken about the b axis with Mn-filtered Fe$K\alpha$ radiation. The general position is eightfold in the space group $C_{2h}^3 - C2/m$, and since there are two formula units of [$CoCl_2 \cdot 6H_2O$], in the unit cell, it follows that the cobalt atoms must lie in twofold special positions, one of which may be chosen for the origin. There were three peaks besides those at (0, 0) and ($\frac{1}{2}$, 0) in the projection. Two peaks of the former were at the distances 2.43 Å and 1.50 Å from the origin and were interpreted in terms of the Co–Cl and the Co–O interatomic distances, respectively. The angle between the two lines joining these two peaks with the origin was about 90°. Although the third lowest peak at the distance 2.42 Å from the origin was not clearly interpreted, it suggested the existence of water molecules located far from Co atoms. Thus, a structure model was tentatively derived, in which two Cl atoms and four water molecules are octahedrally coordinated to Co atom to form the group [$CoCl_2 \cdot 4H_2O$] and the other two water molecules of the formula unit are relatively free. The atoms are located at the following positions:

$(0, 0, 0;\ \frac{1}{2}, \frac{1}{2}, 0) +$

2Co at (a) $0, 0, 0$

4Cl at (i) $x, 0, z;\ \bar{x}, 0, \bar{z}$

$8O_{I}$ at (j) $x, y, z;\ x, \bar{y}, z,\ \bar{x}, y, \bar{z};\ \bar{x}, \bar{y}, \bar{z}$

$4O_{II}$ at (i) $x, 0, z;\ \bar{x}, 0, \bar{z}$.

The parameter values for the positions of the atoms could approximately be determined by the trial-and-error method, using the $F(h0l)$'s obtained from oscillation photographs taken about the *b* axis with Zr-filtered Mo$K\alpha$ radiation. They are listed in Table I. The *y* parameter of O_I was estimated, assuming that four water molecules around Co atom are arranged in a square. The reliability factor, $R=\Sigma||F_0|-|F_c||/\Sigma|F_0|$ was 0.19 for the observed spectra of $F(h0l)$'s. No corrections for temperature were made in the calculation of F_c.

Table I. Parameter values of atoms determined by the trial-and-error method.

Atom	*x*	*y*	*z*
Co	0	0	0
Cl	0.270	0	0.160
O_I	0.0325	(±0.224)	0.261
O_{II}	0.283	0	0.717

As the next step, Fourier projections on (010) and (100) were synthesized, based on the above structure model, using the $F(h0l)$'s and $F(0kl)$'s obtained from oscillation photographs taken about the *b* and the *a* axes with Zr-filtered Mo$K\alpha$ radiation. Improved values of atomic parameters were obtained from these Fourier projections. They are given in Table II. The reliability factors calculated only from observed spectra were 0.154 for the $F(h0l)$'s and 0.145 for the $F(0kl)$'s, respectively. *B*, the coefficient in the exponent of the isotropic temperature factor $\exp[-B\cdot\sin^2\theta/\lambda^2]$, was estimated as 1.5 Å^2 for Co^{2+} and 3.0 Å^2 for Cl^- and O^{2-}, respectively, from comparison between F_c and F_0.

O_I: $4H_2O$ coordinated to Co^{2+} ion. O_{II}: $2H_2O$ far from Co^{2+} ion.

As the final step, the Fourier projections and the difference Fourier projections on (010) and on the plane normal to the *a* axis were synthesized, using the $F(h0l)$'s and $F(0kl)$'s obtained from Weissenberg photographs. In these procedures, the *y* and the *z* parameters were improved as given in Table II. The value of *B* for Co^{2+} was also improved to be 1.7 Å^2. The reliability factors were 0.137 and 0.135 for the $F(h0l)$'s and the $F(0kl)$'s of observed spectra, respectively. The method of least squares was finally applied and the atomic parameters were determined. They are listed also in Table II. The Fourier projections finally synthesized are shown in Fig. 1 (a) and (b). The calculations of the method of least squares and the final Fourier syntheses were carried out with PC-1 Parametron Computer of Tokyo Univ..

Table III gives a comparison between observed and calculated structure factors for the present structure model. The agreement is fairly good, and the reliability factors are 0.196 and 0.160 for all $(h0l)$ and $(0kl)$ amplitudes, for which the maximum observed values of $\sin\theta/\lambda$ were 0.8324 and 0.7773, respectively. These amplitudes include those of unobserved reflections. The reliability factors for $F(h0l)$'s and $F(0kl)$'s of observed spectra alone are 0.132 and 0.121, respectively. In the calculation of F_c, the values of the atomic scattering factors were taken from "*Internationale Tabellen zur Bestimmung von Kristallstrukturen* II" (1935). In the calculation by PC-1 computer, they were taken from the paper of Vand, Eiland and Pepinsky[6].

§ 5. Description of the Structure

The schematic representation and the arrangement of atoms projected on (010) plane

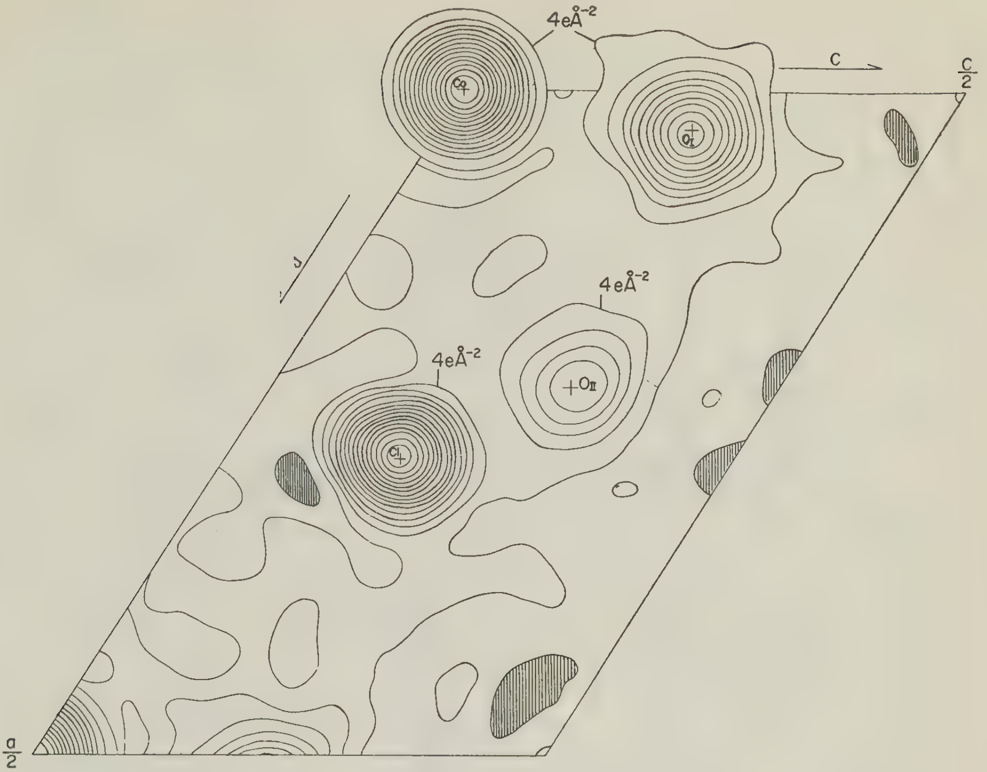

Fig. 1(a).

Fig. 1. The final Fourier projections of electron density on (010), (a) and on a plane normal to the *a* axis, (b). Contours are drawn at intervals of $2e\text{Å}^{-2}$. Co atom is contoured at intervals of $4e\text{Å}^{-2}$. In (b) contours of 15.5 and $15.7e\text{Å}^{-2}$ are drawn at the central region of $O_{I \cdot 1}$ and $O_{I \cdot 2}$. Negative areas are shaded. Crosses show the final atomic positions.

are shown in Fig. 2 and Fig. 3, respectively. As seen from the former figure, two Cl^- ions and four water molecules are octahedrally coordinated to Co^{2+} ion to form the group $[CoCl_2 \cdot 4H_2O]$. These four water molecules are arranged in a square form. The other two water molecules of the formula unit are located far from Co^{2+} ion.

Exactly speaking, the two side lengths of the square of water molecule are not equal but estimated to be 3.05 Å and 2.94 Å, respectively, and hence the form is a rectangle close to a square. The plane of the " square " is perpendicular to (010) and is inclined to the *c* axis by an angle of about 10°. The Cl^-–Co^{2+}–Cl^- bond is perpendicular to the plane of the " square ". Interatomic distances and interbond angles are given in Table IV. From both the distance between O_I and O_{II} and the angle $\angle O_I \cdots O_{II} \cdots O_I$, it is almost certain that the groups $[CoCl_2 \cdot 4H_2O]$ are held together parallel to the *b* axis by $O \cdots H$–O

*: Tnobserved Spectra.

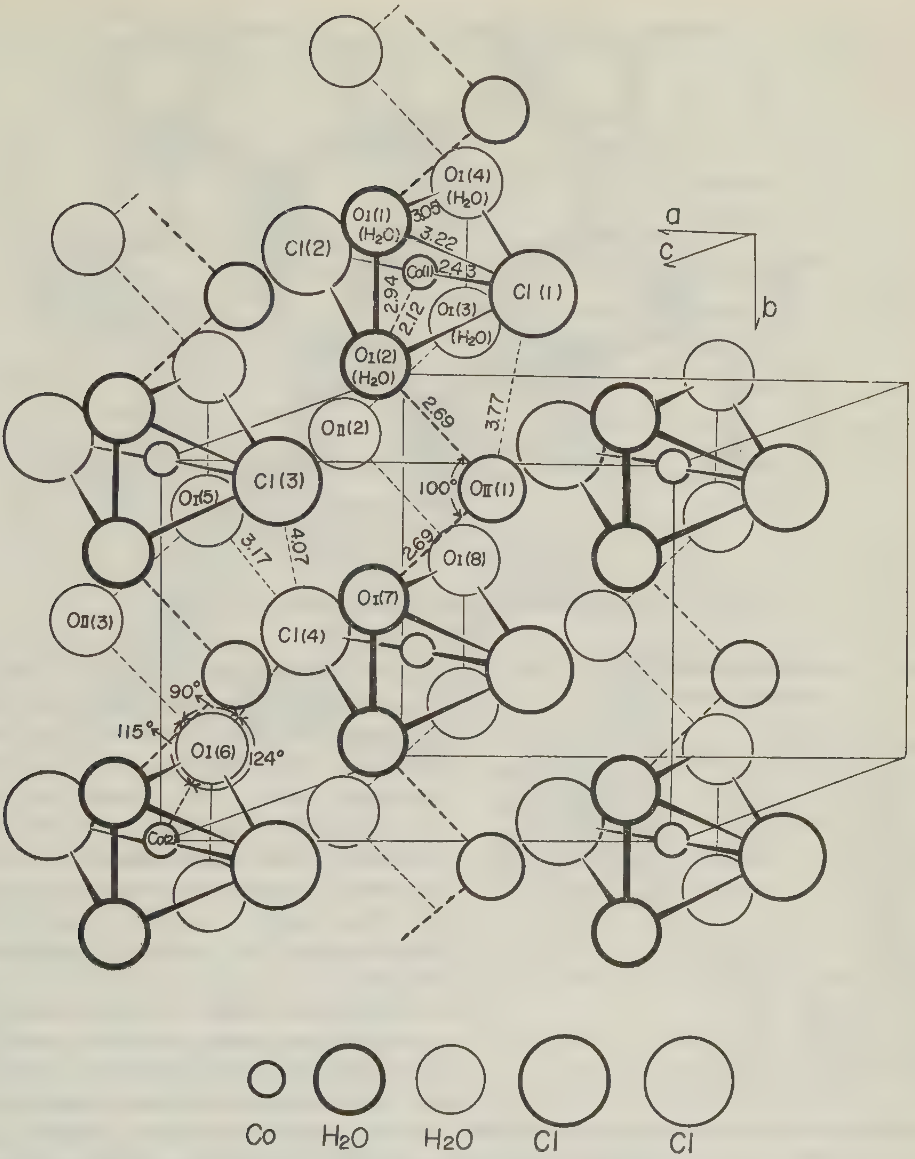

Fig. 2. The schematic representation of the crystal structure of $CoCl_2 \cdot 6H_2O$.

type hydrogen bonds between O_I and O_{II}. As seen from Fig. 3, the structure is also composed of atomic layers parallel to (001). Thus, the perfect cleavage parallel to (001) can reasonably be explained.

§ 6. Discussion

Stroganov *et al.* already reported the crystal structure of $CoCl_2 \cdot 6H_2O$. According to them, important data of the structure are as follows:

i) Space group: $C_{2h}^5 - P2_1/c$

ii) Unit cell dimensions: $a = 6.58$ kX, $b = 7.03$ kX, $c = 11.50$ kX, $\beta = 49°30'$

iii) Four water molecules and two Cl^- ions are coordinated to Co^{2+} ion to form the group $[CoCl_2 \cdot 4H_2O]$, in which four water molecules are arranged in a rectangular form around Co^{2+} ion. The side lengths of the rectangle are 2.6 kX along the *b* axis and 3.3 kX along (010), respectively. The angle between the $Cl^- - Co^{2+} - Cl^-$ bond and the normal to the plane of the rectangle is 19°. The interatomic distances $Co-H_2O$ and $Co-Cl$ in the group are 2.12 kX and 3.10 kX, respectively.

iv) The other two water molecules of the formula unit are located near the group

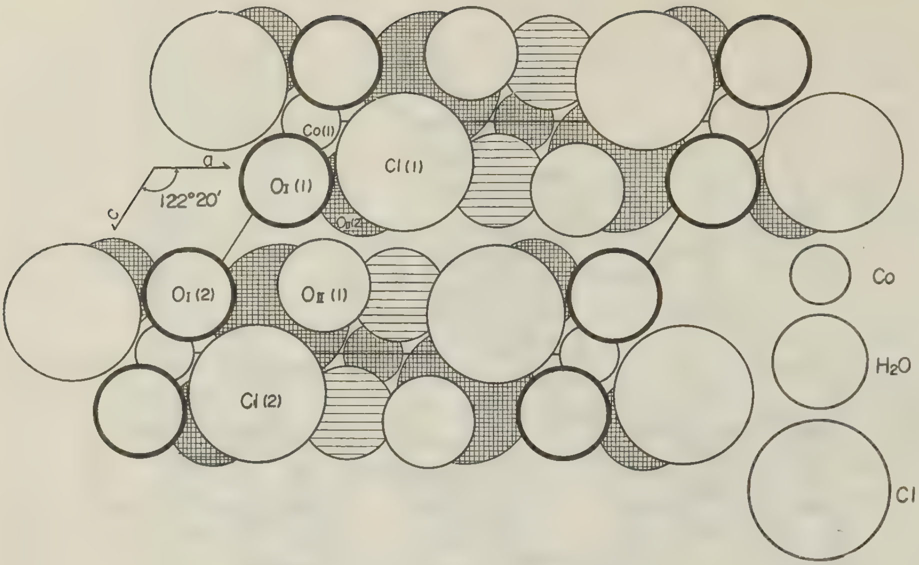

Fig. 3. The arrangement of atoms projected on (010).

Table IV. Interatomic distances (in Å) and interbond angles.

Cl(4)-O$_I$(6)-Co(2)	124°		
O$_{II}$(3)-O$_I$(6)-Cl(4)	90°		

[$CoCl_2 \cdot 4H_2O$] and symmetrically to Co^{2+} ion in the plane (010). The interatomic distance Co-H_2O is 3.20 kX, and the angle between O-Co-O line and the normal to the above rectangle is 40°.

v) The cleavage plane is (010).

Compared with their structure model, the data of the present structure are as follows:

i) Space group: C_{2h}^3-C2/m.

ii) Unit cell dimension: $a=10.34$ Å, $b=7.06$ Å, $c=6.67$ Å, $\beta=122°20'$

iii) The group [$CoCl_2 \cdot 4H_2O$] is formed similarly to their structure model, but its detailed structure is different. Four water molecules are arranged in the "square" around Co^{2+} ion and the Cl^--Co^{2+}-Cl^- bond is perpendicular to the plane of this "square". The Co-H_2O and Co-Cl distances are 2.12 Å and 2.43 Å, respectively. The other two water molecules of the formula unit are by 4.07 Å distant from Co^{2+} ion. The fact that two kinds of water molecules exist in the present salt, namely, one is located near Co^{2+} ion and the other far from it, was also deduced in the study of proton magnetic resonance by Sugawara[7].

iv) The structure leads to the perfect cleavage parallel to (001) in accordance with Groth[5].

Sugawara's result and the result (iv) suggest that the present model is more reasonable one than that reported by Stroganov *et al.*. It is noticed, however, the fact that the following four kinds of the atomic arrangement, (I), (II), (III) and (IV) are conceivable so far as the Fourier projections shown in Fig. 1 (a) and (b) are concerned. In the arrangement (I), which was adopted by the present author, Cl and O_{II} in Fig. 1 (a) are located at $(x, 0, z)$ and $x, \frac{1}{2}, z)$, respectively, and the former atom is coordinated to Co at (0, 0, 0), and $O_{I\cdot 1}$ and $O_{I\cdot 2}$ in Fig. 1 (b) are located at (x, y, z) and $(x, \frac{1}{2}-y, z)$ and coordinated to Co at (0, 0, 0) and Co at $(\frac{1}{2}, \frac{1}{2}, 0)$, respectively. In the arrangement (II), Cl and O_{II} in Fig. 1 (a) occupy the positions of the arrangement (I) and $O_{I\cdot 2}$ and $O_{I\cdot 1}$ in Fig. 1 (b) are coordinated to Co at (0, 0, 0) and Co at $(\frac{1}{2}, \frac{1}{2}, 0)$, respectively. Consequently, four water molecules coordinated to Co are ar-

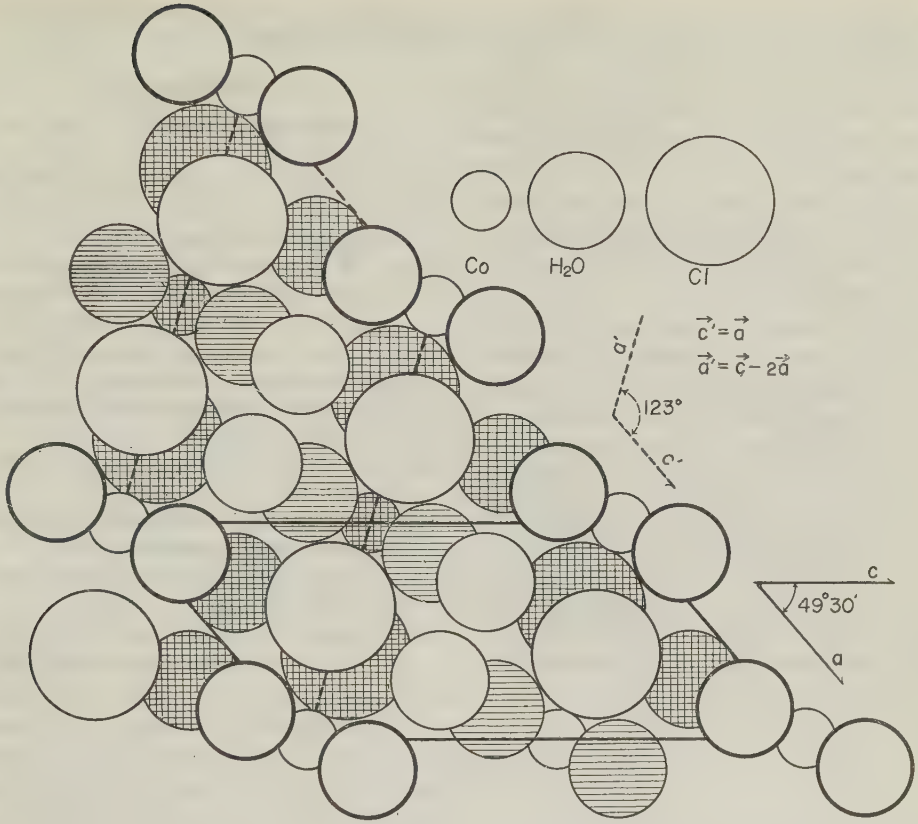

Fig. 4. The arrangement of atoms projected on (010) of the structure determined by Stroganov *et al.*

ranged in a rectangular form. In the arrangement (III), Cl in Fig. 1 (a) is located at $(x, \frac{1}{2}, z)$ and coordinated to Co at $(\frac{1}{2}, \frac{1}{2}, 0)$, and O_{II} is located at $(x, 0, z)$, and $O_{I\cdot1}$ and $O_{I\cdot2}$ in Fig. 1 (b) occupy the positions of the arrangement (I). In the arrangement (IV), Cl and O_{II} in Fig. 1 (a) are located at the positions of the arrangement (III) and $O_{I\cdot1}$ and $O_{I\cdot2}$ in Fig. 1 (b) are located at the positions or the arrangement (II).

It is interesting to note the circumstance that the projections on (010) of the atomic arrangements (III) and (IV) are very similar to the portion surrounded with broken lines in Fig. 4 which represents the atomic arrangement proposed by Stroganov *et al.*. In this figure a' and c' are related to their a and c, respectively by the following vector equations:

$$\vec{c}\,' = \vec{a}$$

$$\vec{a}\,' = \vec{c} - 2\vec{a}$$

The length of a' is 10.4 kX, and $\vec{a}\,'$ makes an angle 123° with $\vec{c}\,'$. As the length of c' is 6.58 kX, the unit cell formed by a', b and c' is nearly equal to that of the present structure.

It is important to determine which one of these four kinds of the atomic arrangement is correct. Because of $F_c = 8\Sigma f \cos 2\pi(hx+lz) \cdot \cos 2\pi ky$, this can not be determined by $(h0l)$ and $(0kl)$ data alone but by $(h1l)$ and $(1kl)$ data. The reliability factors for the above four atomic arrangements were calculated using thirty-one $F(h1l)$'s and seventeen $F(1kl)$'s. They are listed in Table V. These data show

Table V. The reliability factors for four kinds of the atomic arrangement.

Kind of atomic arrangement	Reliability factor	
	for $F(h1l)$'s	for $F(1kl)$'s
(I)	0.11	0.087
(II)	0.25	0.35
(III)	0.91	0.89
(IV)	0.92	0.84

that the structure I is decidedly reliable.

In a single crystal as well as a powdered sample of $NiCl_2 \cdot 6H_2O$ isomorphous to $CoCl_2 \cdot 6H_2O$ the antiferromagnetic transition was found at about 6°K[8),9)]. According to the preliminary study on the structure of the former salt by the author[10)], this salt seems to resemble $CoCl_2 \cdot 6H_2O$ in its atomic arrangement. The structure analysis of $NiCl_2 \cdot 6H_2O$ is now in progress.

The author wishes to express his sincere thanks to Professor S. Ogawa for his continued encouragement throughout the present work. His hearty thanks are also due to Professor T. Sugawara of the Institute for Solid State Physics, Tokyo University and Mr. T. Ukei for their valuable discussions. He is also indebted to Dr. T. Haseda and Mr. T. Satō for preparation of the good single crystals, and to Dr. Y. Takeuchi, Mr. M. Tokonami and the members of Professor R. Sadanaga's laboratory, Tokyo University for their aids in calculations using PC–1 Parametron Computer.

(Received March 15, 1960)

Well oriented silver films have been formed by evaporation onto heated cleavage (001) surfaces of rock-salt in vacuum, the evaporation period having been changed in a wide range in case of the thickness kept at about 400 Å, and the influence of the formation speed on the twinning in the films has been examined by electron diffraction and electron microscopy. The diffraction patterns have shown that the frequency of the twin formation is not seriously decreased by the lowest formation speed, but that imperfections such as bending or twisting of films are largely decreased. The interference fringes caused by the dynamical effect have been observed on the electron micrographs of slowly formed films. This fact means that the slow formation of films decreases also imperfections such as dislocations and vacancies and makes the lattice more perfect. The fringes are believed to be so-called equal thickness fringes originated from wedges due to the twin formation.

§ 1. Introduction

On the transmission electron micrographs of evaporated single-crystal-like films of silver, gold, copper, nickel and palladium, a number of parallel broad striations running along two orthogonal directions were observed, and they were considered to be caused by twin lamellae, the contrast being due to the Bragg reflection[1]. This consideration was later proved by a selected area diffraction[2]. A similar fact was found also in case of nickel films electro-deposited on a single crystal of copper[3]. The twin striations correspond to the twin spots on the electron diffraction patterns.

There is an interesting result obtained by Thirsk[4] that the untwinned single-crystal structure was found by electron diffraction in platinum films very slowly formed on fresh cleavage face of potassium chloride in vacuum by several-hour evaporation. It may be considered that the slowdown of the formation speed increases the perfectness of the crystal lattice because of the removal or the decrease of various kinds of imperfection. Since the growth twinning is caused by a stacking fault which is a kind of crystal imperfection, the decrease of the twin formation might also result from the slow evaporation. It was thought to be interesting to study by electron diffraction and electron microscopy whether such an effect on the twin formation could be observed in cases other than platinum or not, and thus the present work was started.

According to the present results obtained in evaporated silver films, the slowdown of the formation speed does not seriously influence the twin formation but considerably decreases such imperfections as vacancies, dislocations and sub-boundaries. Furthermore, the improvement of perfectness of the lattice gives rise to interference fringes due to the dynamical effect, similar to those observed by Bassett and Pashley[5]. The present report will discuss also the nature of these fringes.

§ 2. Experimental

Many single-crystal-like films of silver were formed on fresh (001) cleavage faces of rock-salt heated at 180°C in vacuum. The mean thickness of each film was always controlled to be about 400 Å, and the formation speed was arranged to range from 400 Å to 0.02 Å per second. For reference, thin films of gold were formed on (001) cleavage surfaces of rock-salt heated at 400°C.

An electron diffraction camera with the camera length of 309 mm and an electron microscope with the resolving power of about 30 Å were used. The applied voltage was 50 kV in both apparatus.

§ 3. Results

Photo. 1 shows electron diffraction patterns and electron micrographs, taken from silver films epitaxially grown on rock-salt, in serial order of the formation speed. On the diffraction patterns of the normal incidence the twin spots appear to decrease their intensity with the decreasing formation speed and to vanish on the pattern, (c_1). On the other hand, they do not seriously change their intensity at the [101] incidence. The twin formation in evaporated silver films, therefore, is not largely influenced by the formation speed, against the expectation. The twin spots were found even on the diffraction pattern of the [101] incidence obtained from the specimen formed by seven-hour-evaporation. The rather strong streaks along the ⟨111⟩ direction were observed on all the diffraction patterns of the [101] incidence and also on the patterns of the normal incidence when the formation speed was low. The streaks behave with the change of the formation speed in almost the same way as the twin spots. They are thought of as due to stacking faults. On all the electron micrographs dark striations are seen. They run along two perpendicular directions which are the intersections of the film plane with two (111) planes*. It seems that the lower formation speed gives rise to a little decrease of the number of the striations. The annealing of the films in vacuum at 180°C had very little effect on the striations.

The lower formation speed, however, seems to influence largely the aspect of the striations. This is seen in Photo. 1 (c_3) and Photo. 2 both of which were taken from the four-hour-evaporation film. In these micrographs, the dark striations are often split into fringes consisting of three or four fine lines. It should be noted that the fine lines are regularly spaced, in most cases, at intervals of about 200 Å. The fringes are quite similar in their feature to those observed in an evaporated gold film by Bassett and Pashley. According to the present authors' opinion, however, they are, mostly, not caused by stacking faults against the opinion of Bassett and Pashley, but are so-called equal thickness fringes caused by wedge-shaped parts due to the twin formation. The discussion will be given in the next section.

§ 4. Interpretations and Discussions of the Results

The twin spots and the streaks passing them, seen on the diffraction patterns of the normal incidence obtained from the quickly formed films, make their appearance owing to bending or twisting of films, as they lie on the body diagonals of the reciprocal lattice. The disappearance of them on the diffraction patterns of the normal incidence obtained from the slowly formed films, therefore, means not the decrease of twins or stacking faults but the decrease of bending or twisting of films. As the bending or the twisting is thought of as originated from sub-boundaries, these boundaries are decreased by the lower formation speed. The decrease of the striations on the micrographs of the normal incidence with decreasing formation speed does not correspond to the actual decrease of twins or stacking faults, too. It is not unnatural to suppose that such imperfections as dislocations and vacancies are also decreased in the slowly formed films, and this tendency of the decrease of such imperfections can be deduced from the fringes obtained from the very slowly formed films, because the dynamical interaction will not be strong unless the perfectness of the lattice is considerably high.

Recently, Bassett and Pashley[5] obtained fringes similar to those in the present work from an evaporated gold film and ascribed the origin of them to stacking faults, as Whelan and Hirsch[6],[7] discussed. There seems, however, to be an alternative explanation in the present case, i.e, that which considers the present fringes as the equal thickness fringes due to the twin formation. As illustrated in Fig. 1, there are wedge parts in both the normal crystal and the twin crystal. The equal thickness fringes may be formed in either of the wedge parts, provided that electrons diffracted in one side of the twinning plane behave incoherently in the other side of the plane. The two lattices on both sides of the (111) plane behave coherently

---

* The striations were also observed in (011) films of silver grown epitaxially on the (011) cleavage surfaces of rock-salt. They run along three directions which are the intersections of the film plane with three (111) planes.

Photo. 1. Electron diffraction patterns and electron micrographs obtained for various formation speeds. (a): 400 Å/1 minute, (b): 400 Å/10 minutes, (c): 400 Å/4 hours. Diffraction patterns were obtained by the normal incidence in (a_1), (b_1) and (c_1) and by the oblique incidence in (a_2), (b_2) and (c_2). The beam is parallel to a face diagonal in the later case. Electron micrographs, (a_3), (b_3) and (c_3), correspond to (a_1), (b_1) and (c_1), respectively. The twin spots and the twin striations are shown by the arrows.

with each other in case of stacking faults.

In order to decide which explanation is adequate in the present case, it is necessary to compare calculated values of the line interval and the whole width of fringes with observed values. MacGillavry's formula[8] for the intensity transmitted through the lattice (Laue case) is approximately expressed as the following equation:

$$I=I_0\left\{\frac{V_{hkl}}{\lambda E}D_0\cos\left(\pi\frac{D}{D_0}\right)\right\}^2. \qquad (1)$$

and

$$D_0=\left\{\left(\frac{V_{hkl}}{\lambda E}\right)^2+\left(\frac{\theta-\theta_0}{d_{hkl}}\right)^2\right\}^{-1/2}, \qquad (2)$$

where I_0 is the intensity of the incident beam, V_{hkl} the Fourier coefficient of the lattice potential for (hkl) reflection, λ the wave length of the incident beam, E the accelerating voltage, D_0 the extinction distance, D the penetration depth along the incident direction, θ the glancing angle of (hkl) plane, θ_0 the Bragg angle of (hkl) plane and d_{hkl} the interplaner spacing of (hkl) plane. In case of the equal thickness fringes arising from such a wedge as shown in Fig. 2(a), the interval of fringes, S_W, on the electron micrograph is given by

$$S_W = D_0 \cot \alpha \,, \tag{3}$$

where α is an angle between the (111) plane and the film surface. In case of a stacking fault, on the other hand, the extinction distance, D_0', is given as the following expression⁷⁾:

$$D_0' = \frac{D_0}{2}(1-x^2)^{-1/2} \,, \tag{4}$$

where x is a parameter indicating the deviation from the Bragg angle. If $(\theta-\theta_0)$ is zero, D_0' is just half of D_0. Thus the interval of fringes due to a stacking fault, S_F, is, at maximum, given by

$$S_F = \frac{D_0}{2} \cot \alpha \,. \tag{5}$$

The circumstances are illustrated in Fig. 2(b).

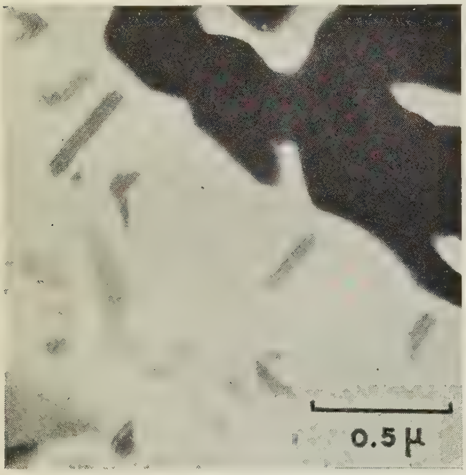

Photo. 2. Electron micrographs of silver film formed by four-hour evaporation.

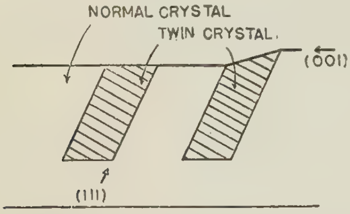

Fig. 1. Schematic picture of (001) film twinned on (111) plane, viewed from <1$\bar{1}$0> direction.

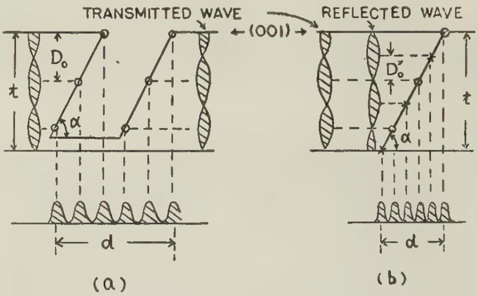

Fig. 2. Formation of fringes due to the twin formation (a) and due to a stacking fault (b). The angle, α, is 54°44′ in both cases.

Table I. Calculated values of extinction distance, D_0, and line intervals of fringes, S_W and S_F, of silver for 50 kV electrons.

Reflection	D_0 (Å)	S_W (Å)	S_F (Å)
(200)	190	134	67
(400)	411	291	145
(600)	723	511	256
(800)	1070	756	378
(220)	273	193	97
(420)	505	357	179
(440)	686	485	243

Under the condition that the incident beam is nearly perpendicular to the [001] film plane, lattice planes parallel to the (001) direction have chances to reflect electrons. They are the planes, (200), (020), (220), (2$\bar{2}$0), (400), (040), (420) etc., of the normal lattice and the planes, (2$\bar{2}$0), (204) etc., of the twin lattice. The line intervals, S_W and S_F, are calculated by using the above mentioned equations and shown in Table I. In the calculated values of S_W, that for (220) reflection, 193 Å, best fits to the observed interval, about 200 Å. In the calculated values of S_F, on the other hand, those for (600), (420) and (440) reflections seem to fit. However, the calculated value of the whole width of the fringe, d, should also be compared with the observation. If the present fringes are caused by a stacking fault, d is calculated by

$$d = t \cot 54°44' \,, \tag{6}$$

as shown in Fig. 2(b). In the present study, the mean thickness of films, t, was always controlled to be about 400 Å, and it gives about 280 Å as the calculated width. This value is far smaller than the observed value, about 600 Å. This discrepancy proves the inadequacy of the explanation by a stacking fault. Though the increase of local thickness due to the patch-like structure may somewhat favour to decrease the discrepancy, it will not change the general trend. According to the explanation by wedges due to the twin formation, on the other hand, the calculated fringe width is possible to be about 600 Å, as shown in Fig. 2(a), if the thickness of a twin layer is moderate. Therefore, there is a considerable possibility that the present fringes are produced by the (220) reflection of the normal lattice in the wedges. This well coincides with the fact that no twin spot is found in the diffraction pattern, (c_1) in Fig. 1. The $(2\bar{2}0)$ reflection can also take place in the twin lattice, but it is a common reflection to both lattices, and hence the equal thickness fringes cannot be produced in that case.

Gold films about 400 Å thick were formed by three-hour-evaporation on cleavage faces of rock-salt at 400°C and examined by electron microscopy. The interference fringes were also observed and the line interval was about 130 Å. The calculated value is 132 Å in the wedge case for the (220) reflection from the normal lattice. This coincidence between calculation and observation strongly supports the present authors' opinion.

The present authors wish to express their sincere thanks to Dr. D. Watanabe and Mr. Y. Fukano for their valuable discussions.

X-ray Line Broadening from the Polished Surfaces of Silver and Gold

By Masao KURIYAMA

The Institute for Solid State Physics, University of Tokyo
Shin-Ryudo-cho, Minato-ku, Tokyo, Japan

(Received March 3, 1960)

The linear relation (Hall's formula) and the quadratic relation between the integral breadth and the scattering angle can be derived from the general formula for intensity distribution by the assumption of the appropriate distribution for both size and strain. The use of these two formulae (line breadth method) can give not only the magnitude but also the plausible distribution for strain and size. The advantage of this method consists in the point that the magnitude and the distribution for size and those for strain can be separately obtained, in contrast with the Fourier analysis of line profile (line profile analysis method). The line breadth method is applied to the polished surfaces of Ag and Au and the results obtained are confirmed to be correct by the line profile analysis. On the other hand, the line profile analysis is required to study the strain variation with the depth in specimens, as far as only one kind of radiation is used. This strain variation can be observed by the line breadth method with the use of different radiations, and the comparison is made between the results from the line breadth method and from the line profile analysis method.

§ 1. Introduction

Fourier analysis of X-ray line broadening (line profile analysis method) has presented a useful information on lattice imperfections since Warren and Averbach[1] first developed this method. The two parts of a Fourier coefficient due to size and strain, however, could not be separated without any assumption. This difficulty was discussed in detail by Williamson and Smallman[2]. On the other hand, Hall[3] had already observed for many cold-worked metals the dependence of line breadth on diffraction angle which he had derived under the simple assumption of additivity of the strain and size effects. Hall's formula is still often used to obtain the magnitude of size and strain in the field of metallurgy, because it is more convenient than the Fourier analysis method.

It has been generally recognized that Hall's formula or another formula (quadratic formula) for the angular dependence of line breadth is simply empirical and cannot give so much information on the distribution of strain and size as the line profile analysis does. As already pointed out in the previous paper[4], these two formulae can be derived simply under the assumption that both the line profile due to size and the one due to strain are either Gaussian or of Gauchy.

In this paper, however, these two formula will be derived with a physical significance from the general formula for the intensity distribution on a diffraction line by the assumption of the appropriate distribution for size and strain. In other words, the plausible distribution and the magnitude for strain and those for size can be obtained separately if any one of these two formulae can well explain the observed angular dependence of line breadth. (This method is, hereafter, called as the line breadth method.) This method seems quite useful because it is not only more convenient than the line profile analysis, but also has the advantage mentioned above.

The line breadth analysis will be applied to the polished surfaces of Au and Ag and the results will be confirmed in § 5 by the line profile analysis. If a specimen gives rise to a dominant strain broadening, the comparison can be easily made between the results from the line breadth method and from the line profile analysis method. Polished surface of metals, as shown in this paper, gives a strain broadening about ten times larger than that due to size and can be considered to be a suitable sample. This is the reason why the polished metals were chosen.

Although the line breadth method gives the same information as the line profile method does, the use of different radiations is required to study the strain variation with the depth in specimens. On the other hand, the line profile analysis method gives enough information to know the strain variation, even if only one kind of radiation is used. This point will be shown in this paper with the comparison between the results from the two methods.

This paper also deals with the study on the distorted structure of the inner part under the Beilby layer by the line breadth method.

§ 2. Experimental Conditions

Some annealed plates of silver and gold (40 mm × 40 mm × 5 mm for Ag and 25 mm × 25 mm × 1 mm for Au) were polished by emery papers and lapped by cloth with carborandum and rouge in order to obtain the flat surface. The surface was etched as heavily as a fresh flat surface appeared, and was finally polished by chamois leather for a considerably long time. During polishing, they were pressed onto a rotating disc with the pressure of 100 g wt./cm². The polishing apparatus has been previously described[4]. The time of polishing is listed in Table I.

After the line profile was recorded, every specimen was annealed for about 40 hours at 400°C, and again recorded. The profile of diffraction lines was observed by the Norelco x-ray diffractometer. A proportional counter operated at 1850 v was covered by a suitable filter. Divergence and scatter slits had 1° openings and a receiving slit 0.006 in. The driving speed of a counter was 1/8° a minute.

As numerous diffraction lines had to be observed, a rate meter and a recorder were used. A reliability of a recorded line profile was confirmed by comparing it with the profile observed by the fixed time counting. The driving speed of a recording chart was half an inch a minute.

The precise intensity distribution of the background scattering was also obtained by counting the intensity at many positions where any diffraction line could be observed. The overlapping of the adjacent lines was estimated by the background scattering curve.

Diffraction lines were observed by using three different radiations (CuKα, FeKα and MoKα), in order to study the change in state with the depth from a surface. In the case of Mo radiation for gold specimens, a nickel filter in addition to a Zr filter was used in front of a counter to eliminate the fluorescent Au L radiation*.

The breadth of lines becomes sharp if more than one day elapses after polishing. This is due to the recovery effect in the polished state. The rapid observation of the line broadening should follow polishing. This is another reason why a rate meter and a recorder were used.

§ 3. Theory of Line Broadening**

The general formula of intensity distribution on a diffraction lines is given by Estabrook and Wilson[5] as

$$I(2\vartheta)=KNF_0^2(2\vartheta)\sum S(R_m)J(H, R_m)\times\exp[2\pi isR_m]\,, \qquad (1)$$

where

$$J(H, R_m)=\int P(e, R_m)\exp[2\pi iHe(R_m)R_m]de(R_m)\,, \qquad (2)$$

and K is dependent upon ϑ but assumed constant in the vicinity of any reflection, N the average number of unit cells in a crystallite, and $s=2(\sin\vartheta-\sin\vartheta_H)/\lambda$, $H=2\sin\vartheta_H/\lambda$.

The range of summation extends to infinity, introducing the shape function $S(R_m)$. $P(e, R_m)$, called the strain distribution function, is a probability of two cells R_m distance apart for which the average strain is $e(R_m)$. Normalization is made respectively for the shape and the strain functions:

$$S(0)=1 \quad\text{and}\quad J(H, 0)=\int P(e, 0)de=1\,. \qquad (3)$$

Let us show below that the typical formulae for the angular dependence of line breadth can be derived from the general formula (1), assuming the appropriate distribution for both strain and size. It will be shown from this calculation that the linear formula (Hall's empirical formula) can be derived from the two different types of distribution for strain and size and the quadratic formula from the Gaussian distribution.

---

* Cu foil is of course the most suitable filter eliminating Au L. As a nickel filter, however, can be readily obtained, it is used here.

** This part and next section have been already read at the meeting of Physical Society of Japan, April, 1959.

I. *Gaussian type*

At first the Gaussian type of distribution function is assumed for both functions:

$$S(R_m)=\exp\left[-(\pi/C^2)R_m{}^2\right] , \quad (4)$$

and

$$P(e,\ R_m)=(1/E)\exp\left[-(\pi/E^2)e^2\right] , \quad (5)$$

where C is the integral breadth of the shape function and E the integral breadth of the strain distribution. E should be in general dependent not only upon R_m but also upon the location of the relevant unit cells. It is, however, assumed here not to depend on these factors for the convenience of calculation. Such an approximation will be discussed in § 6. The root mean square values of size and strain are $C/\sqrt{2\pi}$ and $E/\sqrt{2\pi}$, respectively. Substituting (5) into (2),

$$J(H,\ R_m)=\exp\left[-\pi E^2H^2R_m{}^2\right] \quad (6)$$

is obtained. From (1) the intensity profile is obtained;

$$I(2\vartheta)=KNF_0{}^2\left(\frac{1}{d_H}\right)\left\{\frac{1}{(1/C)^2+E^2H^2}\right\}^{1/2}$$
$$\times\exp\left[-\left\{\frac{\pi s^2}{(1/C)^2+E^2H^2}\right\}\right] . \quad (7)$$

d_H is an interplanar distance for the lowest order. This profile is also of the Gaussian form. The integral breadth in the present case becomes the quadratic formula:

$$(\beta\cos\vartheta/\lambda)^2=(1/C)^2+4E^2(\sin\vartheta/\lambda)^2 . \quad (8)$$

This relation has been so far recognized empirically in some cases.

II. *Cauchy type for the strain distribution*

Shape function is, here, assumed to be of the form

$$S(R_m)=\exp\left[-(2/C)R_m\right] \quad (9)$$

C is the size of a mean crystallite and the physical meaning of this derivation will be discussed in § 6. Strain distribution function is assumed to have another familiar type

$$P(e,\ R_m)=(1/E)\left(\frac{1}{1+(\pi/E^2)e^2}\right) . \quad (10)$$

$(E/2)$ is considered as the magnitude of mean strain, though the Cauchy distribution has not any moments. Then $J(H,\ R_m)$ is given by

$$J(H,\ R_m)=\exp\left[-2EH|R_m|\right] . \quad (11)$$

The line profile, therefore, becomes a Cauchy form:

$$I(2\vartheta)=KNF_0{}^2\left(\frac{1}{d_H}\right)\frac{(1/C)+EH}{\{(1/C)+EH\}^2+\pi^2s^2} \quad (12)$$

The integral breadth is expressed by

$$\beta\cos\vartheta/\lambda=(1/C)+2E(\sin\vartheta/\lambda) . \quad (13)$$

This has been also so far recognized empirically in many cases as Hall's formula[3].

In contrast with case I, the linear formula (13) can also be derived from the different distribution, as shown below.

III. *Exponential type for the strain distribution*

Shape function is a Cauchy type;

$$S(R_m)=\frac{1}{1+(\pi/C)^2R_m{}^2} , \quad (14)$$

and strain distribution is given by

$$P(e,\ R_m)=(1/E)\exp\left[-(2/E)|e|\right] . \quad (15)$$

Then $J(H,\ R_m)$ becomes

$$J(H,\ R_m)=\frac{1}{1+\pi^2E^2H^2R_m{}^2} , \quad (16)$$

The line profile is, therefore, given by

$$I(2\vartheta)=KNF_0{}^2\left(\frac{1}{d_H}\right)\frac{EH}{C\{E^2H^2-(1/C)^2\}}$$
$$\times\left\{Ce^{-(2/EH)|s|}-\frac{1}{EH}e^{-2C|s|}\right\} \quad (17)$$

This profile has a steep decrease around the Bragg angle if either strain or size is dominant or the effects due to strain and size are comparable. Integral breadth thus becomes

$$\beta\cos\vartheta/\lambda=(1/C)+2E(\sin\vartheta/\lambda) . \quad (18)$$

It is noted that this case also gives Hall's formula, but gives the different line profile from case II.

It has been pointed out[4] that (8) in case I and (13)* in case II can be derived simply by the assumption that the line profile due to size and the one due to strain are either Gaussian or of Cauchy.

§ 4. Line Breadths

When the metallic surfaces are highly polished, the Beilby layer covers the surface. The thickness of this layer is considered to be about a few hundred angstroms as Kranert and Raether have estimated[6]. The structure of this layer is heavily distorted with a considerable amount of strain and differs from the crystalline state[7]. It is, therefore, expected that the inner part (more than 1 micron deep from the surface) would have the distorted state with a few percent strain. It is thus worthwhile to obtain from such a specimen the magnitudes of strain and size as well as, if possible, the strain distribution.

---

* Although (13) and (18) have the mathematically same form, (13) means the equation derived under the assumption in II and similarly (18) the equation derived in III.

Line breadths were measured for the spe-

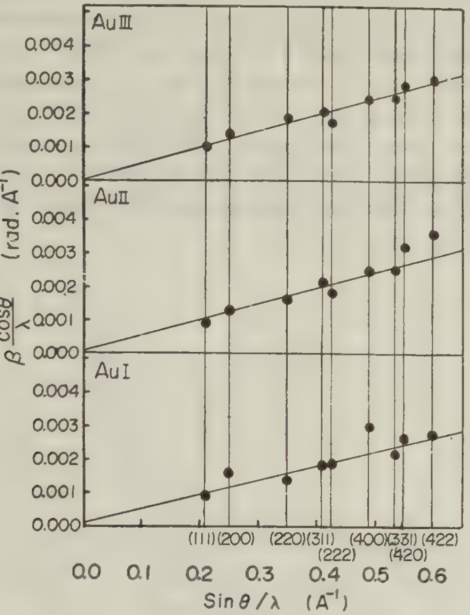

Fig. 1a.

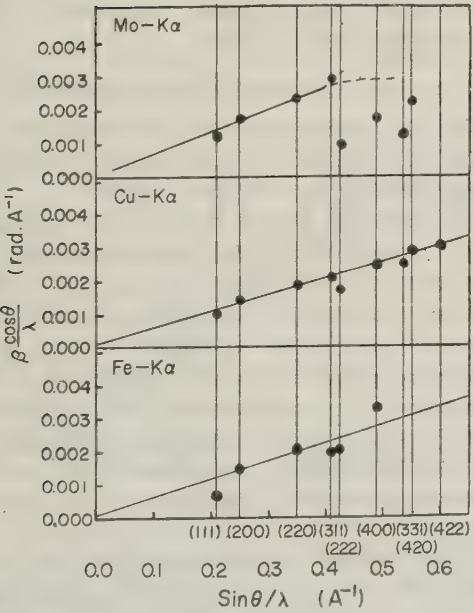

Fig. 1b.

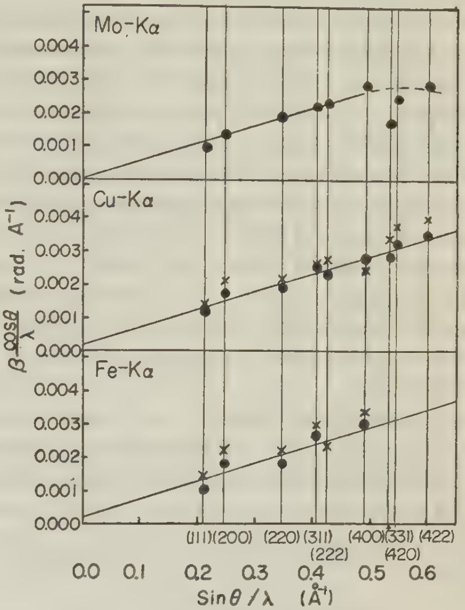

Fig. 1c.

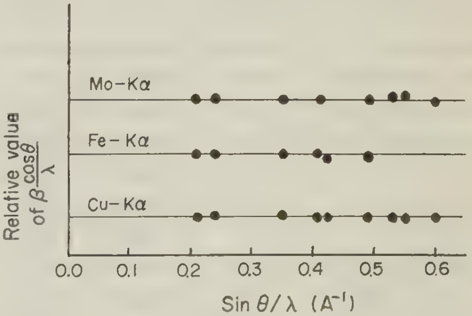

Fig. 1d.

Fig. 1. The angular dependence of line breadth.

a. Specimens, here, of gold polished under different conditions, show different slopes (CuKα).
b. The use of different radiations (FeKα, CuKα and MoKα) makes clear the distinction of slopes even for the same specimen, here Au II.
c. Ag II shows the same slopes for the cases of FeKα and CuKα. Solid circles correspond to breadths obtained by Jones' method and cross marks to breadths from the Fourier coefficients of line profile.
d. A well annealed specimen shows no angular dependence. An example is shown here for Ag II. The different values of $\beta \cos\vartheta/\lambda$ for different radiations shown in this figure has no significance.

cimens listed in Table I. Three different wavelengths were used for Ag II and Au II. The separation of a doublet was made by the Jones method[8], assuming the line breadth from an annealed specimen as an instrumental line breadth. Line breadth thus obtained was attempted to be plotted against both $\sin\vartheta/\lambda$ and $(\sin\vartheta/\lambda)^2$. The former plotting is shown in Fig. 1a, b and c. The angular dependence of line breadth from the annealed specimen is also shown in Fig. 1d with an arbitrary scale for breadth. Figs. 1a, b and c show that the linear relation of (13) or (18) is valid. With the use of (13) or (18) the magnitude of size and strain is obtained and listed in Table I.

It is found from Fig. 1 and Table I that Au II and Ag II show the different properties for strain variation. It is clearly shown for Au II from Fig. 1b and Table I that the observed value of strain decreases in the order of FeKα, CuKα and MoKα, while an effective penetration depth of radiations increases in the above order because of absorption. This implies that the magnitude of strain in Au II decreases with the depth. On the other hand, Fig. 1c and Table I show for Ag II that polishing influences more deeply than in Au and the variation of strain againt depth is much smaller than in Au II, since the uses of FeKα and CuKα show the almost same magnitudes of strain. The latter fact (no strain variation) is necessary for comparing the result from the line profile analysis with that from the line breadth analysis, as described in § 5.

Table I. Polishing conditions and magnitudes of size and strain.
(Line breadth method by (13))

Specimen number	Time of polishing	Mean size	Mean strain
Ag I	15 hrs.	4000 A	0.18%
Ag II (FeKα)	13	5000	0.16
Ag II (CuKα)	13	5000	0.16
Ag II (MoKα)	13	large	(0.13)
Ag III	8	4000	0.11
Ag IV	3	large	0.08
Au I	4	7000	0.11
Au II (FeKα)	8	7000	0.18
Au II (CuKα)	8	7000	0.12
Au II (MoKα)	8	large	(0.10)
Au III	10	7000	0.13

From the fact that line breadths depend linearly on $\sin\vartheta/\lambda$, the strain distribution can be expected to be either of a Cauchy type (case II) or of an exponential type (case III), even if the line profile like (17) corresponding to an exponential strain distribution could hardly be seen. It can be said in the present case without the use of the line profile analysis that the Cauchy distribution of strain is plausible, since the diffraction line profile has no steep decrease around the Bragg position as shown in Fig. 2*.

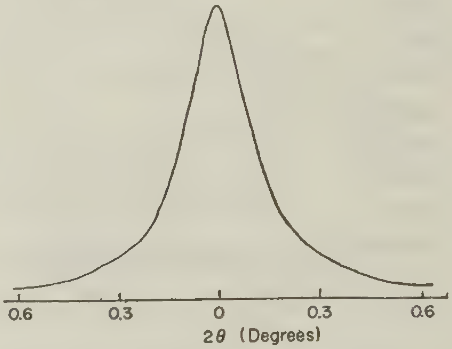

Fig. 2. An example of the pure diffraction profiles without an instrumental broadening. (220)-reflection of Ag II (FeKα).

§ 5. Fourier Analysis of Line Profiles

The line profile analysis is desirable to be made to examine the correctness of the results from the line breadth method.

The observed distribution of x-ray intensity is a convolution of the distribution due to instrumental broadening and that due to diffraction broadening[8]. According to the Stokes method[9], the Fourier coefficient of the pure diffraction profile can be obtained by electronic computer PC-1, assuming the line broadening from a well annealed specimen as an instrumental broadening. Imaginary part of a Fourier coefficient is negligible in the present results.

In the Fourier transformation of the line profile we cannot treat the line profile function as a continuous function extending over the infinite range. Practically we can only treat the Fourier synthesis confined to the definite range with discrete intervals. If $A(k)$ is the coefficient of the Fourier synthesis and $S(R_m)J(H, R_m)$ is abbreviated to $Y(H, R_m)$,

---

* Although Fig. 2 shows the pure diffraction profile without an instrumental broadening, the observed line shape can give the same information on this point, if an instrumental broadening is small.

$$\begin{aligned}A(k)&=\{M\Delta(2\vartheta)\cos\vartheta/\lambda\}^{-1}Y(\lambda k/M\Delta(2\vartheta)\cos\vartheta)\\&=\text{const.}\sum_{t=-\infty}^{+\infty}\sum_{m=-M}^{+M}I(2\vartheta)\exp\left[2\pi it\frac{m\Delta(2\vartheta)}{M\Delta(2\vartheta)}\right]\\&\quad\times\frac{\sin\pi M\Delta(2\vartheta)k-t}{\pi M\Delta(2\vartheta)k-t}\end{aligned}\tag{19}$$

where M is the number of division and $\Delta(2\vartheta)$ is the magnitude of a discrete interval. Here the large value of M is required in order to obtain a precise curve of $A(k)$ against k. M was taken to be 100, 120, 160 or 200. Calculation was performed by the electronic computer PC 1.

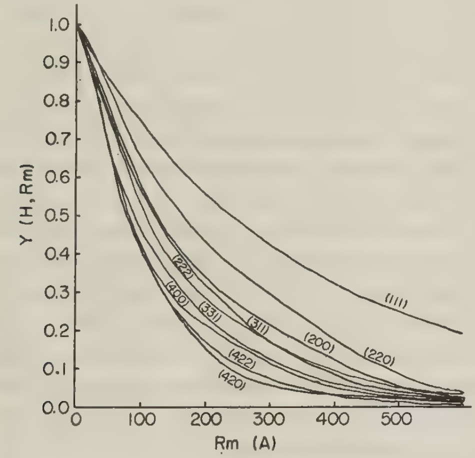

Fig. 3. An example of Fourier coefficients is shown for Ag II (CuKα).

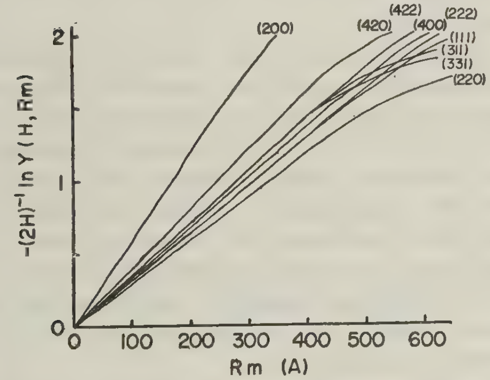

Fig. 4. Logarithmic plotting for Fourier coefficients in Fig. 3. The ordinate corresponds to the value of $-(2H)^{-1}\ln Y(H, R_m)$. (111) and (222) have the same slope, but (200) has the larger slope than (400) does.

In order to examine the correctness of the line breadth analysis, it is desirable that the line profile analysis is performed for the specimen in which strain does not vary to the large extent with the depth. Since Ag II specimen has little gradient of strain against depth as described in § 4, the Fourier coefficients for this specimen were, at first, obtained from line profiles observed by both FeKα and CuKα. Fourier coefficients obtained in the case of CuKα are plotted against R_m in Fig. 3. Moreover, $-(2H)^{-1}\ln Y(H, R_m)$ is plotted against R_m as shown in Fig. 4. The same plottings were performed for the case of FeKα. It is clear in Fig. 4 that a linear relation holds with a good approximation. This fact proves that $Y(H, R_m)$ can be expressed by the product of (9) and (11) and the strain distribution is of the Cauchy form. This result is the one expected from the line breadth analysis alone. In this case the slope of the straight line in Fig. 4 is equal to $(1/CH)+E$. Values for different reflections are listed in Table II. The magnitude of size *i.e.* C can be estimated in both Fig. 1 and Fig. 3. In Fig. 3 the fall-off of Fourier coefficients to zero determines the lower limit of size (a coherent size). This shows that $(1/CH)$ is much smaller than E. Estimated size value is also listed in Table II and shows no great difference from the value obtained by the line breadth analysis. The magnitude of strain $E/2$ is derived from the above values by the assumed C and seen also in Table II. The assumed value of C hardly effects the value of E. It is concluded that E is not seriously dependent on the crystallographic direction in this case. This conclusion also does not contradict the results in § 4.

In contrast with the above case, it is found in Ag IV that, although the Cauchy type distribution of strain is again obtained, the magnitudes of E obtained from the higher order reflections are smaller than those from low order ones, as shown in Table II. It is clear in this case that there is a gradient of strain against depth, because the mean penetrating depth of radiation increases as the scattering angle increases.

Such an effect would be also expected in the case of Au II, since the line breadth analysis in § 4 shows the decrease of the mean strain obtained by CuKα and MoKα com-

paring with that by FeKα.

Integral breadth can be also obtained from the Fourier coefficients and shown in Fig. 1b by a different mark.

§ 6. Discussions

a. *Size distribution function*

The physical meaning of the size distribution function $S(R_m)$ having the form of (9) is the following one: If the two adjacent cells have a probability $p(01)$ for appearing without regard to their locations, the product of structure factors for the two unit cells R_m distance apart is equal to $p(01)^m F_0^2$. For the crystal with an infinite dimension, $p(01)$ should be equal to 1, and for the crystal with a finite dimension $p(01)$ can be put $1-\alpha$. Then $p(01)^m$ becomes $\exp -\alpha m$ approximately. This is the form of (9).

b. *Strain distribution*

For the calculation in § 3, the assumption that $E(H, R_m)$ is independent on R_m, was adopted. If the magnitude of strain does not vary to a large extent at any positions within a crystallite, $E(H, R_m)$ can be replaced by $E(H, 0)$ within a certain range $R_m=0$ to R. On the other hand, $J(H, R_m)$ rapidly decreases as R_m decreases. It can be, therefore, said that this assumption is fairly good if $E(H, R_m)$ can be assumed to be constant where $J(H, R_m)$ is not so small. If the strain is taken to be 0.5% and $J(H, R)$ is 1/100, R is 120 spacings for the Gauss distribution of strain and 230 spacings for the Cauchy one. Since the above assumption is satisfied in the present case as shown in § 5, Hall's formula can be used for the line breadth.

c. *Linear relation of line breadth*

In the present experiment, every specimen of Au and Ag except the case of Mo radiation shows the validity of the linear relation for the line breadth. Judging only from this relation, there might be two possible strain distributions (case (II) and case (III)). The present line shape, however, has not a steep decrease around the scattering angle of $2\vartheta_H$. It thus can be found that the strain distribution is of a Cauchy type.

In the case of Mo radiation, the linear relation does not hold. This is attributed to the variation of the strain with the depth from a surface.

Results obtained from the line breadth analysis in § 4 were also assured by the line profile analysis in § 5 and have no room to be improved. It can be, therefore, concluded that the line breadth analysis can give not only the magnitudes of strain and size but also the distributions of strain and size. It might be, however, necessary to take into account the line shape if Hall's formula is valid, although the line profile like (17) could hardly be seen.

In the present case, the strain is nearly isotropic. If the strain is not isotropically uniform and Young's modulus in any direction is known, Hall's formula is also available, substituting [E/Young's modulus] in place of E.

On the other hand, it is noted that the line profile analysis method can give the information on the strain variation without the use of different radiations.

d. *Discussions for the polished state*

The results obtained in §4 and 5 shows that polishing gives the distortion not only in the shallow part but also in the deep part, and the magnitude of strain decreases slowly with the depth. Heavy polishing influences to the deeper part than light polishing does, as shown in Fig. 1a. These results support the view of the highly distorted state in the Beilly layer reported previously⁷⁾.

The author wishes to express his sincere thanks to Profs. H. Takahashi and E. Goto for allowing him to use the electronic computer PC-1 and to Mr. T. Sakurai for the use of programme. He is also grateful to Profs. S. Takagi, S. Hosoya and Mr. T. Suzuki for their kind discussion. This work was partly supported by a research grant of the Ministry of Education.

X-ray Measurement of the Scattering Factor of Iron in Ordered Fe$_3$Al

By Yukitomo KOMURA

Institute of Polytechnics, Osaka City University,

(Received April 26, 1960)

X-ray measurements on the absolute integrated intensities of several superlattice reflections on an ordered Fe$_3$Al single crystal were made to obtain an estimate of the number of localized 3*d* electrons in iron. The experiments were made with MoK_α radiation with a thin single crystal cut for transmission geometry, so as to avoid surface roughness effects. Extinction effects, minimized by restricting the measurements to the comparatively weak superlattice reflections, were estimated from a wavelength analysis of the integrated intensities. Finally, neutron analysis was used for obtaining a knowledge of the state of atomic ordering in the particular sample and for establishing the temperature factors of the iron and aluminum atoms. Calculations of the iron scattering factor from the final results show it to be in substantial agreement with that of the free iron atom (6 3*d* electrons). This is in agreement with the conclusions of Batterman2),3) and contrasts with the low number of 3*d* electrons given by Weiss and DeMarco1).

§1. Introduction

The number of localized 3*d* electrons in metallic iron has recently been the subject of some controversy. Weiss and DeMarco1) originally reported an unexpectedly low value of of (2.3±0.3) 3*d* electrons in iron. The method used by these authors was to determine the atomic scattering factor from the absolute intensities of Bragg reflections in single crystals of iron, suitably corrected for effects of extinction and surface roughness. To obtain an estimate for the number of 3*d* electrons, the calculated contribution of the argon core was subtracted from the measured absolute scattering factor. Following this work Batterman2),3) reported an atomic scattering factor for iron which was in substantial agreement with the free atom calculated by Freeman and Wood4), based on 6 3*d* electrons. This determination was based on an analysis of cold-worked powder samples which were thought free of extinction, surface roughness, and preferred orientation effects. Weiss and DeMarco5) thereupon repeated Batterman's procedure using the samples, but found once again a low number of 3*d* electrons in confirmation of their single crystal measurements.

As this problem is of some importance in the present theoretical discussions on the outer electron configuration in metallic iron, we have made single crystal measurements on ordered Fe$_3$Al, and have found the outer electron configuration of the iron atoms in this alloy to be close to that calculated for the free iron atom. Since the magnetic scattering data6) from the ordered Fe$_3$Al support the notion that no large difference in the 3*d* electron configuration is expected between the iron atoms in this ordered alloy and those in pure iron, our results can be considered to be in contrast with Weiss and DeMarco's conclusion. A preliminary note has already been reported7), and in this paper experimental procedures, measured data, and the results will be presented in detail.

§2. Method

The expression of the integrated reflection by a single crystal of thickness t in a transmission geometry as shown in Fig. 1 for monochromatized X-ray is given by[8)]

$$\frac{P}{I}=\left(\frac{Ne^2}{mc^2}\right)^2\frac{\lambda^3}{\mu}\frac{1+\cos^2 2\theta_M\cos^2 2\theta}{\sin 2\theta(1+\cos^2 2\theta_M)}F_{hkl}^2$$
$$\times\frac{\sec(\theta-\phi)}{\sec(\theta-\phi)-\sec(\theta+\phi)}$$
$$\times\{e^{-\mu t\sec(\theta+\phi)}-e^{-\mu t\sec(\theta-\phi)}\}, \qquad (1)$$

where P=total diffracted power (counts/sec.), I=power of the incident beam falling on the sample after reflecting by crystal monochromator, λ=wavelength, N=number of unit cells per unit volume, μ=linear absorption coefficient of the sample, θ=Bragg angle for a plane (hkl), θ_M=Bragg angle for the monochromator, F_{hkl}=structure factor and ϕ=angle between the reflecting plane and the normal to the surface of the sample. In this expression the normal to the surface lies in the plane formed by the incident and reflected beams.

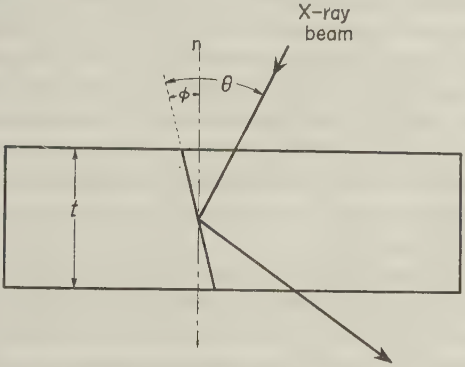

Fig. 1. Transmission geometry used in our measurements. ***n*** is the normal to the surface of the sample.

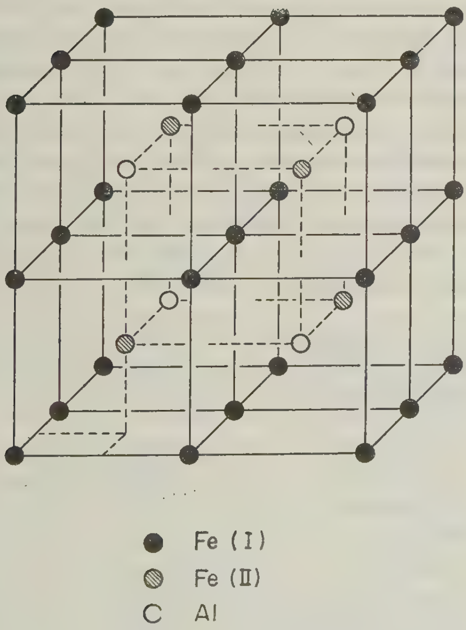

Fig. 2. Ordering arrangement in ordered Fe_3Al.

In the ordered structure of Fe_3Al shown in Fig. 2, F_{hkl}^2 of the superlattice reflections in Eq. (1) is given by

$$F_{hkl}^2=16S_{0,e}^2\left\{(f_{\mathrm{Fe}}^{Ar}+f_{\mathrm{Fe}}^{3d})\exp\left[-B_{\mathrm{Fe}}\left(\frac{\sin\theta}{\lambda}\right)^2\right]\right.$$
$$\left.-f_{\mathrm{Al}}\left[-B_{\mathrm{Al}}\left(\frac{\sin\theta}{\lambda}\right)^2\right]\right\}^2, \qquad (2)$$

where $S_{0,e}^2$=long-range order parameter, for odd and even reflections, f_{Fe}^{Ar}=contribution of the argon core, f_{Fe}^{3d}=contribution of the outer electrons in iron, f_{Al}=atomic scattering factor of alminum and B_{Fe}, B_{Al}=temperature factors of iron and aluminum atoms respectively.

There are two outstanding difficulties in a reflection geometry in estimating the precise absolute scattering factor from single crystal intensities; these are the corrections for extinction effects and surface roughness. In our experimental arrangement, the effect of the surface problem was avoided altogether by using a very thin crystal (t=0.0141 cm) in a transmission geometry. Further the use of superlattice reflections which are of low reflecting power, serves to reduce the extinction effects to the point of insignificance. Intensity measurements of the strongest of the superlattice reflections with two different wavelengths (i.e. MoK_α and its half wavelength) showed the extinction corrections to be negligible within ±3% accuracy of the measurements.

The use of the superlattice reflections has several other advantages over the use of the pure metal: (1) Since the amplitude of superlattice reflection is proportional to the difference between the scattering factor of iron and aluminum, as is seen from Eq. (2), the effect of $3d$ electron contribution on the measured intensities is enhanced. That is, there is a partial cancellation of the argon core contribution by the aluminum. (2) The number of allowed reflections in the Fe_3Al structure is greater in the angular region of interest than that of pure iron as we see in Table

I. Thus, in addition to offering more detailed information on the 3*d* electron distribution, this also permits an intercomparison between different peaks and hence a check on the experimental method.

There are, however, some disadvantages in using an ordered alloy as opposed to the pure iron. It is now necessary to establish the long-range order parameter S^2, as well as to obtain some estimate of the individual temperature factors for the iron and aluminum atoms. Further some assumptions must be made as to the magnitude of f_{Al}. A neutron diffraction study of the same single crystal examined with X-rays has provided this information. The considerations regarding f_{Al} will be discussed in a later section.

§ 3. Experimental

(1) *General considerations*

Absolute intensity measurements were made at room temperature on an ordered Fe_3Al sample by utilizing a Bragg-type spectrometer, the ionization chamber being replaced by a NaI-scintillation counter. On a Norelco X-ray unit, monochromatic MoK_α radiation was scattered from a flat lithium fluoride monochromator. The tube voltage for the measurements was 30 kV in order to eliminate the half wavelength. A pulse height analyzer was used to discriminate against unwanted radiation.

The ordered Fe_3Al sample was made available for us by courtesy of Professor Chikazumi at University of Tokyo. The shape of the specimen was a disk, 0.8 cm in diameter with a thickness of 0.0141 cm. The composition of the specimen was 76 at. % Fe and 24 at. % Al. The specimen was annealed at 800°C, cooled down to 650°C in the furnace and slowly cooled to 300°C at a rate of 0.1°C/min., then allowed to cool down to room temperature. The specimen was then treated by electropolishing. Checks were made for the existence of other phases such as Fe_3AlC[9] by taking Laue and Weissenberg photographs. The surface of the specimen was 10.0° off from (110) so that the angle ϕ in Eq. (1) was equal to 10° for the reflecting plane (001). ϕ's for other planes can be calculated easily by a simple geometry.

Linear absorption coefficient μ of the sample was determined from the attenuation of the incident beam passing through the sample, since tabulated values were found to be unsatisfactory. The uniformity of the thickness of the sample was checked at the same time. The power of the incident beam was measured directly by placing several absorbers with predetermined transmission factors in the beam to reduce the counting rate to manageable proportions.

In taking data for integrated intensities the specimen was rotated manually through a position of Bragg reflections at increments of of 2.5′ step by step, while counter was rotated at the same increment taking counting rate by a fixed counting method. The area beneath the rocking curve thus obtained gave the total diffracted power P after subtracting of the background. This was estimated at points beyond the tails of the peak. For the above condition, the window of the scintillation counter was wide enough so as to detect the entire diffracted beam. The Hönl corrections were taken from the tabulation given by James[10] and that of Dauben and Templeton[11], both values giving no significant difference at least for the lower order reflections. The

parameters used to calculate the atomic scattering factor from the intensity data are given in Table II.

(2) *Determination of the order parameter and the temperature factors*

As we mentioned earlier, the long-range order parameter S^2 and the temperature factors B_{Fe} and B_{Al} (cf. Eq. (2)), must be known in order to obtain atomic scattering factors from observed intensities.

Structure factors of ordered $\mathrm{Fe_3Al}$ structure for unpolarized neutron beam are given as follows:

$$^{N}F^2_{hkl}(f)=16\left\{3b_{\mathrm{Fe}}\exp\left[-B_{\mathrm{Fe}}\left(\frac{\sin\theta}{\lambda}\right)^2\right]+b_{\mathrm{Al}}\exp\left[-B_{\mathrm{Al}}\left(\frac{\sin\theta}{\lambda}\right)^2\right]\right\}^2 \quad (3)$$

for fundamental reflections (such as (220), (400), (440), (800)), and

$$^{N}F^2_{hkl}(s)=16S^2_{0,e}\left\{b_{\mathrm{Fe}}\exp\left[-B_{\mathrm{Fe}}\left(\frac{\sin\theta}{\lambda}\right)^2\right]-b_{\mathrm{Al}}\exp\left[-B_{\mathrm{Al}}\left(\frac{\sin\theta}{\lambda}\right)^2\right]\right\}^2 \quad (4)$$

for supperlattice reflections (such as (111), (222), (311), (511)), where b_{Fe} and b_{Al} are the nuclear scattering amplitudes for neutrons for iron and aluminum atoms.

Regarding the temperature factors B_{Fe} and B_{Al}, the values were taken as consistent with the fall off of the neutron-diffraction intensities of the fundamental and superlattice reflections with $(\sin\theta/\lambda)^2$. The value of B_{Fe} can be obtained by the ratio of the fundamental lines, assuming the difference between two temperature factors being small as a first approximation. The ratios I_{440}/I_{220} and I_{400}/I_{800} gave the value $B_{\mathrm{Fe}}=0.35$. The above assumption was supported by a fact that I_{511}/I_{400} gave a value of S^2 which was not much different from that obtained from I_{111}/I_{400} using same temperature factor for iron and aluminum. The value of B_{Al} was then estimated based on the ratio of the superlattice reflections, such as I_{511}/I_{111}, and came out to be approximately 0.45 which was nearly half of that in metallic aluminum. It should be mentioned that small extinction effects observed for (220) and (400) were corrected using a polarized neutron beam technique.

Knowing the nuclear scattering amplitudes and the temperature factors for iron and aluminum, the ratio of superlattice reflection to fundamental reflection (Eq. (4) to (3)) gives directly the order parameter S^2. Since there are two sets of order parameters for odd and even superlattice reflections, they were evaluated by the ratios I_{111}/I_{220}, I_{111}/I_{400}, I_{511}/I_{220}, I_{511}/I_{400} and I_{200}/I_{220}, I_{200}/I_{400}, I_{222}/I_{220}, I_{222}/I_{400}. The values of S^2 calculated from these ratios were approximately consistent with each other. There was no evidence within the experimental accuracy to suggest that S^2 from the (200) reflections was significantly different from the (111) reflections, therefore we have used the same value of $S^2=0.75\pm0.03$ for both even and odd reflections.

(3) *Results*

A list of the observed F^2_{obs} values for the first five superlattice reflections is given in Table III. These F^2_{obs} are determined in such a way that the values of F^2 obtained from Eq. (1) by X-ray measurements are divided by $S^2=0.75$, so that F^2_{obs} are independent of the order parameter S^2 (cf. Eq. (2)). The uncertainties given for the F^2_{obs} in Table III represent the overall standard deviations in X-ray and neutron measurements. Also given are the F^2_{calc} values calculated from Freeman and Wood's free-atom scattering factor (six 3*d* electrons) and those based on Weiss and DeMarco's results (2.3 3*d* electrons). The calculated values have been corrected for temperature effects using $B_{\mathrm{Fe}}=0.35$, $B_{\mathrm{Al}}=0.45$ and assuming that the argon core contribution is the same as in the free atom. Because of the lack of the precise knowledge for the electronic states of aluminum in this alloy, we have used calculated atomic scattering factors for aluminum with different ionized states[12] for the calculated F^2_{calc} value of (111) and (200). At the (311) reflection and beyond no practical differences of F^2_{calc} are found for the different states of ionization of aluminum.

The results of Table III show that the scattering factor of iron in ordered $\mathrm{Fe_3Al}$ agrees closely with that for the free atom calculated by the self-consistent field wave functions. We have calculated the number of effective 3*d* electrons of iron using Eq. (2), which came out to be 5.0 ± 1.0 electrons.

In Fig. 3, theoretical curve for five 3*d* electrons (solid curve) and for 2.3 3*d* electrons (dotted curve) are shown. The observed

values are indicated along with the estimated experimental errors.

§ 4. Discussions

Since F^2_{calc} for (111) and (200) have uncertainties with respect to the electronic state of aluminum, the (311) and (222) reflections are the critical ones to compare with the calculated values. These two reflections have values of $\sin\theta/\lambda$ near the (110) reflection of pure iron (0.247) which was the essential reflection of Weiss and DeMarco's experiments. Correction of temperature effect for these reflections is small, as these are reflections at such a low Bragg angle. Therefore the calculated F^2 values are not very sensitive to the errors introduced in B_{Fe} and B_{Al} obtained from the neutron analysis.

The difference between the number of $3d$ electrons obtained by us and that calculated for the free iron atom lies within the experimental errors, while the discrepancy between our results and those calculated from the Weiss and DeMarco's estimate of 2.3 $3d$ electrons (more than 25%) is quite evident. It appears unlikely that any combination of errors would make such a large deviation.

There is a question in making a measurement on ordered Fe_3Al as to whether the scattering factor of iron in this alloy differs from that of pure iron. In the ordered state of Fe_3Al two types of iron atoms are present with respect to the nearest neighbor environment (cf. Fig. 2). A neutron diffraction study by Nathans, Pigott and Shull[6] showed that the average magnetic moment per atom at room temperature was 1.46 μ_B for the iron atoms (Fe(I) in Fig. 2) having 4 Fe and 4 Al as nearest neighbors. For the other type of iron atoms (Fe(II) in Fig. 2) surrounded by 8 Fe atoms, the observed average moment was 2.14 μ_B which was close to the value, 2.2 μ_B, observed in metallic iron. The interpretation of these results can proceed along three directions: (1) According to the suggestion of Sato and Arrott[13], the two iron sublattices can be considered as in different states of magnetic saturation at room temperature. In this case, no large difference in the $3d$ electron configuration is expected, at least in the number of localized $3d$ electrons. (2) We may invoke the recent theoretical arguments of Goodenough[14] in which the low moment of the one iron sublattice is explained by putting a fraction of the iron atoms on this sublattice antiparallel to the majority of atoms—a sort of ferrimagnetism. Again since no intrinsic change in the moment of the iron atoms is assumed, $3d$ electron configuration is not expected to be different. (3) We may assume that there is an electron transfer between the iron and aluminum atoms which lowers the intrinsic moment per iron atom. If this is true then a difference in the number of $3d$ electrons in pure iron and in the iron atoms in Fe_3Al would be possible. However, the accurate measurement of the shape of the magnetic form factor in ordered Fe_3Al and in metallic iron showed no large difference between the form factors for two iron sites in ordered Fe_3Al and that found in the pure iron metal was observed.

The authors wish to thank Professor S. Chikazumi of University of Tokyo for providing us with the Fe_3Al single crystal. We would also like to acknowledge the Rigaku-Denki Co., Ltd. for the courtesy to accomodate us with counter instruments. We are particularly indebted to Professors I. Nitta, T. Watanabé, T. Nagamiya of Osaka University and J. Kakinoki of Osaka City University for their stimulating discussions and encouragement on these experiments. Two of the authors (Y.K. and Y.T.) wish to thank the Ministry of Education for the Research Grant.

The Photoionization of H_2 and the Spatial Correlation between Electrons

By Mikio SHIMIZU*

Department of Physics, University of Tokyo

(Received September 23, 1959)

The photoionization of H_2 by photons of sufficiently short wave length produces the molecular ion H_2^+ as well as the atomic ion H^+. The relative yield H^+/H_2^+ has been calculated as the function of energies of photons. The description of the ground state of H_2 is given by the superpositon of two configurations: $\sigma_g^2+\lambda\sigma_u^2$, taking account of the spatial correlation between electrons, while those of H_2^+ by the linear combinations of Wang type atomic orbitals. The results show that the relative yield curve has a plateau in the high-energy range and its height is essentially proportional to λ^2. The various approximations used in our calculation (Franck Condon approximation, Born approximation, dipole velocity approximation, the neglect of possibility of production of H_2^+ and H^+ through autoionization and multiple ionization etc.) have been carefully discussed. The velocity distribution of the ejected protons has also been calculated according to the Franck Condon principle.

§ 1. Introduction

It is well known that the electron bombardment on hydrogen molecules produces the molecular ion H_2^+ as well as the atomic ion H^+. Hence it can be expected that these ions will be produced by the irradiation with photons of sufficiently short wave length as well. Now the production of H_2^+ mostly occurs through the excitation of the molecule from the ground state ${}^1\Sigma_g^+$ to that of molecular ion ${}^2\Sigma_g$, while that of H^+ is made possible through ionization to its repulsive, first excited state, ${}^2\Sigma_u$. The single electrons left in ${}^2\Sigma_g$ and ${}^2\Sigma_u$ have wave functions of σ_g and σ_u type respectively. On the other hand, the ground state ${}^1\Sigma_g^+$ is most simply described as σ_g^2. If this description were exact, ${}^2\Sigma_u$ state could not be reached by single-electron jump from ${}^1\Sigma_g^+$, and the production of H^+ could hardly be expected. A more refined description of ${}^1\Sigma_g^+$ state is given, however, by a superposition of two configurations: $\sigma_g^2+\lambda\sigma_u^2$. Hence the relative yield of H_2^+ and H^+ will give us some information about the magnitude of λ. We shall show later that the curve of the ratio H^+/H_2^+ as a function of photon energies has a plateau in the region of high energies and that its height is essentially proportional to λ^2.

The aspect which has been discussed in the case of the hydrogen molecule will be similarly applicable to the other molecules. The mixing of antibonding orbitals with bonding ones due to the Coulomb repulsion between two bonding electrons may correlate with the composition of ionization products. Hence we can expect that, if the ionization phenomena are investigated experimentally in such a manner described in this paper, we shall be able to obtain further knowledge about the electronic structure of various molecules. Further we may expect that such a calculation gives a fundamental basis to the research for the effects of high energy radiation on the polymers.

In this paper, we are only concerned with the region of high energies of photons, because we find some difficulties in the treatment of the motion of a slow electron in the field of a molecular ion. We shall discuss the effect of the distorsion due to the field of a molecular ion in the photoionization process ${}^1\Sigma_g^+\rightarrow{}^2\Sigma_g$ in the following paper.

The atomic untits have been adopted throughout this paper.

§ 2. Calculation of the Relative Yield

Fig. 1 illustrates the potential-energy curves for some electronic states of the hydrogen molecule and of the hydrogen molecular ion. As can be seen from the figure, the production of the two kinds of ions, H_2^+ and H^+, by irradiation with photons of sufficiently short wave length is possible through many processes. Of these processes concerned, however, the transition to the lowest, ${}^2\Sigma_g$, state of the H_2^+ ion and that to the repulsive, ${}^2\Sigma_u$, state of the same ion are most important. These ions can be produced also through the jumps to the highly excited states of H_2^+. Still another way of their production is through the autoionization from some excited states of H_2 to unstable states of H_2^+. For simplicity, however, we shall neglect these processes except the first two transitions for the time being. Further discussions on this point will be seen in the next section. Under such an assumption, the relative yield H^+/H_2^+ will be determined by the ratio of the transition probability of the process ${}^1\Sigma_g^+ \rightarrow {}^2\Sigma_u$, to that of the process ${}^1\Sigma_g^+ \rightarrow {}^2\Sigma_g$.

---

* Present address: Department of Physics, Ochanomizu University, Tokyo.

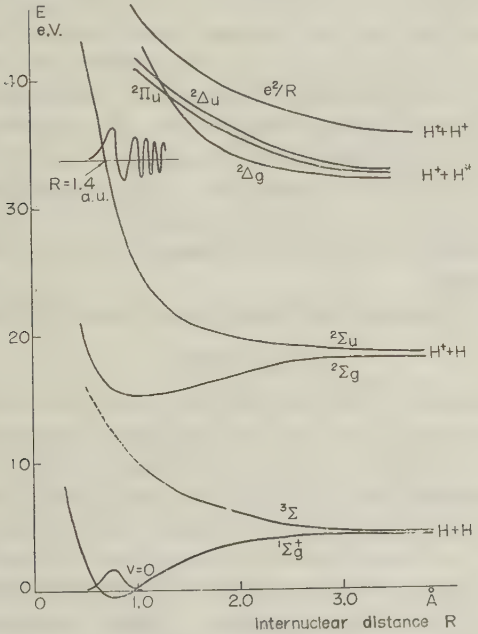

Fig. 1. Potential curves of some states of H_2 and H_2^+.

The states of the total system can be written as

$$\psi = \psi_e(\boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{R}) \frac{\psi_v(R)}{R} , \qquad (1)$$

where ψ_e is the wave function for the electronic state and ψ_v/R is that of the vibrational one, $\boldsymbol{r}_1$ and $\boldsymbol{r}_2$ being the electronic coordinates, $\boldsymbol{R}$ the internuclear distance vector, and R the absolute value of $\boldsymbol{R}$ respectively. Hereafter the excited states will be denoted as ψ_e' etc.. The interaction operator is

$$H' = -\frac{i}{c} \sum_i \boldsymbol{P}_i \cdot \boldsymbol{A}(i) , \qquad (2)$$

where $\boldsymbol{A}(i)$ is the vector potential of the electromagnetic wave, and $\boldsymbol{P}_i$ the momentum operator of each particle. Then the transition probability is given by

$$\frac{1}{2} \sum_v \sum_{v'} N e^{-\varepsilon_v/kT} \sum_j \int d\Omega \int \frac{d\omega}{4\pi} \left| \int \psi_{e'}^* \frac{\psi_{v'}}{R} H' \psi_e \frac{\psi_v}{R} d\tau_e d\tau_R \right|^2 \rho(E) , \qquad (3)$$

where $\sum_v N e^{-\varepsilon_v/kT}$ means the average over the initial vibrational states, $\sum_{v'}$ the sum over the final vibrational states, $1/2 \sum_j$ the average over the polarization of the incident photons, $\int d\Omega$ the sum over the direction of the ejected electron, $1/4\pi \int d\omega$ the average over the direction of the incident photons, and $\rho(E)$ the state density of the ejected electron respectively. In the usual experimental temperatures, we have only to consider the lowest vibrational state $v=0$ for ψ_v, while for $\psi_{v'}$ we must consider various vibrational states.

It is difficult to calculate the transition amplitude

$$\int \psi_{e'}^* \frac{\psi_{v'}^*}{R} H' \psi_e \frac{\psi_v}{R} d\tau_e d\tau_R$$

exactly. So we shall introduce here the following approximations. The integral

$$M = \int \psi_{e'}^* H' \psi_e d\tau_e$$

is a slowly varying function of the internuclear distance R, compared with ψ_v and $\psi_{v'}$. Thus we replace it by the value evaluated at the equilibrium distance R_0 of the ground state of H_2, taking account of the form of ψ_v for $v=0$. Then the transition amplitude becomes

$$4\pi \left(\int \psi_{e'}^* H' \psi_e \, d\tau \right)_{R=R_0} \int \psi_{v'}^* \psi_v dR ,$$

which corresponds to the Franck Condon principle[1]. Further, due to the orthonormality of $\psi_{v'}$, we have

$$\sum_{v'} \left| \int \psi_{v'}^* \psi_v dR \right|^2 = 1 . \qquad (4)$$

Hence only the electronic part of transition amplitude will be taken into account later.

The electronic wave function ψ_e for H_2 is described in the form

$$\frac{\sigma_g^2+\lambda\sigma_u^2}{\sqrt{1+\lambda^2}}\,. \tag{5}$$

This approximation means that we have partly taken account of the spatial correlation between two electrons which cannot be expressed by the simple molecular orbital description σ_g^2. This description is equivalent to that by Coulson and Fischer[2], the semilocalized orbital scheme, and that by Weinbaum[3], the mixing of ionic states in Heitler London treatment.

The importance of the configuration interaction in the calculation of the molecular energies has been stressed by many authors. This is also true for the calculation of the electronic transition probabilities[4]. In our problem, as we have stated in the previous section, the production of atomic ion H^+ can be hardly expected without the use of this description.

Wave functions for the final states, in which the ion is left in ${}^2\Sigma_g$ and ${}^2\Sigma_u$ are

$$\psi_{e'}\propto\begin{cases}\sigma_{g'}(1)f(2)+\sigma_{g'}(2)f(1)\,,\\ \sigma_{u'}(1)f(2)+\sigma_{u'}(2)f(1)\,,\end{cases} \tag{6}$$

respectively without normalization, f denoting the wave functions of the ejected electrons.

The orbitals σ_g and $\sigma_{g'}$ are approximated as linear combinations of ls type atomic orbitals with appropriate effective charges Z and Z', and similarly with Z and Z'' for σ_u and $\sigma_{u'}$ orbitals. Z and λ are obtained from the result of the calculation by Weinbaum[3]:

$$Z=1.193 \quad \text{and} \quad \lambda=-0.113\,.$$

We calculated Z' and Z'' by the variational method, fixing the nuclear distance at $R_0=1.4$, i. e., the equilibrium internuclear distance of H_2, in accord with the Franck Condon principle. The results are

$$Z'=1.386 \quad \text{and} \quad Z''=0.773\,.$$

Comparing Z' with the effective charge $Z=1.288$ determined at the equilibrium internuclear distance of H_2^+,[5] we can see that Z' becomes a little larger, which means the shrinking of the wave function to the central region. Z'', the effective charge of a repulsive state, is far smaller than those of the stable states.

Bates et al. have calculated the transition probabilities between various states of H_2^+ and HeH^{2+} using the exact wave functions and some approximate ones[6]. According to them, the accuracy of a calculation of this type depends rather sensitively on the way of approximations. In respect of this, our approximate functions are not so satisfactory one. But, as no calculation seems to have ever been carried out about the ionization of the hydrogen molecules, we believe that the calculation even in such an approximation has still some meaning.

As the next step of simplification, we shall approximate the wave functions of the ejected electron, $f(r)$, by plane waves (Born approximation). The plane waves for the ${}^2\Sigma_g$ case and that for the ${}^2\Sigma_u$ case differ only in the magnitude of their wave number vectors, which we call hereafter $\boldsymbol{k}_1$ and $\boldsymbol{k}_2$ respectively. In the photoionization, almost all the energy of the absorbed light quantum is consumed for ejecting an electron. Thus this approximation may be fairly reasonable. The state density $\rho(E)$ is also calculated in this approximation.

The exponential factor in the vector potential

$$\boldsymbol{A}=\exp(i\boldsymbol{q}\cdot\boldsymbol{r})\boldsymbol{e}\,,$$

where $\boldsymbol{q}$ is the propagation vector and $\boldsymbol{e}$ the polarization vector, can be approximated by unity (dipole velocity approximation) for the photons with the wave lengths longer than several Å. The dipole length approximation is not suitable for our calculation because of the lack of orthogonality of the initial and the final wave functions. When we used it, the transition amplitude would come to depend on the choice of the origin of coordinates.

Then the calculation of the transition probabilities is made straightforwardly using the spherical wave expansion of the plane waves and the Coulson integrals[7]. By referring to the coordinate system fixed in the molecule, and by taking the molecular axis as z axis, the vector components of transition amplitudes are expressed as proportional to

$$\left.\begin{aligned}&\int\sigma_g P_x f_{k_1}d\tau\int\sigma_g\sigma_{g'}d\tau\,,\\ &\int\sigma_g P_y f_{k_1}d\tau\int\sigma_g\sigma_{g'}d\tau\,,\\ &\int\sigma_g P_z f_{k_1}d\tau\int\sigma_g\sigma_{g'}d\tau+\lambda\int\sigma_u P_z\sigma_{g'}\,d\tau\int\sigma_u f_{k_1}d\tau\,,\end{aligned}\right\} \tag{7}$$

for H_2^+, and

$$\left.\begin{aligned}&\lambda\int\sigma_u P_x f_{k_2} d\tau \int\sigma_u\sigma_{u'} d\tau\ ,\\&\lambda\int\sigma_u P_y f_{k_2} d\tau \int\sigma_u\sigma_{u'} d\tau\ ,\\&\lambda\int\sigma_u P_z f_{k_2} d\tau \int\sigma_u\sigma_{u'} d\tau + \int\sigma_g P_z \sigma_{u'} d\tau \int\sigma_g f_{k_2} d\tau\ ,\end{aligned}\right\} \tag{8}$$

for H^+ respectively. The second terms in each z component represent the indirect transitions through the overlap between f and σ_g or σ_u. The result of the numerical calculation will show that the contribution from these terms is, as can be expected, far smaller than that from the direct transitions explained in the previous section.

After averaging over the polarization and over the direction of the photon, and finally integrating over the direction of the ejected electron, we have obtained the relative yield H^+/H_2^+ as

$$\frac{k_2{}^3\mathrm{I}^2(k_2)\left\{\lambda^2 k_2{}^2\dfrac{\varDelta^2_{uu'}}{1-S}\left(1-\dfrac{\sin k_2R_0}{k_2R_0}\right)+\lambda A+C\right\}}{k_1{}^3\mathrm{I}^2(k_1)\left\{k_1{}^2\dfrac{\varDelta^2_{gg'}}{1+S}\left(1+\dfrac{\sin k_1R_0}{k_1R_0}\right)-\lambda B+\lambda^2 D\right\}}\ , \tag{9}$$

where

$$A=\frac{4Z''J_6(Z'',Z,R_0)k_2\varDelta_{uu'}}{2\pi}j_2(k_2R_0)\sqrt{\frac{Z^3Z''^3}{(1+S)^2(1-S)(1-S'')}}\ , \tag{10}$$

$$B=\frac{4Z'J_6(Z',Z,R_0)k_1\varDelta_{gg'}}{2\pi}j_2(k_1R_0)\sqrt{\frac{Z^3Z'^3}{(1-S)^2(1+S)(1+S')}}\ , \tag{11}$$

$$C=\frac{Z^3Z''^4J_6{}^2(Z'',Z,R_0)}{\pi^2(1+S)^2(1-S'')}\left(1+\frac{\sin k_2R_0}{k_2R_0}\right), \tag{12}$$

and

$$D=\frac{Z^3Z'^4J_6{}^2(Z',Z,R_0)}{\pi^2(1-S)^2(1+S')}\left(1-\frac{\sin k_1R_0}{k_1R_0}\right). \tag{13}$$

The meaning of notations is as follows: S, S' and S'' are the overlap integrals $\int\varphi_a\varphi_b d\tau$ where φ_a is 1s type atomic orbitals around the nucleus, say a, with effective charges Z, Z' and Z'' respectively. $\varDelta_{gg'}$ and $\varDelta_{uu'}$ are $\int\sigma_g\sigma_{g'}d\tau$ and $\int\sigma_u\sigma_{u'}d\tau$ respectively. $\mathrm{I}(k)=\dfrac{2Z}{k(k^2+Z^2)}$, j_2 is the spherical Bessel function of the second order and J_6 is the Coulson integral in his notation.

When the wave length of photons is very short, the dipole approximation becomes bad and the calculation of the indirect transition amplitude becomes difficult. But, taking account of the fact that the contribution from the indirect transitions decreases as $k\to\infty$, we may safely neglect these terms. Then, in the limit of short wave length, we need not use the dipole approximation and the relative yield is essentially represented as follows:

$$\frac{\varDelta^2_{uu'}}{\varDelta^2_{gg'}}\cdot\frac{1+S}{1+S}\lambda^2\ . \tag{14}$$

This conclusion is, however, valid subject to the condition that Compton scattering is negligible, which, in reality, sets in as the wave length gets shorter than about 1Å.

The numerical calculations have been carried out for the wave lengths of photons 60Å, 20Å, 10Å and the short wave limit $\nu/c\to\infty$. The resulting relative yields are

$$\begin{aligned}&4.98\lambda^2 &&\text{for}\quad \nu/c\to\infty\\&\left.\begin{aligned}&\frac{0.156+0.330\lambda+262\lambda^2}{55.9-0.666\lambda+0.149\lambda^2} &&\frac{c}{\nu}=10\text{Å}\ ,\\&\frac{0.185-1.12\lambda+154\lambda^2}{26.5+0.972\lambda+0.147\lambda^2} &&\frac{c}{\nu}=20\text{Å}\ ,\\&\frac{0.212-0.597\lambda+63.8\lambda^2}{6.97-0.653\lambda+0.14\lambda^2} &&\frac{c}{\nu}=60\text{Å}\ ,\end{aligned}\right\}\end{aligned} \tag{15}$$

without inserting the numerical value in λ. Further the numerical values of the relative yields are tabulated in Table 1 for a special

Table 1. The calculated relative yield.

Wave length	$(c/\nu)\to 0$	10Å	20Å	60Å
H^+/H_2^+ (%)	6.37	6.18	7.36	12.96

value of $\lambda=-0.113$.

We can see from the above results that the yield curve has a plateau in the high-energy range and that the height of the plateau depends on the value of λ sensitively, namely, it is essentially proportional to λ^2.

The value of the relative yield for $c/\nu=60$Å is unexpectedly larger than the others. This is partly due to the approximations employed in our calculation, particularly the Born approximation for $f(r)$ and the LCAO approximations for σ_g's and σ_u's. We shall show later that the wave function of the ejected electron is considerably distorted in this energy range by the long range Coulomb force. The invalidity of the LCAO approximations is suggested from the large contribution of the indirect transitions which is expected to be small in the exact treatment.

Finally, we shall investigate how much the relative yield changes when we adopt the linear combinations of s–p hybridized atomic orbitals for σ_g's and σ_u's. The assumed forms for the electronic wave functions are, for ${}^1\Sigma_g{}^+$,

$$\psi_e=\tilde{\sigma}_g(1)\tilde{\sigma}_g(2)+\mu\tilde{\sigma}_u(1)\tilde{\sigma}_u(2)\ , \tag{16}$$

where

$$\tilde{\sigma}_g=(\varphi^a_{1s}+\nu\varphi^a_{2p\sigma})+(\varphi^b_{1s}+\nu\varphi^b_{2p\sigma})\ ,$$

and

$$\tilde{\sigma}_u=(\varphi^a_{1s}+\nu\varphi^a_{2p\sigma})-(\varphi^b_{1s}+\nu\varphi^b_{2p\sigma})\ ,$$

φ^a_{1s} and $\varphi^a_{2p\sigma}$ being $1s$ and $2p\sigma$ atomic functions around one nucleus, say a, with a common effective charge Z. Similar expressions are used for $\sigma_{g'}$ and $\sigma_{u'}$ with ν', Z' and ν'', Z'' respectively. The parameters in ψ_e are obtained by transforming the calculated values by Weinbaum[3)], while those in $\psi_{e'}$ are calculated using the variational method, the internuclear distances being fixed at R_0. Those are

$$Z=1.190\ ,\quad \mu=-0.100\ ,\quad \nu=0.07\ ,$$
$$Z'=1.3979\ ,\qquad \nu'=0.1573\ ,$$
$$Z''=1.0438\ ,\qquad \nu''=-0.3312\ .$$

The calculation has been carried out only for the short wave length limit. The results are $6.64\,\mu^2$ or 6.64%, which is very close to the previous value.

The experimental data with which these theoretical results are to be compared are not yet available. The experiments for photoionization phenomena have been carried out rather for photons of wave lengths more than 500Å. In this energy range, however, some of our approximations may be invalid. The distortion of the wave of an ejected electron must be taken explicitly into account and the higher accuracy will be required in the functional form of the molecular orbitals.

It is interesting to see the experimental results about the ionization of H_2 by electron impact. We, of course, cannot compare the theoretical results for light quanta directly with this experiment. But, as is well known, the electromagnetic field around an electron with high velocity is quite similar to that of light quanta. Thus we may expect that the relative yield curves in these two cases behave in a similar manner in the high-energy range. Bleakney measured the curve up to the electron energy 600 eV by use of a mass-spectrograph[8)], of which the results were reported in detail on the survey by Smyth[9)]. According to his result, the curve has a plateau in the high-energy range, and its height is about 7%. Later Newhall pointed out a defect of this experiment and measured again the relative yield curve up to the electron energy 180 eV by another mass-spectrographic method[10)]. His results are quite different from those by Bleakney; the curve increases throughout the investigated energies and the height at 180 eV is only about 0.5%. Unfortunately his experiment is restricted in too low electron energies. Thus we cannot obtain a decisive conclusion from the electron impact data yet.

§ 3. Discussions on the used Approximations

In the previous section we have calculated the relative yield of two kinds of ions H^+ and H_2^+ which are produced through the ionization of the hydrogen molecules by the irradiation of photons of short wave length, using some approximations. In this section, we shall try to discuss the accuracy of these approximations used and the effects of other ionization processes which we have not taken into account.

3.1. *Franck Condon Approximation*

We have separated the wave function of hydrogen molecule into the electronic and the vibrational parts according to the Franck

Condon principle[1]. Thus the transition amplitude is approximated by

$$\int \psi_{e'}{}^* \frac{\psi_{v'}{}^*}{R} H' \psi_e \frac{\psi_v{}^*}{R} d\tau_e d\tau_R$$
$$\sim 4\pi \left(\int \psi_{e'}{}^* H' \psi_e d\tau_e \right)_{R=R_0} \int \psi_{v'}{}^* \psi_v dR \ . \quad (17)$$

In this approximation, we have only to calculate the overlap integrals to obtain the transition probabilities from the lowest vibrational state in the electronic ground state of H_2 to the vibrational states v' of an upper electronic state. Of course, such an approximation will be admitted when the variation of these electronic integrals with the nuclear distance R is sufficiently small. But it is rather troublesome to show it directly from the calculation. Thus we shall calculate the vibrational transition probabilities under this assumption and derive the velocity distributions of ejected protons and electrons. Then, by comparing them with experimental data when available, a necessary condition for the validity of the approximation will be obtained.

As for the electrons, they will be ejected from ions with the energy $h\nu - E({}^2\Sigma_g \text{ or } {}^2\Sigma_u; v') + E({}^1\Sigma_g{}^+; 0)$, but the measurement of this velocity distribution seems to be difficult. That of protons which are produced through the jump to either continuous states of ${}^2\Sigma_g$ or repulsive ${}^2\Sigma_u$ state are more tractable. On account of the large masses of the ions, their initial velocities may be negligible. Then, the kinetic energies of the ejected protons are half the differences of energies $E_c - E_\infty$, where E_∞ is the energy at $R=\infty$ and E_c the energies of the continuous states.

In order to calculate the transition probabilities, it is necessary to determine the wave functions for ${}^1\Sigma_g{}^+$, ${}^2\Sigma_g$ and ${}^2\Sigma_u$ states. Neglecting the effects of the centrifugal force on the vibrational states, we obtain the equations for the wave functions of the form,

$$\frac{d^2\psi}{dR^2} + \{2\mu(\mathcal{E} - V(R))\}\psi = 0 \ , \quad (18)$$

where $\mathcal{E}$ is the proper energy value, μ the reduced mass.

As the types of the potentials, we shall assume the Morse curve for ${}^1\Sigma_g{}^+$ and ${}^2\Sigma_g$ and the repulsive exponential curve for ${}^2\Sigma_u$.

In the first two cases, numerical values of the parameters are determined from the data given in the book by Herzberg[11]. Then

$$V = \begin{cases} 0.174(1 - e^{-1.03(R-1.4)})^2 & \text{for } H_2({}^1\Sigma_g{}^+) \ , \quad (19) \\ 0.102(1 - e^{-0.704(R-2.0)})^2 & \text{for } H_2{}^+({}^2\Sigma_g) \ . \quad (20) \end{cases}$$

For the above choice of parameter values, the number of bound states are 16 and 18 for H_2 and $H_2{}^+$ respectively. The transition probabilities from the lowest vibrational state of ${}^1\Sigma_g{}^+$ to the various vibrational states of ${}^2\Sigma_g$ have been calculated numerically. The result is tabulated in Table 2. It shows that the transition probabilities have a maximum at $v'=2$, and the sum of the probabilities up to $v'=6$ is already about 95.2%. Thus we may expect that, if the validity of the Franck Condon principle is not very poor in this case, the number of protons produced from the jumps to continuous states of ${}^2\Sigma_g$ should be very small.

Table 2. The ratio of transition for various vibrational states of ${}^2\Sigma_g$.

v'	0	1	2	3	4	5	6	...	total
ratio (%)	10.2	19.0	21.3	17.9	13.3	8.6	4.9	...	100

For the repulsive state ${}^2\Sigma_u$, we put $V = Ae^{-\beta R}$, A and β fitted with the calculated values by Morse and Stückelberg at $R=1$ and $R=3$[12]. Then

$$V = 2.7976 e^{-1.0891R} \quad \text{for} \quad H_2{}^+({}^2\Sigma_u) \ . \quad (21)$$

The wave $\psi(E_c)$ in this potential can be expressed by the Bessel function of imaginary order. But, on account of the practical reason, they have been numerically calculated for some E_c. The integration were carried out from the origin outwards. The wave functions were connected smoothly with the WKB type solutions at the approximate loops of waves, and the asymptotic amplitudes without normalization were determined.

The normalization condition for the continuous state is that

$$\lim_{\tau_0 \to \infty} \int_{\Delta E} dE_c' \int_{\tau_0} \psi^*(E_c')\psi(E_c) d\tau = 1 \ . \quad (22)$$

This condition requires that the asymptotic amplitude of $\psi(E_c)$ is $1/\sqrt{\pi}\sqrt{2\mu(E_c - E_\infty)}$ as shown by Hargreaves[18].

As representatives of $\psi(E_c)$, we have taken five functions of the repulsive states with the total energies which cut the potential curves at $R=1.1$, 1.25, 1.4, 1.55, 1.7 respectively. (see Fig. 1)

Table 3. The transition probabilities for various continuous states of ${}^2\Sigma_u$.

R at the cutting point	$E_{\text{kin.}}$ energy of protons	Pelative transition probabilities		Absolute transition probabilities
		δ function approx.	numerical cal.	numerical cal.
1.1 (a. u.)	11.1 (eV)	9.1	8.0	$.084\times10^{-3}$
1.175	10.2	24.0		
1.25	9.4	49.4	43.2	.454
1.325	8.6	76.8		
1.4	7.9	100.0	100.0	1.045
1.475	7.2	101.0		
1.55	6.6	81.6	82.0	.860
1.7	5.6	34.3	37.0	.389
1.9	4.7	7.8		

In the case of relative transition probabilities, the value at $R=1.4$ is taken as 100.

A rough approximation of $\psi(E_c)$ of repulsive states is to replace the first mountains of $\psi(E_c)$ by δ functions and neglect the other parts of the functions[1),11)]. Because, the contribution from the latters to the overlap integrals will be very small by the cancellation of mountains and valleys. This method gives us the relative transition probabilities and are applied together with the exact one.

The overlap integrals between the ψ_v and $\psi(E_c)$ states were numerically calculated, the results of which are shown in Table 3. Both the solutions from the exact and δ functional methods give a nearly equal energy distribution of ejected protons as can been seen from Table 3. When the experiment of photoionization in the high energy range becomes available in future, it is interesting to compare the experimental energy distribution with this theoretical one.

3.2. *The Born approximation and the dipole approximation*

We have approximated the wave function of the ejected electron as a plane wave (Born approximation). But, to be more accurate, we must take account of the distorsion of the wave caused by the Coulomb force between the ejected electron and the molecular ion left behind. We will show that the distortion is not so large when the wave length of incident light quanta is shorter than 20Å.

The field of hydrogen molecular ion can be approximated by that of two $+\frac{1}{2}e$ charges fixed at a distance R. Then we may expect the degree of the distorsion in the present problem will be estimated by comparing the plane wave with the distorted one in this field. We will not distinguish ${}^2\Sigma_g$ and ${}^2\Sigma_u$, and fix the nuclear distance R at 1.4. Only the partial waves $s\sigma$ will be compared, because the effect of distortion may appear most appreciably in those components.

By adopting the elliptic coordinates ξ, η and ϕ, the wave equation in the above potential can be separated as

$$\Phi=X(\xi)Y(\eta)e^{im\phi} \qquad (m=0,1,\cdots)\,, \tag{23}$$

$$\frac{d}{d\xi}\left[(\xi^2-1)\frac{d}{d\xi}X\right]+\left[c^2\xi^2+R\xi-\lambda_{n,m}-\frac{m^2}{\xi^2-1}\right]X=0\,, \tag{24}$$

$$\frac{d}{d\eta}\left[(\eta^2-1)\frac{d}{d\eta}Y\right]+\left[c^2\eta^2-\lambda_{n,m}-\frac{m^2}{\eta^2-1}\right]Y=0\,, \tag{25}$$

where c is $kR/2$, $\lambda_{n,m}$ the separation constant.

The equation (25) has been investigated by many authors[13)] and the solution which is regular at $\eta=\pm1$ has been obtained in the form of expansion in terms of the associated Legendre functions,

$$Y_n{}^m=\sum A^m_{n,l}Pe_l{}^m(\eta) \qquad (|l-n|\ \text{odd})\,. \tag{26}$$

We can find the formulae for the separation constant $\lambda_{n,m}$ and expansion coefficients $A^m_{n,l}$, for instance, in the text book by Stratton, Morse, Chu and Hunter[13]. On the other hand, the equation (24) is rather difficult to solve analytically. A plausible form suggested from the eigenvalue problem of hydrogen molecular ion is[14]

$$X=Ne^{-(ikR/2)\xi}(\xi^2-1)^{m/2}\left(\frac{1}{\xi+1}\right)^{m+1+(i/k)}\sum_n a_n\left(\frac{\xi-1}{\xi+1}\right)^n , \tag{27}$$

where N is the normalization constant, and the complex coefficients a_n should be determined by a three terms recurrence formula. The logarithmic phase which is characteristic in the Coulomb field comes, of course, from the third factor. Unfortunately the convergence of the series is not so good. Therefore, we have adopted the numerical calculations to obtain the wave functions for some parameters. By writing

$$X=\frac{U}{\sqrt{\xi^2-1}} , \tag{28}$$

the equation (24) has been transformed into the equation

$$\frac{d^2}{d\xi^2}U+\frac{1}{\xi^2-1}\left[c^2\xi^2+R\xi-\lambda_{n,m}-\frac{m^2-1}{\xi^2-1}\right]U=0 . \tag{29}$$

The calculation has been carried out for $c=3$ and 5 which correspond to the photons of wave length 50Å and 17Å respectively. The normalization of the wave has been determined by connecting them with the WKB solutions just in the same way as in (3.1).

The corresponding solutions in the free field can be obtained in the form of expansion in terms of the spherical Bessel functions,

$$X_0{}^0=\kappa_0\sum_{l=0}^{\infty}{}'(-)^{l/2}A^0_{0,l}(c)j_e(c\xi)\xrightarrow{\xi\to\infty}\frac{\sin c\xi}{c\xi} , \tag{30}$$

where $\kappa_0=1/\sum_{l=0}^{\infty}{}'A^0_{0,l}$ and Σ' means the sum over even integers only.

Comparing the partial wave in the Coulomb field with those of the plane wave, we have found that in the case of $c=5$ there is no appreciable distortion, while for $c=3$ the effect of Coulomb field has come to appear. This results will support the assumption that the Born approximation is reasonable for the wave function of the electron which is ejected by the incident light with wave length shorter than about 20Å.

Next we will make a remark about the dipole approximation. In the previous section the vector potential has been replaced by unity. In other words, the electromagnetic field over the molecule has been assumed nearly constant. In order to make sure, we have estimated the magnitude of the next term in the expansion of exponential function. A similar calculation like the previous section has been carried out. The ratio of the magnitude of the electric diole transition elements to the magnetic diole and electric quadrupole ones has been found to be 20 : 1 for the wave length 10Å. Then we may conclude the dipole velocity approximations in the previous section is fairly sufficient.

3.3. *Remarks on the neglected ionization processes*

So far we have been exclusively concerned with the accuracy of our calculations. Now we will discuss some other factors which we have not taken into account. In the previous section we have assumed that the relative yield $H^+/H_2{}^+$ can be determined by the processes ${}^1\Sigma_g{}^+\to{}^2\Sigma_g$ and ${}^1\Sigma_g{}^+\to{}^2\Sigma_u$. But, in general, other processes such as the excitation to the higher states than these two and the autoionization through potential crossings will also contribute to produce these ions. It is difficult to estimate these contributions theoretically because it requires much knowledge about the wave functions of the highly excited states of H_2 and $H_2{}^+$. Hence we will here investigate the experimental data on these phenomena[15] and try to estimate these contributions.

As for the autoionization, each state of hydrogen molecule shown in Table 4 has the

Table 4. The levels which may cause the autoionization.

possibility of dissociation to H_2^+. For instance, the autoionization through the level $^1\pi_u$ was concluded from the diffuseness of a emission band and this phenomenon was interpreted as the result of radiationless transition from $^1\pi_u$ to $^2\Sigma_g$ of H_2^+[16]. But the number of H_2^+ produced through the processes of this type will be very small, because the number of the diffused bands is rather small and the degree of their diffuseness is usually not so great. Knowledge about the group of doubly excited states 3^1K, ^1N etc. are less little[15]. But, as can be seen from their large internuclear distances, there are some possibilities that these levels cross over $^2\Sigma_g$ or $^2\Sigma_u$. The crossing of levels is also probable in the case of many repulsive potentials of H_2. Though we cannot deny the roles of these levels, we must say, at the same time, that the transition probabilities to these states are probably very small.

Further the transitions to the highly excited states of H_2^+ will produce H_2^{+*}, $H^+ + H^*$ and $H^+ + H^+$. In the experiment of electron impact, only small trace of double ionization has been found[17]. This may be also true in the case of irradiation with light quanta. On the other hand, the transition probabilities to the lower excited states seem to be not so small enough. Unfortunately adequate simple wave functions for these states have not been obtained so that we could not estimate their contribution distinctly.

The author wishes to express his sincere thanks to Prof. M. Kotani for suggesting this problem and for his invaluable advices throughout his work. The author is also very grateful to Dr. K. Takayanagi for reading the manuscript and showing profound interest, and to the members of Kotani Laboratory for their fruitful discussions.

The Binding Energy of the σ Bond, III. Discussion on the Ionic Structures

By Kiyoshi O-OHATA

Physics Department, Tokyo Institute of Technology,
O-okayama, Meguro-ku, Tokyo

(Received December 2, 1959)

The ionic terms of the σ bonds are explicitly considered by the use of the semi-localized orbitals and their contribution to the binding energy of the bond is discussed. A theoretical basis for the relation between Pauling's scale of electronegativity and Mulliken's one is given under some assumptions. The value of the binding energy of the C-C bond in the diamond crystal is computed to be 3.64 eV per bond, if the ionic terms of the bond are included. It is shown that the value of the binding energy of the diamond crystal in the Heitler-London approximation is almost equal to that in the molecular orbital method and less than the above value by about 0.4 eV per bond. The resultant state, however, is found to be rather well expressed by the Heitler-London approximation.

§1. Introduction

In the preceding papers I and II[1], we discussed mainly the binding energy of the σ bond by the use of the Heitler-London approximation, where the ionic structures were neglected. This is not adequate when we discuss the heteropolar bond. Even in the case of the homopolar bond like the C-C bond in the diamond crystal this is by no means a good approximation. Mueller and Eyring[2] proposed the semi-localized orbital method to discuss the electronic states of diatomic molecules. We shall also use this method in order to take the ionic structures of a chemical bond into account, because this method has several advantages as follows. According to this method we can describe the heteropolar bond by using the wave function involving the ionic structures adequately, can take into consideration the correlational interaction between the two electrons which are responsible for a chemical bond, and can obtain a simple formula to give the total energy.

We consider a bond A-B between the atoms A and B in a saturated molecule (we use this term to express a molecule contructed only by σ bonds) and denote the directional atomic valence orbitals of the atoms A and B as ϕ_i and ϕ_j, respectively. The orbital ϕ_i proects out from A to B and the orbital ϕ_j from B to A. The pair of orbitals (ϕ_i, ϕ_j) is n charge of the formation of the bond A-B in the Heitler-London approximation. In the semi-localized orbital method we replace the paired orbitals (ϕ_i, ϕ_j) by a pair of semi-localized orbitals (ψ_i, ψ_j). (We shall use the notation (ij) for the pair of orbitals (ψ_i, ψ_j) and it will be also used to express the corresponding bond.)

Following Eq. (2.2) in I, we get the semi-localized orbitals ψ_i and ψ_j:

$$\left.\begin{aligned}\psi_i&=\frac{1}{\sqrt{N_i}}(\phi_i+\lambda\phi_j)\,,\\ \psi_j&=\frac{1}{\sqrt{N_j}}(\phi_j+\mu\phi_i)\,,\end{aligned}\right\}\tag{1.1}$$

where $N_i=1+2\lambda S_{ij}+\lambda^2$, $N_j=1+2\mu S_{ij}+\mu^2$, S_{ij} is the overlap integral between the directional atomic valence orbitals ϕ_i and ϕ_j, and λ and μ are the parameters which are related to the inclusion of the ionic structures. The total electronic wave function Ψ of the molecule can be expressed by the use of an assembly of the pairs of the orbitals, that is,

$$\Psi:\ (ij)(kl)(pq)(st)\cdots\,,\tag{1.2}$$

where we can include not only the pairs of the valence orbitals but also the lone pairs and the pairs of the core orbitals. The parameters λ and μ may take the different values in the individual orbital pairs and their values should be determined by the minimization of the total energy. The expression for the total energy of the saturated molecule was given in I, where the total energy was expanded as a power series of the overlap integrals between the unpaired orbitals. (We have used the notation T for these overlap integrals in order to distinguish them from those between paired orbitals S.) As the exchange integrals between the unpaired orbitals are considered to be of the order of T^2, we can express the total energy of the molecule as

$$E=\frac{H_0}{\Delta_0}+\frac{H_2}{\Delta_0}-\frac{H_0\Delta_2}{\Delta_0^2}\,, \tag{1.3}$$

taking terms up to the order of T^2 into account. This equation is the same as Eq. (3.10) of I. The term H_0/Δ_0 is the zeroth order term in T and its explicit form was given by Eqs. (4.2)-(4.4) of I. The second and third terms in Eq. (1.3), which are the second order terms in T, were given by Eqs. (4.5)-(4.8) of I. The only difference from the previous case is that the orbitals involved in the molecular integrals in Eqs. (4.2)-(4.8) of I are $\psi_i, \psi_j, \cdots$ instead of $\phi_i, \phi_j, \cdots$. The formulae in § 5 of I are unable to be used, as they were deduced under the Heitler-London approximation. In the next section we shall discuss the results due to the mixing of the ionic structures of the bond. In § 3 we shall give some qualitative discussion on the heteropolar bonds. In § 4 we shall give the result of the calculation of the binding energy of the C-C bond in the diamond crystal with the inclusion of the ionic structures of the bonds. The maximum value of its binding energy has been computed to be 3.64 eV per bond at $\lambda=\mu=0.16$.

§ 2. Details of the Energy Expression

As mentioned above it is sufficient, for obtaining the binding energy of a bond by the semi-localized orbital method, to find the values of the molecular integrals in Eqs. (4.2)-(4.8) of I which involve the orbitals (1.1). We will express the energy formulae in terms of the parameters and the molecular integrals involving ϕ_i, ϕ_j, $\cdots$, to find out the effect of the ionic structures on the binding energy of a bond. Thus we express the zeroth order term H_0/Δ_0 in the total energy as follows:

$$\frac{H_0}{\Delta_0}=\sum_{(ij)}H(ij)+\sum_{\{(ij)(kl)\}}A(ij,\,kl)+\sum_{(XY)}\frac{Z_XZ_Y}{R_{XY}}, \tag{2.1}$$

with

$$\begin{aligned}H(ij)=&\frac{1}{N_{ij}}[A_iI_{ii}+A_jI_{jj}+2B_{ij}I_{ij}+(1+\lambda\mu)^2C_{ij}\\&+\{(1+\lambda\mu)^2+4\lambda\mu\}K_{ij}+2\lambda^2C_{jj}+2\mu^2C_{ii}+4(1+\lambda\mu)(\lambda D_{j,ij}+\mu D_{i,ij})\,,\\A(ij,\,kl)=&\frac{1}{N_{ij}N_{kl}}[A_iA_kC_{ik}+A_jA_kC_{jk}+A_iA_lC_{il}+A_jA_lC_{jl}\\&+2B_{ij}(A_kD_{k,ij}+A_lD_{l,ij})+2B_{kl}(A_iD_{i,kl}+A_jD_{j,kl})\\&+4B_{ij}B_{kl}N_{ij,kl}]\,,\end{aligned} \tag{2.2}$$

where

$$\left.\begin{aligned}&N_{ij}=N_iN_j+R_{ij}^2,\quad A_i=N_i\mu^2+2R_{ij}\mu+N_j\,,\\&A_j=N_j\lambda^2+2R_{ij}\lambda+N_i,\quad B_{ij}=N_i\mu+N_j\lambda+R_{ij}(1+\lambda\mu)\,,\end{aligned}\right\}$$

and

$$R_{ij}=\lambda+\mu+(1+\lambda\mu)S_{ij}\,, \tag{2.3}$$

The other notations represent the molecular integrals with respect to the atomic orbitals and were already defined by Eq. (4.4) of I. With Mulliken's notation they are expressed as

$$\left.\begin{aligned}&I_{ij}=(\phi_i|h|\phi_j)\,,\quad C_{ij}=(\phi_i\phi_i;\ \phi_j\phi_j)\,,\quad K_{ij}=(\phi_i\phi_j;\ \phi_i\phi_j)\,,\\&D_{k,ij}=(\phi_k\phi_k;\ \phi_i\phi_j)\,,\quad N_{ij,kl}=(\phi_i\phi_j;\ \phi_k\phi_l)\,,\quad S_{ij}=(\phi_i|\phi_j)\,,\end{aligned}\right\} \tag{2.4}$$

where h denotes the part of the total Hamiltonian depending on only one electron. The summations $\sum\limits_{(ij)}$ and $\sum\limits_{\{(ij),(kl)\}}$ in Eq. (2.1) extend over all the orbital pairs and all the pairs of orbital pairs, respectively. The last term in Eq. (2.1) represents the repulsive potentials between the constituent nuclei.

There is a relation among the coefficient (2.3) as follows:

$$2N_{ij}=A_i+A_j+2S_{ij}B_{ij}\,, \tag{2.5}$$

Using this relation and assuming the Mulliken approximation (5.6) of I for the estimation of the values of the many center energy integrals, we obtain from Eq. (2.1)

$$\frac{H_0}{\varDelta_0}=\sum E_A{}^*+\sum_{(ij)}F_{ij}(AB)+\sum_{(ij)}P(ij)+\sum_{\{(ij)(kl)\}}R(ij,\,kl)+G \tag{2.6}$$

with

$$\begin{aligned}F_{ij}(AB)=&\frac{1}{2}\,\frac{A_i+A_j}{N_{ij}}\,(V_{ii}{}^B+\sum_{b\neq j}{}' C_{ib}+V_{jj}{}^A+\sum_{a\neq i}{}' C_{ja})\\&+\frac{1}{N_{ij}}\,[(1+\lambda\mu)^2C_{ij}+\{(1+\lambda\mu)^2+4\lambda\mu\}K_{ij}\\&+(\lambda^2+\mu^2)(C_{ii}+C_{jj})+2(\lambda+\mu)(1+\lambda\mu)(D_{i,ij}+D_{j,ij})]\\&+\frac{2B_{ij}}{N_{ij}}\{I_{ij}{}^{AB}+\sum_{a\neq i}{}' D_{a,ij}+\sum_{b\neq j}{}' D_{b,ij}\}+\sum_{a\neq i}{}' V_{aa}{}^B+\sum_{b\neq j}{}' V_{bb}{}^A\\&+\frac{1}{2}\sum_{a\neq i}{}'\sum_{c\neq j}{}' C_{ab}+V_{AB}-\frac{S_{ij}B_{ij}}{N_{ij}}(\varepsilon_i{}^A+\varepsilon_j{}^B)\,,\end{aligned} \tag{2.7}$$

$$P(ij)=\frac{1}{2}\,\frac{A_i-A_j}{N_{ij}}\,(\chi_i-\chi_j)\,, \tag{2.8}$$

$$R(ij,\,kl)=\frac{1}{4}\,\frac{A_i-A_j}{N_{ij}}\,\frac{A_k-A_l}{N_{kl}}(C_{ik}-C_{jk}-C_{il}+C_{jl})\,, \tag{2.9}$$

and

$$G=\sum_{(AC)}Q(AC)\,, \tag{2.10}$$

where the notations are almost the same as those defined in I, that is, $V_{ij}{}^B=(\phi_i|\,V^B|\phi_j)$, $I_{ij}{}^{AB}=(\phi_i|-\frac{1}{2}\varDelta+V^A+V^B|\phi_j)$, V^A and V^B are the core potentials of the atoms A and B, respectively, the subscripts a and b denote the atomic orbitals of the atoms A and B, respectively, the summations $\sum\limits_a{}'$ and $\sum\limits_b{}'$ extend over all the valence orbitals of the atoms A and B other than the orbitals ϕ_i and ϕ_j, respectively, and V_{AB} represents the interaction energy between the atomic cores A and B. The intra-atomic exchange integrals are involved in Eq. (2.6), since these integrals are considered to be the zeroth order terms in T. Then the quantity $E_A{}^*$ represents the total energy of the valence state of the atom A, and the quantity $-\varepsilon_i{}^A$ denotes the ionization potential for the orbital ϕ_i of the atom A. The quantity χ_i is expressed as

$$\chi_i=\varepsilon_i{}^A+\frac{1}{2}\,C_{ii}+\sum_X{}'\,\{V_{ii}{}^X+\sum_x C_{ix}\}\,, \tag{2.11}$$

where the summation $\sum\limits_X{}'$ extends over all the constituent atoms of the molecule other than the atom A and the summation $\sum\limits_x$ extends over all the valence orbitals of the atom X. We have assumed the approximate relations $D_{j,ij}=\frac{1}{2}S_{ij}(C_{ii}+C_{ij})$ and $D_{j,ij}=\frac{1}{2}S_{ij}(C_{ij}+C_{jj})$ in order to derive Eq. (2.11). As we may assume that the term $\sum\limits_X{}'\,\{V_{ii}{}^X+\sum\limits_x C_{ix}\}$ in Eq. (2.11), which represents the contribution from the neutral atoms, is small enough to be neglected, we consider that the quantity $-\chi_i$ represents the electronegativity with respect to ϕ_i of the atom A in Mulliken's scale. The term $Q(AC)$ which represents the interaction energy between the atoms A and C is defined by

$$Q(AC)=\sum_a V_{aa}{}^C+\sum_b V_{cc}{}^A+\frac{1}{2}\sum_a\sum_c C_{ac}+V_{AC}\ , \tag{2.12}$$

where the summations $\sum\limits_a$ and $\sum\limits_c$ extend over all the valence orbitals of the atoms A and C, respectively, and the summation $\sum\limits_{(AC)}$ in Eq. (2.10) is taken over all the pairs of the second or more remote neighbours.

According to Eq. (2.6), we can define the binding energy $D_0(AB)$ of the bond A-B in the zeroth order approximation as

$$D_0(AB)=F_{ij}(AB)+P(ij)+\frac{1}{2}\sum_{(kl)\neq(ij)}{}' R(ij,\ kl)+G'+U\ , \tag{2.13}$$

with

$$G'=\sum_C\frac{1}{n_A+n_C}Q(AC)+\sum_D\frac{1}{n_B+n_D}Q(BD)\ ,$$

$$U=\frac{1}{n_A}(E_A{}^*-E_A)+\frac{1}{n_B}(E_B{}^*-E_B)\ ,$$

where the terms G' and U are the same as those defined in §6 of I, n_A is the total number of the valence orbitals of the atom A, the summation $\sum\limits_C$ extends over the atoms which are not directly bonded to the atom A, E_A is the atomic energy of the ground state of the atom A, $E_A{}^*-E_A$ is the promotional energy from the ground state to the valence state in the atom A, and so on.

Next, we shall discuss the energy terms in the second order approximation. They are $H_2/\varDelta_0-H_0\varDelta_2/\varDelta_0{}^2$ in Eq. (1.3) and expressed as

$$H_2/\varDelta_0-H_0\varDelta_2/\varDelta_0{}^2=-\frac{1}{2}\sum_{[(ij)(kl)]}J(ij,\ kl) \tag{2.14}$$

with

$$\begin{aligned}J(ij,\ kl)=B(ij,\ kl)-\varDelta(ij,\ kl)[&H(ij)+H(kl)\\&+A(ij,\ kl)+\sum_{(pq)}{}''\{A(ij,\ kl)+A(kl,\ pq\}]\ ,\end{aligned} \tag{2.15}$$

where $B(ij,\ kl)$ has a rather complicated expression as shown by Eq. (4.6) of I and will not be written here again. The summation $\sum\limits_{(pq)}{}''$ in Eq. (2.15) is taken over all the bonds other than the bonds (ij) and (kl). $\varDelta(ij,\ kl)$ which represents the effect of the non-orthogonality between the bonds (ij) and (kl) is expressed as

$$\begin{aligned}\varDelta(ij,\ kl)=\frac{1}{N_{ij}N_{kl}}\{&A_iA_kT_{ik}{}^2+A_jA_kT_{jk}{}^2+A_iA_lT_{il}{}^2+A_jA_lT_{jl}{}^2\\&+2B_{ij}(A_kT_{ik}T_{jk}+A_lT_{il}T_{jl})+2B_{kl}(A_iT_{ik}T_{il}+A_jT_{jk}T_{jl})\\&+2B_{ij}B_{kl}(T_{ik}T_{jl}+T_{il}T_{jk})\}\ ,\end{aligned}$$

where T_{ik} is the overlap integral between the atomic orbitals ϕ_i and ϕ_k and so on. We can easily rewrite the expression of $\varDelta(ij,\ kl)$, deviding it into the terms with the even or odd symmetry with respect to the interchange of λ and μ:

$$\begin{aligned}\varDelta(ij,\ kl)=&q_{ij}q_{kl}(T_{ik}{}^2+T_{jk}{}^2+T_{il}{}^2+T_{jl}{}^2)+2B_{ij}q_{kl}(T_{ik}T_{jk}+T_{il}T_{jl})\\&+2B_{kl}q_{ij}(T_{ik}T_{il}+T_{jk}T_{jl})+2B_{ij}B_{kl}(T_{ik}T_{jl}+T_{il}T_{jk})\\&+p_{ij}p_{kl}(T_{ik}{}^2-T_{jk}{}^2-T_{il}{}^2+T_{jl}{}^2)+2B_{ij}p_{kl}(T_{ik}T_{jk}-T_{il}T_{jl})\\&+2B_{kl}p_{ij}(T_{ik}T_{il}-T_{jk}T_{jl})\ ,\end{aligned}$$

where $q_{ij}=(A_i+A_j)/2N_{ij}$, $p_{ij}=(A_i-A_j)/2N_{ij}$, and so on. The quantities q_{ij} and p_{ij} have the even and odd symmetry with respect to the interchange of λ and μ, respectively. The term $B(ij, kl)$ in Eq. (2.15) can be shown to have the similar expression as $\Delta(ij, kl)$, as that term comes mainly from the overlap between unpaired orbitals. As seen from Eq. (2.17), we can expect that the odd part of $B(ij, kl)$ and $\Delta(ij, kl)$ gives a rather small contribution to the binding energy, since the terms appearing in this part cancel each other.

The contribution of the second order terms, $-\frac{1}{4}\sum_{\{(ij)(kl)\}} J(ij, kl)$, to the binding energy of a bond should be added to Eq. (2.13), if we take terms up to the second order in T into account. We here note, however, that we must subtract the terms of the intra-atomic exchange integral,

$$\left(1-\frac{S_{ij}B_{ij}}{N_{ij}}-\frac{S_{kl}B_{kl}}{N_{kl}}+p_{ij}+p_{kl}\right)K_{jk}$$

from $J(ij, kl)$, if the two bonds (ij) and (kl) are adjacent and ϕ_j and ϕ_k are the atomic orbitals of the same atom.

§ 3. Consideration about the Pauling Scale of Electronegativity

Considering the relation (2.5) among the coefficients (2.3), we may interpret that the quantities A_i/N_{ij} and A_j/N_{ij} are the charge densities of the atoms A and B, respectively, and the quantity $2S_{ij}B_{ij}/N_{ij}$ is the charge density in the overlap region due to the bond (ij). Then, the quantity p_{ij} represents the amount of charges in the bond (ij) which are transferred from the atom B to the atom A. In the expression of the binding energy of a bond, the terms involving the coefficient p_{ij} are $P(ij)$, $R(ij, kl)$ and a part of $J(ij, kl)$. If we assume that the contribution from $R(ij, kl)$ is small enough to be neglected, we can interpret that $P(ij)$ is the extra binding energy for the bond (ij) due to the polarity of the bond. As shown later, the assumption holds at a large inter-bond separation. If we assume that the homopolar part of the binding energy of the bond A-B is replaced by the additive mean of the binding energies of the bond A-A and B-B, we may assume that $-P(ij)$ is the "extra ionic resonance energy" given by Pauling.[3] Then we get the expression

$$-P(ij)=(x_A-x_B)^2\ , \qquad (3.1)$$

where x_A and x_B are the electronegativities of the atoms A and B in the Pauling scale, respectively. On the other hand, $-\chi_i$ is approximately equal to the electronegativity of the atom A in the Mulliken scale, as mentioned in the preceding section. According to Mulliken's discussion,[4] $-\chi_i$ may be a little smaller than the electronegativity X_A of the atom A in the Mulliken scale, that is, $-\chi_i=cX_A$, where $c\simeq 0.7$. According to the physical meaning of the Mulliken scale of electronegativity, it may be reasonable to assume p_{ij} proportional to (X_A-X_B). From Eq. (2.8), we get the relation

$$-P(ij)=-p_{ij}(\chi_i-\chi_j)=c\gamma(X_A-X_B)^2\ , \qquad (3.2)$$

where γ is the proportionality factor between p_{ij} and (X_A-X_B). From Eqs. (3.1) and (3.2), we obtain the linear relation between the two scales of electronegativity which are given by Pauling and Mulliken independently:

$$x_A-x_B=\sqrt{c\gamma}(X_A-X_B)\ . \qquad (3.3)$$

From the results of the measurement of eQq, Gordy[5] gave an empirical relation

$$p_{ij}=\frac{1}{2}(x_A-x_B)\ ,$$

from which we get $\gamma=c/4$. Thus, we have the relation

$$x_A-x_B=\frac{c}{2}(X_A-X_B)\simeq 0.35(X_A-X_B)\ .$$

This agrees excellently well with the empirical rule:

$$x_A-x_B=0.36(X_A-X_B)\ .$$

Similar discussion was given by Mulliken[4] with the use of the molecular orbital method. His theory is, however, applicable only when the atoms A and B are rather similar atoms, since the energies of the molecular orbitals are given as a power series of the ratio of the difference of the Coulomb integral for the atomic orbital ϕ_i from that of ϕ_j to the resonance integral between them.

The term $R(ij, kl)$ which represents the interaction energy between the polar bonds may give the so called inductive effect. This term will decrease rather rapidly with increase of the separation between the bonds (ij) and (kl), because the Coulomb integrals appearing in the expression (2.9) of $R(ij, kl)$ cancel each other. There are, of course, the terms depending on both of the coefficients p_{ij} and p_{kl} in the second order term $J(ij, kl)$, but the magnitudes of these terms will also decrease rapidly with increase of the separation between the bonds (ij) and (kl). This may be seen from the corresponding terms in $\Delta(ij, kl)$ of Eq. (2.17).

§ 4. Application to the C-C Bond in the Diamond Crystal

We here consider the application of the present method to the C-C bond of the diamond crystal, in which the individual bonds are homopolar and equivalent. Then, we can put $\lambda=\mu$ in the wave functions (1.1). Each carbon atom in the diamond crystal has four equivalent valence orbitals. Each bond has six nearest neighbour bonds and eighteen second nearest neighbour bonds in which twelve bonds locate at the gauche positions and other six bonds at the trans positions. Considering the above facts, the expression for the binding energy of a bond is derived from Eq. (2.13) with including the second order term as

$$\begin{aligned} D(AB)=F_{ij}(AB)+\frac{1}{8}\{\sum_C Q(AC)+\sum_D Q(BD)\} \\ -\frac{3}{2}J(ij,\ kl)-3J(ij,\ st) \\ -\frac{3}{2}J(ij,\ pq) \\ +\frac{1}{4}\{E_A{}^*-E_A)+(E_B{}^*-E_B)\}\ , \end{aligned}$$

where the summations $\sum_C$ and $\sum_D$ are taken only over the second nearest neighbour atoms from the atoms A and B, respectively, because of smallness of the contribution from the more remote neighbours, (kl) is an adjacent bond of the bond (ij), (st) is the second nearest neighbour bond at gauche position for the bond (ij), and (pq) is the one at the trans position. In Eq. (4.1), we neglected the second order terms owing to the third nearest or more remote neighbour bonds, since their effect will be small enough to be neglected. Following the scheme of calculation as in II, the value of $D(AB)$ is obtained as a function of the parameter λ. The result is shown in Fig. 1. From this figure we find 3.92 eV as the binding energy of the C-C bond in the diamond crystal and the optimum value of λ is 0.16. It is also shown in this figure that the value of the binding energy of the bond in the Heitler-London approximation ($\lambda=0$) is almost equal to that in the molecular orbital one ($\lambda=1$), and they are less than the resultant value of the binding energy by about 0.4 eV per bond. This value can be interpreted as the ionic effect from the point of view in the Heitler-London scheme and as the correlational effect from that in the molecular orbital scheme. Furthermore, in our calculation we found that the second order terms are scarcely influenced by the inclusion of the ionic terms and the minimum point in Fig. 1 is almost determined by the zeroth order terms. The effect of the non-orthogonality between a valence orbital of one atom and a core orbital of another atom in the semi-localized orbital method, which is almost equal to that in the Heitler-London approximation, reduces the binding energy by about 0.28 eV per bond. Finally we obtain 3.64 eV per bond as the approximate binding energy of the C-C bond in the diamond crystal.

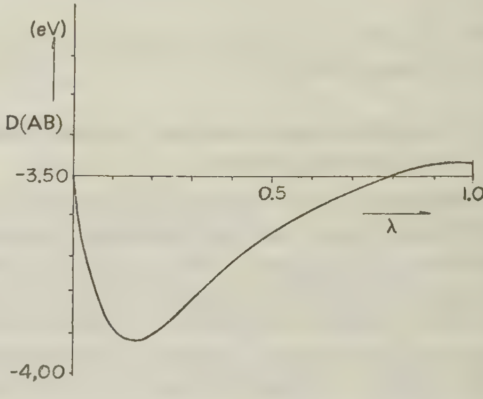

Fig. 1. The variation of the value of $D(AB)$ with λ for the C–C bond in the diamond crystal.

§ 5. Conclusion

We discussed the ionic structure of the σ bond with the use of the semi-localized orbital method, for this method has several advantages as mentioned in § 1, and so can extract the contribution of the ionic structures on the binding energy in a simple manner. We, hen, found an interesting fact that the difference between the electronegativities of he atoms A and B in the Mulliken scale is found in the expression of the binding energy of the bond A-B in connection with the polarity of this bond. Under the assumptions mentioned in § 3, it was shown that we can find theoretically the relation between the scale of electronegativity given by Pauling and that given by Mulliken. We also obtained a qualitative interpretation for the rapid decreasing of the inductive effect with increasing the separation between the bonds. We, however, postpone the quantitative discussion on the heteropolar bonds.

We calculated the binding energy of the C-C bond in the diamond crystal with including the ionic structures of the bonds. We found that the maximum value of the binding energy of the bond was 3.64 eV per a bond and the corresponding value of λ was 0.16. The calculated value of the binding energy of the C-C bond is in good agreement with the experimental one 3.716 eV per bond.$^{6)}$ From the best value of λ it is found that the resultant wave function is rather well expressed by the Heitler-London approximation. This result is different from that given by Schmid$^{6)}$ who concluded the molecular orbital approximation to be almost near to the best. Our criticism against Schmid's calculation was already cited in § 4 of II. Our calculation shows that the correlational effect on the binding energy neglected in the molecular orbital scheme is about 0.4 eV per bond, that is, 0.8 eV per atom in the diamond crystal.

The author wishes to express his sincere thanks to Professor K. Niira for his incessant encouragement and for his kind reading of the article. The author is indebted to the Ministry of Education for the research grant.

On the Effect of Heat Treatment in a Magnetic Field on Magnetic Properties of Iron-Aluminium Alloys

By Makoto Sugihara

The Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Tokyo, Japan

(Received December 14, 1959)

When the specimens of iron-aluminium alloys were cooled in a magnetic field from high temperatures, the percent increase of initial permeability is generally not large, but that of maximum permeability is considerably large and it has a maximum at the concentration of 10.20 percent aluminium. The effect of heat treatment in a magnetic field is small for the concentration of more than 11.5 percent aluminium. When the quenched specimen of 10.20 percent aluminium was annealed again at various temperatures in a magnetic field and cooled in the field, the lowest effective temperature of heat treatment in a field becomes about 225~250°C. This temperature is 100°C lower than the usual lowest effective temperature for the specimen without quenching. Maximum permeability of the specimen which was quenched at first and heat treated at about 250°C in a magnetic field reaches to the highest value of about 30,000.

1. Introduction

Masumoto and Saitō[1] studied the effect of heat treatment on alloys containing up to 17 percent aluminium and found the maximum and initial permeabilities, the coercive force, and the residual induction are sensitive to cooling rate, especially in the neighbourhood of 14 16 percent aluminium. The highest permeabilities were obtained with the alloys containing about 16 percent aluminium that were quenched from 600°C. These alloys were named Alperm. The alloy containing about 13 percent aluminium that has high magnetostriction, was named Alfer. Alperm was noticeable as a new magnetic material at that time, since its specific resistance was 140 $\mu\Omega$–cm and it did not contain the expensive material, such as nickel or cobalt. The questions of manufacturing, however, could not be settled at that time. Afterwards, Nachman and Buehler[2] reported that the alloy containing about 16 percent aluminium can be rolled to 0.01 mm in thickness at room temperature after it has been rolled to about 0.1 mm at about 575°C.

In the range of solid solubility, 0–32 percent aluminium, two types of superstructure are formed. They are designated Fe_3Al and FeAl corresponding to 13.9 and 32.6 percent aluminium by weight. Saitō[3] reported that an other phase than the two phases mentioned above should exist in the alloy containing about 10 percent aluminium, considering from the variation of electrical resistance and specific heat with temperature. Saitō supposed that this phase is a superlattice $Fe_{13}Al_3$ (10.03 percent aluminium). Recently, Taylor and Jones[4] reported that this phase exists, as a result of X-ray analysis.

Arrott and Sato[5] reported the alloys above 19.2 percent (33 atomic percent) aluminium exhibit antiferromagnetism and those below 15.8 percent (28 atomic percent) aluminium are ferromagnetic. They also found that between 15.8 and 19.2 percent aluminium, the behaviour is ferromagnetic at room temperature but shows a transition to Antiferromagnetism on lowering the temperature, and the antiferromagnetism exists only in the ordered structures.

These investigations make our attention again direct to this alloy. Recently, Nachman and Buehler[6], and the author[7] found that the initial and maximum permeabilities of the alloys containing about 12 percent aluminium are very high in an annealed state. The present paper reports the result of the further study on these alloys especially on the effect of heat treatment in a magnetic field on the permeability and hysteresis loop of the alloys.

§ 2. Specimens and Experimental Methods

Specimens were prepared by induction melting in vacuum from electrolytic iron (99.9%) and pure aluminium (99.99%) were used for the preparation of the alloys. One part of each cast was hot roll-forged to prepare a square-rod specimen (about 2 mm square and 50 cm in length), and the other part was hot rolled to about 0.8 mm in thickness in order to prepare a ring-shape specimen (27 mm in outer diameter, 19 mm in inner diameter).

All the specimens were first annealed at 1000°C for 1 hour and then furnace cooled in vacuum. Subsequent various heat treatments were applied thereafter.

The measurement of magnetization was made at room temperature by a usual ballistic method for the rod specimens and by a recording flux meter for the ring-shape specimens. Before each measurements, the specimens were always demagnetized with a.c. field.

§ 3. Experimental Results

The rod specimens were heated in vacuum in a non inductive electric furnace at 800°C for 30 minutes, cooled to 120°C at the rate of 150°C per hour without a magnetic field or under an application of longitudinal magnetic field with the strength of 12.5 Oe and then furnace cooled to room temperature. The results of measurement on the initial and maximum permeabilities of these specimens are given in Fig. 1 together with those of the specimens quenched in water from 600°C. As is shown in the figure, in a case of initial permeability, the values are not so different between the two slow cooled specimens with and without a magnetic field, whereas, in the case of maximum permeability, the values are quite different and the values with a magnetic field have a maximum in the vicinity of 10 percent aluminium as already reported by the author[7].

Fig. 2 shows the magnetization curves and the hysteresis loops of the ring-shape specimens of seven alloys containing about 5–12 percent aluminium. Curve (a) indicates the case that each specimen was heated at 800°C in vacuum in a non inductive electric furnace for 30 minutes and cooled without a field. Curve (b) indicates the case that each specimen heat treated as mentioned above was reheated to 550°C and furnace cooled in a circular magnetic field with the strength of 12 Oe. It had been known from the other preliminary experiment, that such a strength of magnetic field is sufficient for the effect. Fig. 3 shows the variation of initial and maximum permeabilities with composition. In this case also, the permeability of the alloy containing 10.20 percent aluminium was increased most remarkably by heat treatment in a field. The minimum of coercive force is also obtained with the alloy containing 10.20 percent aluminium. In this case, we found that the maximum permeability of the alloy of 12.12 percent aluminium decreases extremely after the second heat treatment in a magnetic field.

From Figs. 1~3, it is concluded that the change of permeability and hysteresis loop by heat treatment in a field is most remarkable at the concentration of about 10 percent of aluminium. The following experiment was made mainly on the rod specimen of containing 10.20 percent aluminium. The relation between the permeability at room temperature and the temperature at which the magnetic field was first applied was observed for three different procedures. At first the specimen was cooled from 800°C at the rate of 150°C per hour and the magnetic field of 12.5 Oe was applied from various temperatures of the cooling. Curves (a) in Figs. 4 and 5 show the result.

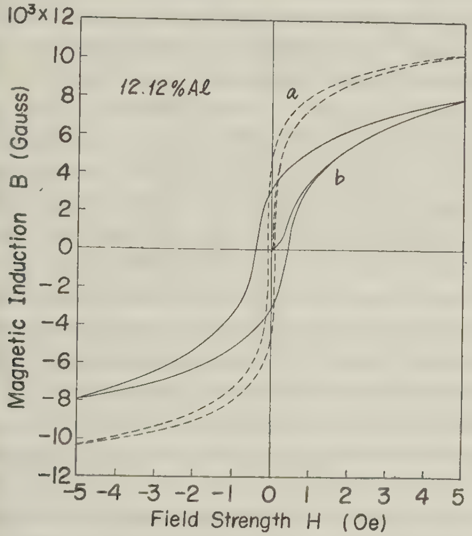

Fig. 2. Magnetization curves and hysteresis loops of the ring-shape specimens of several iron-aluminium alloys heat treated without or with a field.

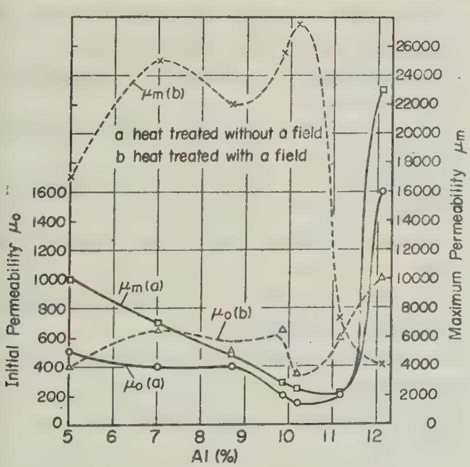

Fig. 3. Initial and maximum permeabilities of the ring-shape specimens of seven iron-aluminium alloys heat treated without or with a field.

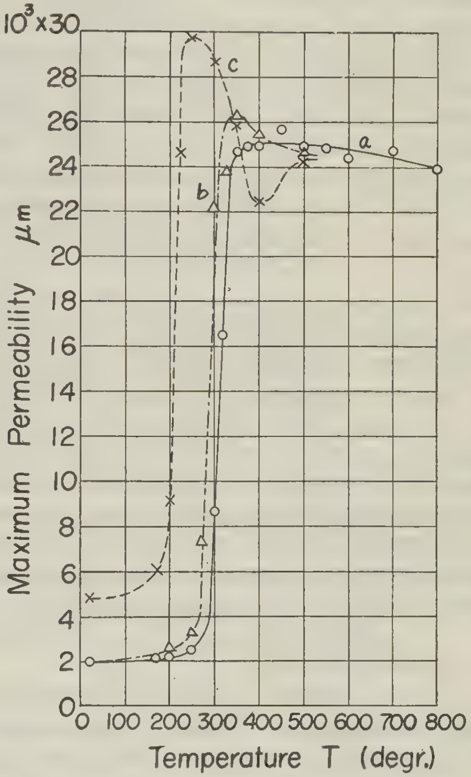

Fig. 4. Relation of maximum permeability (μ_m) of the specimen containing 10.20 percent aluminium to the temperature (T) from which a magnetic field was applied.

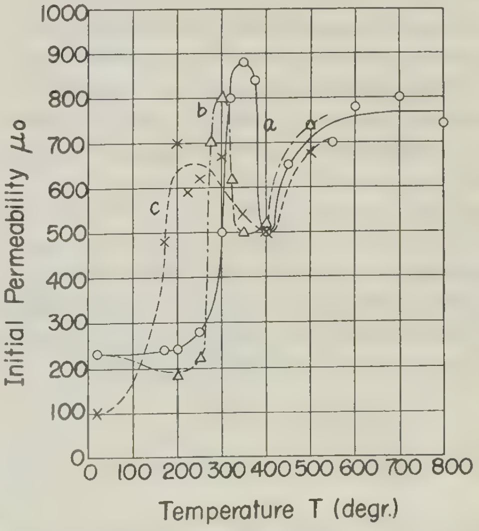

Fig. 5. Relation of initial permeability (μ_0) of the specimen containing 10.20 percent aluminium to the temperature (T) from which a magnetic field was applied.

Next the specimen which was first cooled from 800°C at the rate of 150°C per hour without a magnetic field was again inserted into the furnace at various temperatures and with a magnetic field, kept 30 minutes and cooled with the field at the rate of 150°C per hour. Curves (b) in Figs. 4 and 5 show the result. Lastly the specimen was first quenched from 600°C during cooling from 800°C, and the procedure identical to the case (b) followed. The result is shown by curves (c) in Figs. 4 and 5.

In Fig. 4, remarkable decreases in the maximum permeability μ_m are seen in the temperature range from 200°C to 320°C and the critical temperature is appreciably lower for curve (c). The maximum value of about 30,000 for curve (c) at $T=250$°C is the largest value of the maximum permeability in this study. In Fig. 5, considerably sharp maxima are observed in curves (a) and (b), and the corresponding temperatures are 350°C and 300°C for curves (a) and (b) respectively.

§ 4. Short Discussion

It is first pointed out in Fig. 4 that the effective temperature range of the magnetic field annealing is extended to 250∼225°C for the quenched specimen and the maximum permeability reaches its maximum value at this temperature range. This result will show that the most available effect of heat treatment in a magnetic field is present when the magnetic field is applied to the alloy that is recovering slowly from the quenched state. It is remarkable that such an large effect of heat treatment in a magnetic field is present at a comparatively low temperature range, ∼250°C.

In both curves (a) and (b) in Fig. 5, maximum values of initial permeability μ_0 are obtained by critical heat treatments in a magnetic field. This phenomenon is analogous to the one that was found in 65 permalloy and 45 25 perminvar by the author[8]. It is also interesting that a maximum value of μ_0 of iron-aluminium alloys was obtained when the heat treatment in a magnetic field was set up from the temperature at which the effect of this treatment on μ_m decreases rapidly.

§ 5. Summary

The permeabilities of vacuum melted ferromagnetic iron-aluminium alloys were measured and the relation of permeabilities to concentration of aluminium was also investigated for specimens heat treated with and without a magnetic field. In the concentration range of about 5 to 11 percent aluminium, the maximum permeability was increased and the hysteresis loop became rectangular after the heat treatment in a magnetic field. The change in these properties by heat treatment in a field was most remarkable at the concentration of about 10 percent aluminium, and the maximum permeability increased to 10–11 times as large as in the annealed state.

In conclusion the author wishes to express his hearty thanks to Dr. Y. Shichijō, the chief of the magnetic material research section of the Electrical Communication Laboratory, for encouragement.

Magnetic Anisotropy of Iron-Cobalt Ferrite measured by Ferromagnetic Resonance

By Yoshikazu SUGIURA

Electrotechnical Laboratory, Nagata-cho, Tokyo, Japan

(Received February 6, 1960)

The magnetic anisotropy of iron-cobalt ferrite is studied by means of ferromagnetic resonance. The cubic magnetic anisotropy K_1/M and the uniaxial magnetic anisotropy K_T/M induced by heat treatment in magnetic field are measured in the temperature range between 70°C and 250°C.

The secondary peak observed in the ferromagnetic resonance of iron-cobalt ferrite are explained by the domains having different orientation of uniaxial magnetic axis. From the experimental results g-factor of iron-cobalt ferrite is determined to be 2.86. The temperature dependence of g-factor has not been observed within limits of errors.

§ 1. Introduction

Numerous investigations have recently been made on single crystals of cobalt ferrite. It is well known that cobalt ferrite has a positive cubic magnetic anisotropy of large magnitude and exhibits a uniaxial magnetic anisotropy by heat treatment in magnetic field(1),(2),(3),.

The magnetic anisotropy of cobalt-substituted magnetite single crystals was measured by Bickford *et al*(4) and the origin of its magnetic anisotropy was explained by Slonczewski(5), considering the spin-orbit coupling energy of divalent cobalt ions placed in the crystal electric field of trigonal symmetry.

However, up to date, there have not been enough experiments for the mechanism of magnetic anisotropy of cobalt ferrite to be cleared. Especially, the temperature dependence of the uniaxial magnetic anisotropy constant has not been measured.

The ferromagnetic resonance of cobalt ferrite cannot be observed at room temperature by an ordinary method because of its large anisotropy energy, and its observations have been made only at elevated temperature at 24 KMc or higher frequencies(6). The resonance line is not simple, but secondary peaks are observed. Artman(7) suggested that the secondary peaks could be explained by the effect of unsaturated magnetization.

Our purposes are to show (1) how uniaxial magnetic anisotropy induced by magnetic annealing and cubic magnetic anisotropy of $Co_{0.8}Fe_{2.2}O_4$ depend on temperature and (2) whether secondary peaks of resonance lines can be explained by the domains having different orientations of uniaxial magnetic anisotropy, with results of ferromagnetic resonance observed at temperatures between 70°C and 250°C, using single crystals of the material with or without magnetic annealing.

§ 2. Experiment

The single crystals of iron-cobalt ferrite used for the measurement of ferromagnetic resonance are the same one reported by Sawaguchi *et al*(8), which are grown from the melt in a platinum crucible in air, using borax as flux. The composition was determined by chemical analysis as $Co_{0.8}Fe_{2.2}O_4$. The single crystals having regular shapes of octahedron of about 0.5 mm in side were selected.

A typical microwave transmission technique at 24.4 KMc is applied to measure the ferromagnetic resonance. The cavity used is that of TE_{109} mode, constructed of rectangular waveguide. As shown in Fig. 1, a mica plate is inserted in the middle point of the cavity to insulate thermally the lower part of the cavity from the upper. Chromel wires insulated with mica plates and glass ribbons are wound around the cavity to act as a furnace. In this way the temperature of the specimen is changed from room temperature to about 250°C. The loaded Q of the cavity is about 1000.

The electromagnet has pole pieces of 12 cm diameter with 2.95 cm gap between them. The maximum value of magnetic field is about 11300 oersteds at 10 amperes.

The specimen is rotated in such a way that the magnetic field is in the (010) plane.

The measurements are performed using the same specimen, under the three conditions as follows: (1) The specimen is fresh and magnetic annealing is not performed on it. (2) The specimen is annealed in the magnetic field parallel to its ⟨001⟩-axis. (3) The specimen is annealed in the magnetic field parallel to ⟨101⟩.

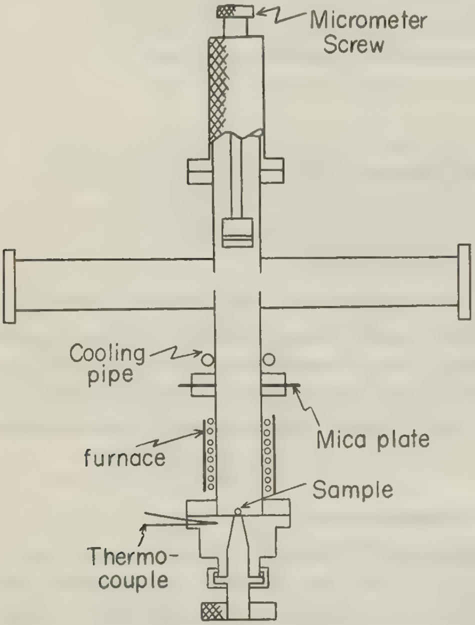

Fig. 1. Resonant cavity

The results obtained in each case will be described successively.

(1) *No magnetic annealing*

Magnetic resonance absorption cannot be observed at room temperature, but broad lines are found above about 70°C. In Fig. 2, the absorption lines at 148°C are shown as examples for various angles between the crystallographic axis and the external magnetic field. The angle zero means that the external magnetic field is parallel to ⟨001⟩.

Two peaks are observed in the resonance curve for each case and values of magnetic field at peaks depend on the angle and the temperature. This behaviour is shown in Fig. 3 at 82°C and 148°C. At 82°C the secondary peaks are not observed; from the curve given later in Fig. 4, which shows the temperature dependence of the secondary peaks, it is seen that the value of H where the secondary peaks appear decreases as the temperature is decreased, and will become zero for a certain temperature between 82°C and 148°C.

Taking the temperature of the specimen as absissa, the values of magnetic field at resonance are plotted in Fig. 4 at directions of ⟨001⟩, ⟨101⟩ and 23° from ⟨001⟩ in (010) plane.

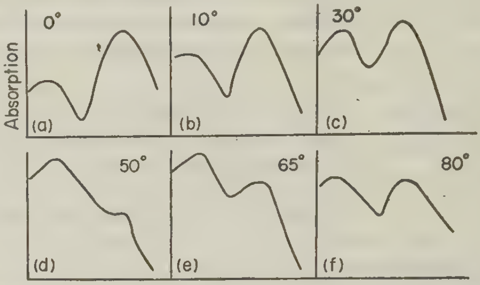

Fig. 2. Absorption *vs.* magnetic field at 148°C and 24.4 KMc.

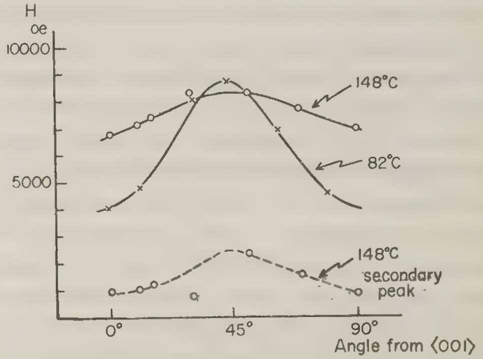

Fig. 3. Magnetic field at resonance *vs.* angle in (010) plane.

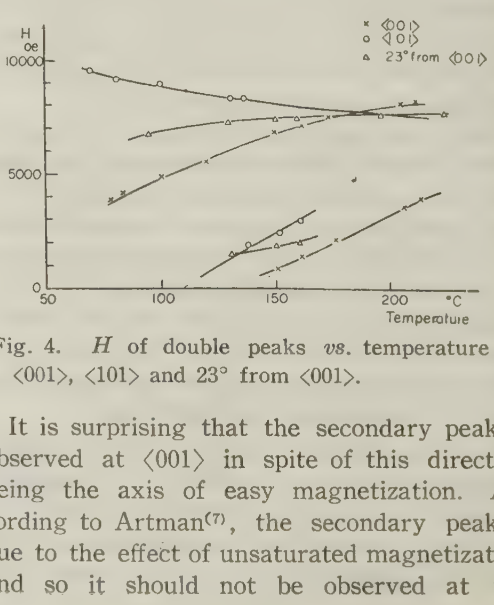

Fig. 4. H of double peaks *vs.* temperature at ⟨001⟩, ⟨101⟩ and 23° from ⟨001⟩.

It is surprising that the secondary peak is observed at ⟨001⟩ in spite of this direction being the axis of easy magnetization. According to Artman⁽⁷⁾, the secondary peak is due to the effect of unsaturated magnetization and so it should not be observed at the direction of easy magnetization. It should be concluded that these secondary peaks appear from another causes; this problem will be discussed in the next section.

Above 170°C the secondary peaks at ⟨101⟩ and 23° from ⟨001⟩ are not distinguished from the primary peaks. The broad primary peak seems to have masked the secondary one. Therefore, the values of magnetic field at resonance in this temperature region are not reliable. So it may not be concluded whether the magnetic anisotropy changes its sign at higher temperatures, although the upper curves in Fig. 4 cross one another at ca. 200°C.

(2) *Magnetic annealing parallel to* ⟨001⟩

The cobalt ferrite single crystal was cooled in air from 580°C to 200°C in one hour in a magnetic field of 10,000 oersteds parallel to ⟨001⟩. Then it was cooled down to room temperature in the same magnetic field within about half an hour.

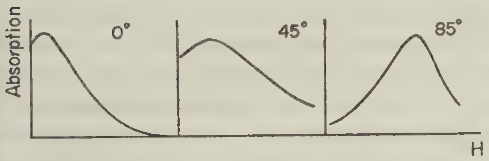

Fig. 5. Absorption *vs*. magnetic field at 115°C and 24.4 KMc, magnetic annealing parallel to ⟨001⟩. 0° shows the direction of ⟨001⟩.

Fig. 5 shows examples of the results obtained with the sample treated in this way, for various angles between the external magnetic field and ⟨001⟩ axis at 115°C. As shown in the figure, the line shape is simple and the secondary peak observed in the case of no magnetic annealing disappears. In Fig. 6 the magnitude of magnetic field at resonance is plotted against the angle. The measurements were performed at 66°C, 115°C and 165°C. The values of the external magnetic field at ⟨001⟩ and ⟨100⟩ are different from each other. This fact shows that the uniaxial magnetic anisotropy has been induced in the direction of ⟨001⟩ by heat treatment. The uniaxial anisotropy constant can be determined from the difference of these values. Its magnitude will be given in the following section.

Fig. 7 indicates the temperature dependence of resonance magnetic field strength for three different directions of the magnetic field relative to the crystal axes, namely ⟨001⟩, ⟨100⟩ and ⟨101⟩, of which ⟨001⟩ is parallel to the direction of the field at magnetic cooling.

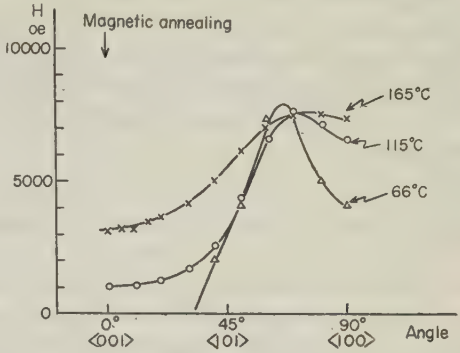

Fig. 6. Magnetic field at resonance *vs*. angle in (010) plane, magnetic annealing paralell to ⟨001⟩.

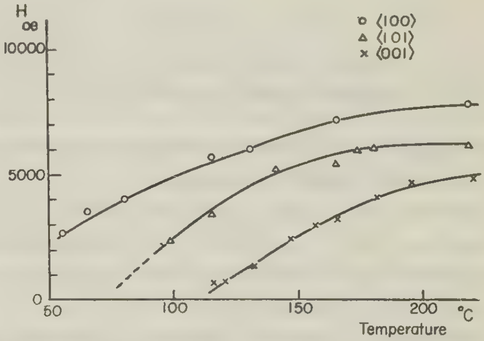

Fig. 7. Magnetic field at resonance *vs*. temperature, magnetic annealing parallel to ⟨001⟩.

(3) *Magnetic annealing parallel to* ⟨101⟩

In this case the line shapes are similar to those of ⟨001⟩ magnetic annealing given above. The resonance magnetic field strength is plotted in Fig. 8 against the direction of the magnetic field for three temperatures,

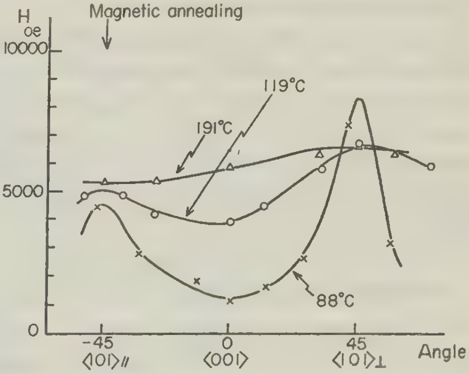

Fig. 8. Magnetic field at resonance *vs*. angle in (010) plane, magnetic annealing parallel to ⟨101⟩.

88°, 119° and 191°C. The same is plotted in Fig. 9 against temperature for the direction of the magnetic field at ⟨001⟩ and ⟨101⟩.

From these results it is found that the uniaxial magnetic anisotropy is induced in ⟨101⟩ by heat treatment in magnetic field.

The values of anisotropy constant will be given later.

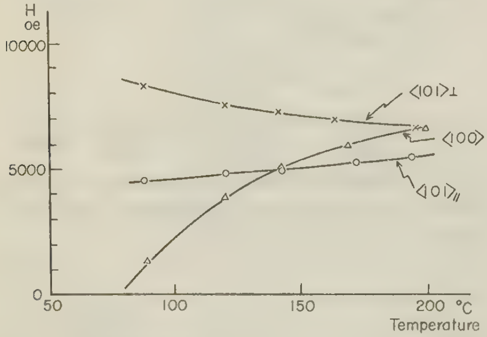

Fig. 9. Magnetic field at resonance *vs.* temperature, magnetic annealing parallel to ⟨101⟩.

§ 3. Relations between frequency and magnetic field at resonance

At first we shall consider the relations between the frequency and the external magnetic field at resonance in order to analyse the results of experiment.

It has been known from the observations that iron-cobalt ferrites have uniaxial magnetic anisotropy besides the ordinary cubic one. As there have been no quantitative studies on such a case, we shall calculate the conditions for the resonance according to the method used by Smit *et al*(9) and Suhl(10). We describe cubic and uniaxial magnetic anisotropy as K_1 and K_T, respectively. The higher terms of magnetic anisotropy are neglected in the following calculations.

Taking the cubic crystallographic axes as coordinates, we shall denote with α_1, α_2 and α_3 the direction cosines of the direction of magnetization M and β_1, β_2 and β_3 those of external magnetic field H. For a magnetic system the free energy can be written as follows.

$$\begin{aligned}F=&K_T\sin^2\theta+K_1(\alpha_1{}^2\alpha_2{}^2+\alpha_2{}^2\alpha_3{}^2+\alpha_3{}^2\alpha_1{}^2)\\&-MH(\alpha_1\beta_1+\alpha_2\beta_2+\alpha_3\beta_3)\\&+\frac{M}{2}(N_x\alpha_1{}^2+N_y\alpha_2{}^2+N_z\alpha_3{}^2),\end{aligned}$$

where θ is the angle between the uniaxial axis induced by magnetic annealing and M; N_x, N_y and N_z are the geometrical demagnetization factors.

The first term on the right-hand side is the uniaxial magnetic anisotropy energy and the second term is the cubic one. The third term is the magnetic interaction with the external magnetic field. The last term is the energy of demagnetization. The term of magnetostrictive energy is neglected.

The direction, in which this free energy has minimum value, is that of magnetization at equilibrium. Using this free energy, F, the resonance frequency is in general as follows.

$$\frac{\omega}{\gamma}=\frac{1}{M\sin\theta}\left[\frac{\partial^2F}{\partial\theta^2}\frac{\partial^2F}{\partial\varphi^2}-\frac{\partial^2F}{\partial\theta\partial\varphi}\right]^{1/2}.$$

θ and φ are the angles of magnetization in the spherical coordinate. γ is the gyromagnetic ratio. For simplicity, we assume henceforth that the sample is a shpere and $N_x=N_y=N_z=\frac{4\pi}{3}$ and external magnetic field is large enough that the magnetization can be considered homogeneous in the specimen.

The detail of calculations of resonance condition in various cases are not shown here, but it has been preformed according to the method by Artman(7). The relations between frequency and the magnetic field at resonance are summarized in the following.

Case I: H and uniaxial axis are always in (010) plane. The frequency at resonance is

$$\begin{aligned}\left(\frac{\omega}{\gamma}\right)^2=&\left[\frac{K_T}{M}\{1+\cos 2(\theta^1-\theta_0)\}\right.\\&\left.+\frac{K_1}{2M}\{3+\cos 4\theta_0\}+H\right]\\&\times\left[\frac{2K_T}{M}\cos 2(\theta^1-\theta_0)+\frac{2K_1}{M}\cos 4\theta_0+H\right].\end{aligned}$$

θ_0 is the angle between H and ⟨001⟩, and θ^1 is the angle between uniaxial axis and ⟨001⟩.

In this case the angle between H and M is given as

$$\varepsilon=\theta_0-\theta=-\frac{K_T}{MH}\sin 2(\theta^1-\theta)+\frac{K_1}{2MH}\sin 4\theta.$$

If cubic magnetic anisotropy only exists, it is seen from this equation that M coincides with H at $\theta=0$, $\frac{\pi}{4}$ and $\frac{\pi}{2}$. But if there is uniaxial magnetic anisotropy parallel te ⟨001⟩, $\varepsilon=0$ at $\theta=0$ and $\frac{\pi}{2}$. In general, except in the case where H is large enough compared with K/M, M dose not coincide with H at any direction. When this departure is large, the magnetic field at resonance differ considerably from the one obtained by putting $\varepsilon=0$. So when K/M is large, the magnetic fields at resonance cannot be used to estimate the anisotropy energy except the point of $\varepsilon=0$.

Case II: Uniaxial axis coincides with z-axis, but H is rotated in the (001) plane perpendicular to uniaxial axis.

In this case the frequency at resonance is given as follows.

$$\left(\frac{\omega}{\gamma}\right)^2=\left[\frac{2K_1}{M}\cos 4\varphi_0+H\right]$$
$$\times\left[-\frac{2K_T}{M}+\frac{K_1}{2M}\{3+\cos 4\varphi_0\}+H\right].$$

φ_0 is the angle between H and x-axis. Coincidence of M and H happens at $\varphi=0$, $\frac{\pi}{4}$ and $\frac{\pi}{2}$.

In the case of H and uniaxial axis being in the (110) plane the resonance frequency is given as follows, which we need not use for the present experiment.

$$\left(\frac{\omega}{\gamma}\right)^2=\left[\frac{K_T}{M}\{1+\cos 2(\theta^1-\theta_0)\}\right.$$
$$\left.+\frac{K_1}{8M}\{3\cos 4\theta_0+16\cos 2\theta_0-3\}+H\right]$$
$$\times\left[\frac{2K_T}{M}\cos 2(\theta^1-\theta_0)\right.$$
$$\left.+\frac{K_1}{2M}\{3\cos 4\theta_0+\cos 2\theta_0\}+H\right].$$

Although K_1/M and K_T/M can be obtained from the equations of resonance frequency mentioned above, the result is very complicated. But if K_1/M, $K_T/M \ll \boldsymbol{H}$, these equations are simplified in a good approximation as follows.

$$\text{Case I:}\quad H=\frac{\omega}{\gamma}-\frac{K_T}{2M}\{1+3\cos 2(\theta^1-\theta_0)\}$$
$$-\frac{K_1}{4M}\{3+5\cos 4\theta_0\},$$

$$\text{Case II:}\quad H=\frac{\omega}{\gamma}+\frac{K_T}{M}-\frac{K_1}{4M}\{3+5\cos 4\varphi_0\}.$$

In this case these simplified relations may be used to estimate magnetic anisotropy constant.

§ 4. Results

(A) K_1/M, K_T/M and g factor

We shall first discuss the case of magnetic annealing. The K_1/M and K_T/M values of the samples annealed in magnetic fields parallel to ⟨001⟩ and ⟨101⟩ are plotted in Fig. 10 against temperature.

(1) It can be known from this figure that K_1/M are nearly equal in both cases. These values are somewhat smaller than the one obtained for cobalt ferrite by Tannenwald(6), which are shown in the same figure by crosses. However, the temperature dependence of K_1/M obtained by him seems to agree with our results, as shown with dotted line. The discrepancy in K_1/M is likely to be due to the difference in the composition of cobalt ferrite used.

It might seem from Fig. 10 that K_1/M changes its sign at 200°C in the case of ⟨001⟩ magnetic annealing, but too much emphasis should not be put on this point, since there should be some error coming from the neglect of the effect of demagnetization in calculating such a small magnitude of K_1/M from the experimental results.

(2) The values of K_T/M depend on the direction of magnetic annealing. K_T/M in ⟨001⟩ magnetic annealing are twice as large as the one in ⟨101⟩.

According to the experimental results by Bozorth *et al*(1), the magnitudes of uniaxial magnetic anisotropy induced by magnetic annealing should be equal in all directions. In conflict with this conclusion, Iida *et al*(3) and Bickford *et al*(4) showed that ⟨100⟩ is the most effective direction for the magnetic annealing, while ⟨110⟩ is the least effective one in (001) plane. Our results lead to the same conclusion as the one obtained by Iida and Bickford. According to Iida's results using the sample $\frac{Co}{Co+Fe}=0.253$, $K_T=3.0\times10^5$ erg/g for ⟨100⟩ magnetic annealing and 1.6×10^5 erg/g for ⟨101⟩ at room temperature. In our experiment K_T are only measured above 100°C, and the composition of the sample, $\frac{Co}{Co+Fe}=0.267$, is different from Iida's. So our results are not directly compared to the one obtained by Iida. However, it should be noted that both results lead to the same conclusion that the ratio of K_T in ⟨001⟩ and ⟨101⟩

magnetic annealing is about two and ⟨001⟩ is the most effective direction for heat treatment in magnetic field.

(3) The temperature dependence of K_1/M and K_T/M are shown in Fig. 10. It is known from these curve that K_T/M in ⟨001⟩ and ⟨101⟩ magnetic annealing vary similarly with temperature, and that while K_1/M decreases rapidly with temperature and almost disappears at about 200°C, K_T/M values slowly and takes finite value 200°C.

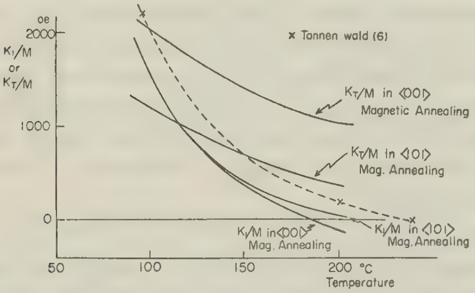

Fig. 10. K_1/M and K_T/M in magnetic annealing *vs.* temperature.

As a matter of course, these phenomena relate to the origin of induced uniaxial magnetic anisotropy and shall be discussed in section 5.

(4) *g* factor of iron-cobalt ferrite

The *g* factor of $Co_{0.8}Fe_{2.2}O_4$ is estimated from these experimental results as 2.86±0.06 in all range of temperature measured. The *g* factors reported by Tannenwald(6) are 2.7±0.3 at 90°C and 2.27±0.05 at 200°C. The reason for the discrepancy is not distinct, but it seems to be owing to the method of analysis.

(B) Secondary peaks

We consider the case of no magnetic annealing.

As shown in Fig. 2, resonance lines are broad and have secondary peaks. In crystals having large magnetic anisotropy the secondary peaks have previously been explained as follows(7). The external magnetic field is comparable with the magnetic anisotropy and hence magnetization cannot be aligned. Therefore, there exist domains with various direction of magnetization and the effect of domain walls produce the secondary peaks. According to this explanation, secondary peaks are not expected to be observed in the direction of easy axis.

We shall try the explanation from another point of view. Iron-cobalt ferrites, being cooled in zero magnetic field, have many domains. When they pass the Curie point and cool down, they are under the influence of a magnetic field parallel to their spontaneous magnetization. So in this specimen there are three kinds of domains having induced uniaxial anisotropy parallel to ⟨100⟩, ⟨010⟩ and ⟨001⟩, respectively. These domains cannot be brought to resonance for the same value of external magnetic field. When the magnetic field strength satisfies the conditions necessary for resonance for each domain, absorption takes place at different field strengths and secondary peaks are observed.

The experimental results shall be analized on this standpoint, with the assumption that each domain has the same volume.

When *H* is parallel to ⟨001⟩, the resonance condition is satisfied at two points of magnetic field by two parts of domains. The one has easy axis parallel and the other perpendicular to *H*. The volume of the latter is twice that of the former and is expected to show stronger resonance absorption, which is actually the case shown in Fig. 2 (a).

When *H* is parallel to ⟨101⟩, it makes 45° with the easy axis in the domains having uniaxial axis parallel to ⟨100⟩ and ⟨001⟩, but is perpendicular to easy axis in the domain having uniaxial axis parallel to ⟨010⟩. So the resonance absorption lines observed at lower and higher magnetic field and the former is twice as strong as the latter, as shown in Fig. 2 (d).

In the general case of *H* rotated in (010) plane, the domain having uniaxial axis parallel to ⟨010⟩ always satisfies the same condition of *H* being perpendicular to each axis, but the other domains satisfy different conditions depending upon angles, so three lines must exist, but they are not distinguished because of their broadness.

In calculating the value of K_1/M and K_T/M from Fig. 4, only the results with *H* in the ⟨001⟩-direction should be used, since the direction of *H* and *M* is not expected to be the same unless *H* is either parallel or perpendicular to uniaxial axis.

The results of the calculations for temperatures 100°, 150°, and 200°C are tabulated in Table I in comparison with these for magneti-

Table I.

	No magnetic annealing		<001> Magnetic Annealing		<101> Magnetic Annealing	
Temperature	K_1/M oe	K_T/M oe	K_1/M oe	K_T/M oe	K_1/M oe	K_T/M oe
100	1750	2180	1540	2030	1590	1670
150	640	1960	360	1420	400	700
200	−140?	1620	−100?	1050	50	370

cally annealed samples. The same g factor as obtained in the magnetic annealing has been used.

The values of K_1/M and K_T/M obtained from non-magnetically annealed samples are somewhat larger than these obtained from magnetically annealed samples, but considering the uncertainty due to the broadness and the different heat treatment, they seem to be rather in a good agreement.

It seems to be clear from these results that secondary peaks observed in cobalt ferrite are due to the domains having different uniaxial axis induced by the magnetic annealing owing to spontaneous magnetization.

§ 5. **Discussions**

(1) Cubic magnetic anisotropy K_1/M

The origin of magnetic anisotropy of ferrite has been recently discussed from many points of view. Among these theories, the assumption that the anisotropy is due to that of the crystalline field acting on the ions under question seems to be the most important in Mn- and Ni-ferrite. However, magnetic anisotropy of Co-ferrite has not been explained sufficiently.

K_1 of cobalt-substitued magnetite was measured by Bickford *et al*(4) between 120°K and 450°K. It was found that the total anisotropy of the cobalt-substituted magnetite is the additive effect of a contribution of the divalent cobalt ions superimposed on the anisotropy of magnetite itself and the contribution of the cobalt ions appears to be a linear function of concentration as long as the concentration is small.

Slonczewski(5) gave one-ion model. According to this model, cobalt ions occupying the octahedral sites of ferrite suffer from crystal electric field with trigonal symmetry and their spin couples to the axis through the spin-orbit coupling, so cubic anisotropy is produced on an average.

Slonczewski succeeded in explaining Bickford's results with his model. But his theory cannot be applied to the present cases, as the cobalt concentration is high in our experiment. Indeed, a formal calculation after Slonczewski's model gives about 10 times larger anisotropy value than our experimental anisotropy at 100°C.

Tachiki(11) has suggested that for a high concentration of cobalt ions the effects of Fe^{2+}, Fe^{3+}, and Co^{2+} ions should be taken into account. Our results may be explained with one-ion model in his regard. The temperature dependence of anisotropy will give a useful aid for the validity of the theory.

(2) Uniaxial magnetic anisotropy K_T/M

On the origin of uniaxial magnetic anisotropy induced by magnetic annealing, many theories based on following mechanisms has been presented. (1) Néel-type directional order between cobalt and iron ions(12), (2) The directional order between cobalt ion and cation vacancy(3), (3) Interaction between cobalt ion and the nearest cation through spin-orbit coupling(4), (4) The preferential growth of micro-precipitates of a second phase(13).

Iida and Bickfard discussed these mechanisms in detail and pointed out certain difficulties involved in them. However, it has not been understood which of the second and the third mechanisms is likely to be correct. No decisive conclusion can be obtained from our results.

From the facts obtained from the present experiment we shall consider the mechanism producing the uniaxial anisotropy. In magnetic field at higher temperature cations and cation vacancies in iron-cobalt ferrite line up in such a way that the interaction energy of cobalt ions with surrounding ions through spin-orbit coupling becomes minimum. While the sample is being cooled the alignment of cations and vacancies are left as it was, so cobalt ion will be placed in a crystalline field whose symmetry is different from trigonal one due to averaged cations in octahedron site, which gives cubic anisotropy on an average, and will have uniaxial anisotropy parallel to magnetic field.

(3) *g* factor

It is assumed generally that *g* factor is insensitive to temperature. Indeed, almost all ferrites have *g* factor independent or slightly dependent on temperature and our result shows the same behaviour within limits of errors. However, *g* factor of cobalt ferrite obtained by Tannenwald shows large temperature dependence. It seems reasonable that uniaxial magnetic anisotropy gives rise to an error for *g* factor, if only cubic anisotropy is taken into consideration.

(4) Secondary peaks

The secondary peaks observed in resonance absorption lines of iron-cobalt ferrite are discussed in the above section. It is worth while describing that if specimen has a large uniaxial anisotropy and has various domains even in an external magnetic field, subsidiary peaks owing to these domains must be considered. Indeed the secondary peaks suggested by Artman would also exist in this case.

The author would like to express their gratitude to Dr. G. M. Hatoyama for his kind encouragement. He is also indebted to Mr. E. Sawaguchi and Mr. N. Sakamoto for disucussions and preparations of specimen and to Mr, K. Matuura for measurements.

The Recovery of Initial Magnetic Susceptibility in Pure Nickel

By Mitsuru ASANUMA

Department of Physics, Faculty of Science, Hokkaido University

(Received February 18, 1960)

The process of recovery in cold-worked pure nickel was investigated by means of the initial magnetic susceptibility and the electrical resistance measurements. In our specimens, which were elongated by about 5 percent, the recovery of the initial magnetic susceptibility was observed above 450°C, and could not be observed below that temperature. The recovery in the temperature range of our investigation was expressed by logarithmic law, and analysed by Kuhlmann's formulation, its activation energy being 3.0 ev. This value is in good agreement with the activation energy of self-diffusion in pure nickel. Therefore, it is considered that the recovery of the initial magnetic susceptibility is due to the disappearance of dislocation in the stage of recrystallization

On the other hand, the recovery below 450°C in which the change of initial magnetic susceptibility could not be observed was investigated by measuring the electrical resistance and the activation energy 0.91 ev was obtained. This value is in good agreement with the activation energy of vacancy migration. Therefore, it must be assumed that the disappearance of vacancy does not affect the initial magnetic susceptibility.

1. Introduction

Since the cold-worked condition is themoynamically more unstable than the unstrained ne, cold-worked metal undergoes spontaneous hanges to reduce the extra free energy which as gained from the work done on metal. he processes which reduce the extra free nergy, that is, recovery, primary recrystalization, secondary recrystallization and grain rowth are distinguished one another in etallographic observation. Recovery is the henomenon in which cold-worked metal is oftened without recrystallization, and can not e detected by conventional metallographic ethod, but detected by means of measureents of specific heat, mechanical hardness, ield stress, electrical resistance and the line idth of X-ray Debye-Scherrer line. In addiion to the above mentioned annealing process he phenomena which is called polygonization s found by Orowan and Chan¹⁾. It seems referable to regard this phenomenon as one f the process of recovery, but this is not the hole of recovery. This is shown by the fact hat the recovery occurs after laminar plastic ow in hexagonal crystals where there is no attice bending to provide the excess edge islocations of one sign needed for polygonizaion. Thus the mechanism in recovery is omplicated. In the past, many investigators attempted to explain the basic process in recovery. Burgers²⁾ suggested that this process was the annihilation of two dislocations of opposite signs in the same slip system, but he did not discuss how they annihilate one another when they are on different planes.

Kuhlmann³⁾ considered that the recovery occurs by dislocations gliding in their slip planes over barriers with aid of thermal activation, and developed a formal theory under the idea that the activation energy for recovery is a decreasing function of mean internal stress in the material, and explained the logarithmic law of softening during recovery in the experiments of Kuhlmann, Masing and Raffelsieper⁴⁾, Cottrell and Aytekin⁵⁾ and Borelius⁶⁾.

On the other hand, Mott⁷⁾ believed that the basic process is the climbing of dislocations out of their slip planes by the migration of vacancies, and formulated an expression of recovery.

Thus, the details of recovery has not yet been clarified. In such an investigation it is needed to investigate by using the sensitive quantities to structural changes in material due to recovery.

In ferromagnetic metals, a typical one of the structure-sensitive quantities in the initial magnetic susceptibility or the coercive force, and these quantities can more precisely be measured than the mechanical hardness or the yield stress. Moreover it was qualitatively shown that the initial magnetic susceptibility and the coercive force were connected with the internal stress in materials by Becker and Kersten[8], and these quantities were recently discussed in association with dislocation which was the origin of internal stress by Kersten[9], Kneller[10] and Vicena[11]. Then, in order to investigate the annealing process of metals, the initial magnetic susceptibility was used.

§ 2. Specimen and Experimental Procedures

The specimen in which the internal stress has predominant effect on the initial magnetic susceptibility must be selected for the purpose of the present investigation. The internal stress affects the initial magnetic susceptibility through the magnetostriction. Thus a metal whose magnetostriction constant is large must be selected. Among the pure metal nickel is adapted for the above conditions.

Nickel wires which were of 1.2 mm in diameter and 180 mm in length were prepared, and at first they were annealed in vacuum at 1100°C during two hours. Then they were streched by 5 percent as uniformly as possible, and tempered at an appropriate temperature. And the changes of the initial magnetic susceptibility or the electrical resistance were measured as a function of tempering time.

The initial magnetic susceptibilities were measured by means of ballistic galvanometer method, and the values of the initial magnetic susceptibilities were about 30 *emu* in annealed state and about 2 *emu* in cold-worked state, respectively.

§ 3. Experimental Results and Analysis

Tempering temperatures were chosen at 50°C interval from 300°C to 700°C, and at each temperature the relation of the initial magnetic susceptibility to the tempering time was shown in Fig. 1. The changes of the initial magnetic susceptibilities were not recognized at temperatures below 450°C, but clearly detected in tempering above 500°C. The time dependences of the initial magnetic susceptibilities were followed by logarithmic law for all temperature. Therefore, the author attempted to analyse this experimental result according to Kuhlmann's formulation[3]

The apparent activation energy for recovery is assumed to decrease linearly to internal stress as far as it is small:

$$U(\sigma)=U_0-\beta\sigma$$

where U_0 is the intrinsic activation energy, U is the apparent activation energy, β is a constant for the range of stress chosen and σ is internal stress. The rate of recovery of internal stress is

$$\frac{d\sigma}{dt}=-C\exp\left\{-\frac{U_0-\beta\sigma}{kT}\right\}. \qquad (1)$$

On the other hand, the internal stress is related approximately by the initial magnetic susceptibility χ as follows;

$$\sigma=\frac{D}{\chi}, \qquad (2)$$

where D is a function of the saturation magnetization and the magnetostriction constant, and depends upon the mechanism that the magnetization proceeds, or magnetic domain distribution. As the saturation magnetization I_s and the magnetostriction constant do not sensitively depend on cold-working, D is approximately regarded as a constant which depends on ferromagnetic materials.

From equation (1) and (2)

$$t=\frac{kT}{C\beta}\exp\left(\frac{U_0}{kT}\right)$$

$$\left\{\exp\left(-\frac{\beta D}{kT}\frac{1}{\chi}\right)-\exp\left(-\frac{\beta D}{kT}\cdot\frac{1}{\chi_0}\right)\right\},$$

where χ_0 is the value of χ in $t=0$, i.e. just after cold-working. When one takes to

$$t_0=\frac{kT}{C\beta}\exp\left\{\frac{U_0-\beta D\frac{1}{\chi_0}}{kT}\right\}, \qquad (3)$$

and reduces by $1/\chi$ values in $t=0$,

$$\frac{1}{\chi}\bigg/\frac{1}{\chi_0}=\mathrm{B}-A\ln(t+t_0), \qquad (4)$$

$$\text{where}\quad \left.\begin{aligned}A&=\frac{kT}{\beta D}\\ B&=\frac{kT\chi_0}{\beta D}\ln\frac{kT}{C\beta}+\frac{U_0\chi_0}{\beta D}\end{aligned}\right\} \qquad (5)$$

Therefore, the recovery of the initial magnetic susceptibility is expressed by the logarithmic law, when $t_0 \ll t$, that is,

$$\frac{1}{\chi}\bigg/\frac{1}{\chi_0}=B-A\ln t. \qquad (6)$$

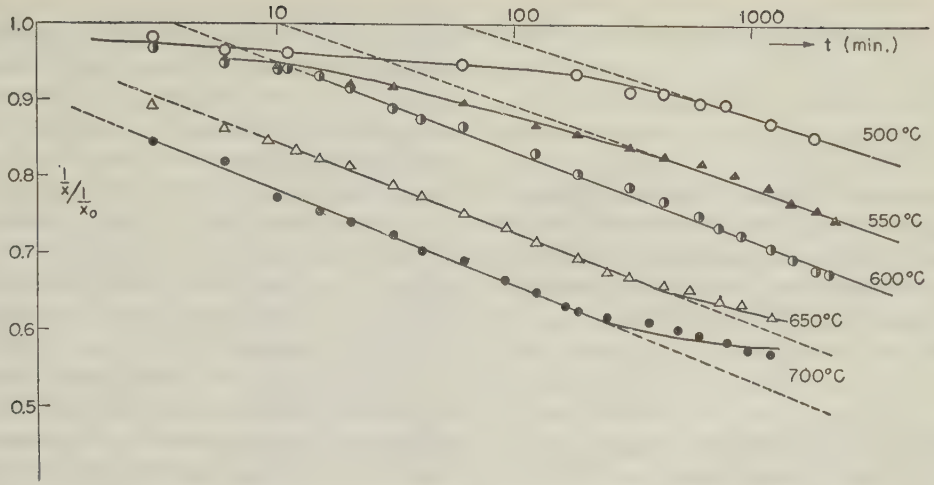

Fig. 1. Isothermal recovery of the initial magnetic susceptibility of pure nickel.

Now, from the inclinations of linear parts of he curves in Fig. 1 the values of A correspon-ing to each temperature are obtained. When the values of A are plotted against bsolute temperature T, Fig. 2 is obtained, nd the curve is represented as the straight ine through the origin as follows:

$$A=6.26\times10^{-5}T. \qquad (7)$$

From the equations (5) and (7)

$$\frac{\beta D}{\chi_0}=\frac{k}{6.29}\times10^5=1.37\text{ ev}. \qquad (8)$$

Further, considering B in equation (5), logari-hmic factor in the expression of B changes nly about 2% in the present temperature ange, so that it is approximately regarded s that first term of B is proportional to bsolute temperature T. The values of B vere determined by extrapolating the parts f the straight lines in Fig. 1, and finding the ntersecting points with longitudinal axis. And vhen these values are plotted against the bsolute temperature, B curve in Fig. 2 is btained and this curve is represented as ollowing straight line:

$$B=2.19-1.32\times10^{-3}T \qquad (9)$$

ombining equations (5) and (9)

$$\frac{U_0\chi_0}{\beta D}=2.19. \qquad (10)$$

rom equations (8) and (10)

$$U_0=3.0\text{ eV}.$$

hus the activation energy for recovery of e initial magnetic susceptibility is 3.0 ev.

On the other hand, the recovery in the temperature range below 450°C which does not affect the initial magnetic susceptibility can be detected by measuring the change of the electrical resistance followed by isothermal tempering. If the change of the electrical resistance is expressed by the following relation;

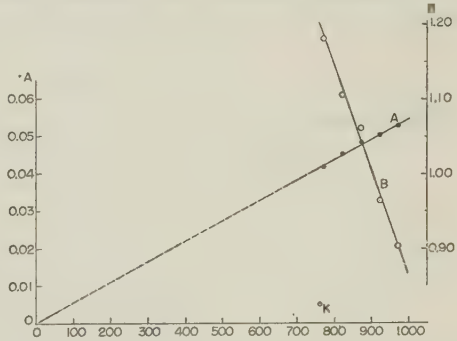

Fig. 2. The dependence of parameter A and B on temperature.

$$\frac{R_0-R_t}{R_0-R_\infty}=1-\exp\left(-\frac{t}{\tau}\right),$$

or

$$\ln\frac{R_t-R_\infty}{R_0-R_\infty}=-\frac{t}{\tau}, \qquad (11)$$

where R_0, R_∞ and R_t are the values of the electrical resistance in $t=0$, $t=\infty$ and $t=t$, respectively, and t is an annealing time and τ is the relaxation time.

Plotting the experimental values according to the equation (11), Fig. 3 is obtained. The relation between the relaxation time τ and the activation energy U' is expressed as follows:

$$\tau=\tau_0\exp\left(\frac{U'}{kT}\right). \tag{12}$$

Therefore

$$\ln\tau=\ln\tau_0+\frac{U'}{kT} \tag{13}$$

The relaxation times are determined from the inclinations of the straight lines in Fig. 3 at various temperatures, and plotted against the inverse temperature. Fig. 4 shows this result. From Fig. 4 it is determined that

$$U'=0.91\text{ eV}.$$

§ 4. Discussion

In order to investigate the annealing kinetics. Boas[12] measured the changes in internal energy, electrical resistivity, density and hardness which occur during the annealing of nickel deformed at room temperature. According to his result, the energy stored during deformation is released in three stages and the change in internal energy has two distinct peaks. The first stage is accompanied with the decrease in electrical resistivity, but any reduction in hardness does not occur. The second stage occurs over a temperature range where there are only a slight decrease in hardness and electrical resistivity. The third stage is associated with a large and sudden decreases in hardness and electrical resistivity.

He has explained the origins of the first, the second and the third stages as being due to the disappearance of vacancies, the rearrangement of dislocations into configurations with lower energy and the disappearance of dislocations during recrystallization, respectively. His experiment shows that the activation energy for the first stage is 1.0 eV and it is in good agreement in order of magnitude with the results of the experiments in quenched or neutron irradiated pure nickel.

The results obtained in the present work at the temperature range below 400°C show that the activation energy for recovery in this range is about 0.9 eV, and the change of the initial magnetic susceptibility has not been recognized. Since the magnetic properties are of volume-effect, and the internal strain caused by the vacancy in material is considered as of short-range, it is not unreasonable to assume that the disappearance of vacancies shows no effect on the initial magnetic susceptibility. Furthermore, this activation energy, 0.9 eV, agrees with the result by Boas[12] and it is concluded that the origin of recovery at the temperature range below 400°C is the disappearance of excess vacancies created into material by cold-working. While it seems that the change of the electrical resistance is described at least in one simple vacancy mechanism below 400°C, the critical temperature in which the another mechanism is superposed on it is not clearly determined.

Recently, the effect of quenching vacancy on the magnetization in earth magnetic field was studied by Takamura and Nakamura[13], and they explained that the climbing of dislocations following the vacancy migration to dislocations affects the magnetization in earth magnetic field. However, the defects which are created on quenching are a large number of vacancies and small amounts of dislocations, and if these vacancies diffuse towards the dislocations and the dislocations climb out of their slip planes at room temperature, a sufficient number of jogs must be always present. The climbing of the dislocation without jog needs a large activation energy in nickel having half-dislocation and will hardly occur. A sufficient number of jogs will be created only by the motion of dislocations through the forest of screw dislocations. In their quenching experiments, therefore, the number of jogs will not be sufficiently much, and the rate of climbing of the dislocation should be greatly reduced as compared with the case in which a sufficient number of jogs is present, and the activation energy of climbing should be equal to that of self-diffusion. From these view points, it seems that their explanations of the results in their experiments which were done in room temperature are not appropriate. However, as the diffusion of vacancy and the climbing of dislocation depend on the purity of specimen, in order to conclude the problem, more detail experiments on the specimens having various purities are desirable to be attempted.

On the other hand, the result at the temperature range above 450°C shows the remarkable increases of the initial magnetic susceptibility which depends on internal stress in material according to the equation (2). The decrease of internal stress following annealing will be caused by the disappearance or the rearrangement of dislocations which were created by cold-working. The activation energy obtained in the present work at high temperature is 3.0 eV, and this is in good agreement with the activation energy of self-diffusion in pure nickel which Seeger[14] has obtained. This energy is also nearly equal to the activation energy for the steady-state creep at high temperature which is explained by the climbing of dislocations, wnich is promoted by self-diffusion. According to Kersten[9], the initial magnetic susceptibility is inversely proportional to square root of dislocation density and Vicena[11] has been suggested that the coercive force of pure bulk ferromagnetics is proportional to square root of dislocation density. In the former regular arrangement of dislocations, in the latter statistical distribution of dislocations were assumed, respectively. Moreover, according to Seeger[15] the flow stress in the case in which the dislocations are distributed at random is given by the equation, $\sigma = \alpha b G\sqrt{n}$, where n, b, G and α are the number of dislocations in unit area, Burger's vector, shear modulus and constant which depens on the arrangement of dislocations, respectively. From the above mentioned results, it is concluded that the decrease of the number of dislocations which is caused by self-diffusion plays an important role in the increase of the initial magnetic susceptibility. The dependence of the initial magnetic susceptibility on the rearrangement of dislocations is not clear.

The apparent activation energy of recovery of the initial magnetic susceptibility at high temperature, $U_0 - \beta\sigma_0$, depends on the degree of cold-working. In the present work, this activation energy is evaluated from Fig. 5, which is drawn according to the equation (3), and

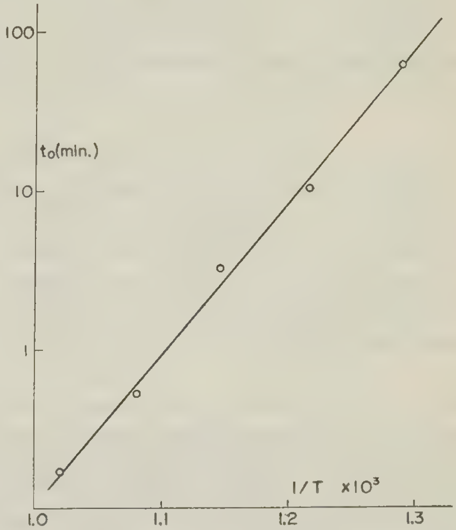

Fig. 5. The dependence of t_0 on temperature.

$$U_0 - \beta\sigma_0 = 43.6\ \text{kcal/mol}. \qquad (14)$$

Hence, $\beta\sigma_0 = 25.4$ kcal/mol. The apparent activation energy which is shown in equation (14) must be distiguished from the activation energy of recovery of the electrical resistance at low temperature, since in the present degree of cold-working $\beta\sigma_0$ is 25.4 kcal/mol and the apparent activation energy at $t=0$ is 43.6 kcal/mol and is greater than the activation energy of vacancy migration. If the degree of cold-working is more high, in other words, if $\beta\sigma_0$ is more large, the apparent activation energy become less and the recovery of the initial magnetic susceptibility will be found at lower temperature than the present case.

The change of the electrical resistance in high temperature region was not measured. But it is expected that both mechanism of the disappearance of dislocations and vacancies will be superposed.

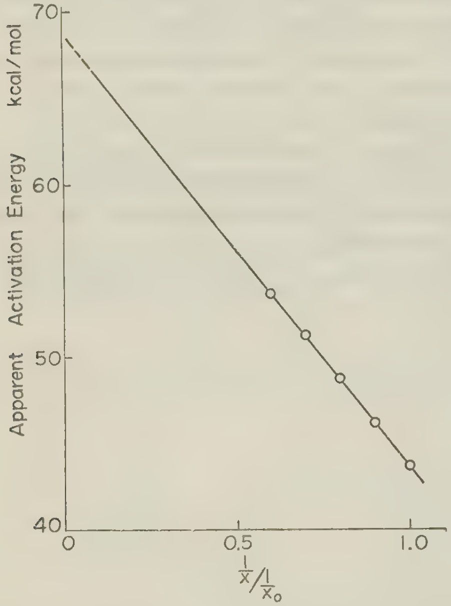

Fig. 6. The dependence of the apparent activation energy on $\frac{1}{\chi}\Big/\frac{1}{\chi_0}$.

When the apparent activation energy, $U_0-\beta\sigma=U_0-\frac{\beta D}{\chi}$, is plotted against $\frac{1}{\chi}\Big/\frac{1}{\chi_0}$, fig, 6 is obtained. This result shows that β is a constant for the range of stress chosen, as one assumed in equation (1). The evaluation of β is difficult, unless σ is measured directly, because D depends on the magnetic domain distribution and the mechanism of magnetization in weak magnetic field and can not be precisely determined.

§ 5. Conclusions

The recovery of the initial magnetic susceptibility was followed by logarithmic law at all temperatures, and it was analysed by Kuhlmann's formulation. Its activation energy was 3.0 eV and agreed with that of self-diffusion in pure nickel. It is concluded that the mechanism of recovery of the initial magnetic susceptibility is disappearance of dislocations followed by climbing of dislocations through the self-diffusion and it corresponds to the stage of recrystallization.

The recovery in the region where the change of the initial magnetic susceptibility could not be found was investigated by the measurement of electrical resistance, and the activation energy was estimated to be 0.9 ev. This activation energy agrees with that of vacancy migration. Hence, it is concluded that the recovery at low temperature is caused by the disappearance of excess vacancies. It is noted that the structure-sensitive magnetic properties are successfully adopted for the investigation of the recovery.

The author wishes to express his sincere thanks to Professor S. Miyahara and Professor S. Kôda for valuable advice and discussion throughout the course of the present study.

The Electron Paramagnetic Resonance of Mn^{2+} Ions Surrounded by an Octahedron of Fluorine Ions

By Shinji Ogawa

Research Institute of Applied Electricity,
Hokkaido University, Sapporo

(Received March 3, 1960)

The measurements of the EPR of Mn^{2+} ions as dilute, substitutional impurities in the single crystals of $KMgF_3$, $KCdF_3$, $KCaF_3$, K_2MgF_4 and $NaMgF_3$ were made. An X-ray examination revealed that divalent metal ions in these crystals were surrounded by an octahedron of six fluorine ions. The F^{19} "super-hfs" superimposed on the usual hfs of Mn^{55} has been observed. The dependence of the F^{19} hf interaction constant (A_s) upon the Mn^{2+}–F^- distance has been noticed and discussed. The A_s in $KMnF_3$ has been estimated to be somewhat smaller than $16.7\times10^{-4}\,cm^{-1}$.

1. Introduction

Since Griffiths and Owen[1] observed the yper fine structure (hfs) due to the nuclear pins of neighboring anions in the electron aramagnetic resonance (EPR) of Ir ions in he alkali chloroplatinates, the so-called "super-fs" has been observed in a few fluorides[2–5] nd found to be very powerful tool, together vith the shift in the NMR[6], in investigating he electronic state of magnetic electrons in rimarily ionic crystals.

On the other hand, the strong magnetic iteraction in an antiferromagnetic or ferri-iagnetic compound of ionic nature has been xplained by the superexchange interaction[7] vhich result from a departure from a purely onic state, due to partial covalency and overapping with neighboring ions. Therefore, ie observation of the super-hfs will also offer n important information to understand the uperexchange interaction.

In the EPR experiment of Mn:ZnF_2, Tinkam[2] found a rather large difference in two ^{19} hf interaction constants which correspond) two types of Mn–F pairs with slightly diferent separations. Although a recent rexamination[3] has diminished the difference, ie dependence of the F^{19} hfs upon the Mn– distance should be studied in order to know ie F^{19} hf interaction constant in a dense, iagnetic crystal and compare the EPR data vith the NMR data.

In connection with the antiferromagnetism bserved in $KMnF_3$[8], an EPR experiment of ie Mn^{2+} ions diluted in many compounds as ossible which have a similar anion environment to $KMnF_3$ was intended. The present paper reports the EPR experiment of Mn^{2+} ions in the single crystals of $KMgF_3$, $KCdF_3$, $KCaF_3$, K_2MgF_4 and $NaMgF_3$. Although the result of Mn^{2+}:$KMgF_3$ has been reported briefly[9], it is included in this paper for the detailed account and a slight correction.

§ 2. Preparation of Crystals

The compounds such as $KMgF_3$, K_2MgF_4, $KCdF_3$, $KCaF_3$ and $NaMgF_3$ have been hitherto prepared by several ways; by precipitating from aqueous solutions, by a direct fusion of RF and MF_2, or by the reaction $MO+3RF\rightarrow RMF_3+R_2O$ (where R is K or Na and M is Mg, Cd or Ca).

In the present study, a flux method was tried and found to be suitable to get the single crystals being sufficiently large for our purpose. To prepare the KMF_3, anhydrous MCl_2 and $3KHF_2$ were heated up to melt in a platinum crucible in the air and cooled slowly at the rate of about 50°~20°C per hour. They melted above ca. 850°C and the reaction $MCl_2+3KHF_2\rightarrow KMF_3+2KCl+3HF\uparrow$ occurred. On cooling, the compound KMF_3 precipitated in the flux KCl. After the flux was washed out by water, single crystals of cubic shape with surfaces parallel to {100} planes were obtained. The crystal K_2MgF_4 was prepared from $MgCl_2$ and $4KHF_2$ at first. After a few trials, an addition of excess KHF_2 was found to be useful to prevent a growing of the mixed crystal of $KMgF_3$ and K_2MgF_4 which had grown frequently when the exact 1 to 4 ratio of mixing had been used. The single crystal of $NaMgF_3$ was obtained in a similar way using $NaHF_2$ instead of KHF_2. The largest single crystal obtained was that of $KMgF_3$ with a dimension $12 \times 10 \times 7\ mm^3$. It was rather difficult to grow up the single crystals of $KCdF_3$ and $KCaF_3$. A long time and a slow cooling rate of about 20°C per hour were necessary to get a single crystal of $3 \times 3 \times 2\ mm^3$.

For the purpose of EPR study, manganese ions were solved in the above crystals by adding the anhydrous $MnCl_2$ in about 0.1% molar concentration to the starting mixture, but the intensity of EPR spectrum suggested that about one tenth of added manganese ions had solved into the single crystals. The pink color of the KCl flux showed that the rest of manganese ions remained as solved in KCl.

§ 3. X-ray Examination

There have been many studies of the crystal structure of the above mentioned compounds, but some are contradictory to others. For example, cubic perovskite and monoclinic structures are reported for $KMgF_3$. Because of this confusion, all crystals used in the EPR experiment were examined by X-ray measurements through Debye-Scherrer and rotating crystal methods. In contrary to the lower symmetry reported earlier, our specimens of $KMgF_3$, $KCdF_3$ and $KCaF_3$ had a perfectly cubic symmetry. The width of diffraction lines was very narrow, less than 0.15 degree in 2θ. The discrepancy in crystal symmetry is possibly due not to the error in measurement but to the crystals themselves prepared in different ways. The data of our examination are listed in Table I.

Table I.

Compound	Crystal structure and lattice constant	M^{2+}–F^- distance	Structures reported hitherto
$KMgF_3$	Cubic (perovskite-like) $a=3.987 \pm .001$Å	1.994Å	Cubic[a,b,c,d,e], monoclinic[f,g]
$KCdF_3$	〃 〃 $a=4.334 \pm .001$Å	2.167Å	Cubic[h], pseudo-cubic[i]
$KCaF_3$	〃 〃 $a=4.375 \pm .001$Å	2.188Å	Pseudo-cubic[a], monoclinic[h]
K_2MgF_4	Tetragonal, D_{4h}–17 $a=3.982 \pm .002$Å $c=13.145 \pm .005$Å	1.991Å	Tetragonal[e], D_{4h}–17[j]
$NaMgF_3$	Orthorhombic $a=5.485$Å, $b=7.678$Å $c=5.356$Å all in ± 0.005Å	——	Tetragonal[j]

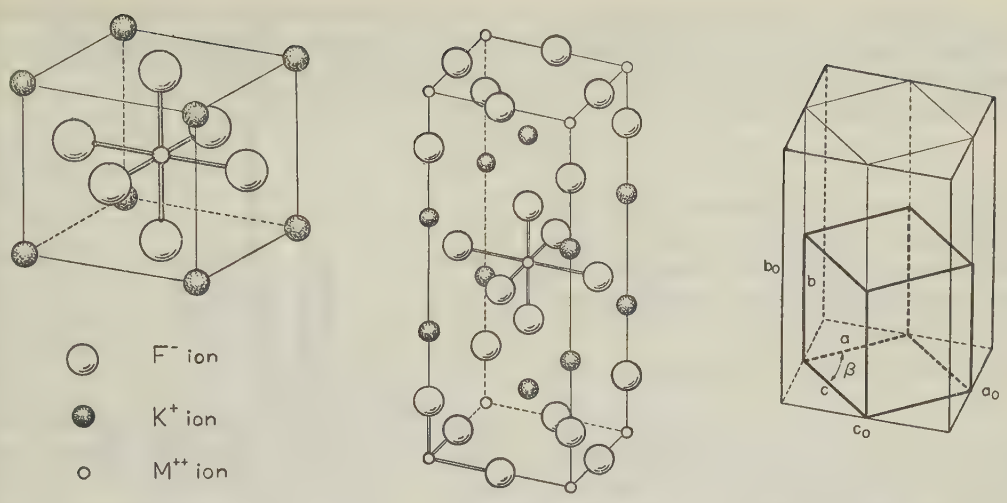
The rotating crystal photograph revealed that the most probable space group of $NaMgF_3$ was D_{2h}–16, though the lower symmetry was not impossible. This orthorhombic lattice can be regarded as a distorted perovskite-like structure. The relation is shown in Fig. 1 together with the crystal structure of K_2MgF_4.

§ 4. EPR Experiment

The EPR experiment was carried out by a standard X-band ($\sim 0.3\ cm^{-1}$) spectrometer with a cavity of reflection type. A technique of magnetic modulation of small field (about 2∼3 Oe.) and phase sensitive detection was used. A derivative of absorption was therefore recorded. The measurement was made at room temperature and at 77°K.

Divalent metal ions in the compounds KMF_3 having a cubic perovskite structure occupy only one crystallographic site (1b) which is surrounded by six fluorine ions at the corners of an octahedron. All manganese ions which were substituted for the divalent metal ions are therefore expected to show an equivalent spectrum.

The ground state of the Mn^{2+} ion, $3d^5\ {}^6S$,



(a) (b) (c)

Fig. 1(a). A cubic perovskite structure. (b) The crystal structure of K_2MgF_4, D_{4h}-16. (c) The relation between an orthorhombic unit cell (a_0, b_0, c_0) and a distorted perovskite-like (monoclinic) pseuao-cell ($a=c, b, \beta$).

in a crystalline field of cubic symmetry is described in a good approximation by the spin Hamiltonian:

$$\mathscr{H}=g\beta\boldsymbol{S}\cdot\boldsymbol{H}+A^{55}\boldsymbol{S}\cdot\boldsymbol{I}+(a/6)[S_x^4+S_y^4+S_z^4-(1/5)S(S+1)(3S^2+3S-1)]\,, \tag{1}$$

where S and I are both 5/2, A^{55} is the hf interaction constant of a divalent Mn^{55} ion, a the cubic crystalline field splitting parameter, and g and A^{55} are assumed to be isotropic. The resonance field, H_r, can be deduced[10] from (1) in an approximation in first order of a and second order of A^{55};

$$g\beta H_r=h\nu_0-A^{55}m_I-[(A^{55})^2/2h\nu_0][I(I+1)-m_I^2+m_I(2M-1)]+F(a)\,, \tag{2}$$

where

$$F(a)=\begin{cases}0 & (\text{for } M=+1/2\leftrightarrow-1/2 \text{ transition})\\ \pm(5/2)pa & (\text{for } M=\pm3/2\leftrightarrow\pm1/2 \text{ transitions})\\ \mp2pa & (\text{for } M=\pm5/2\leftrightarrow\pm3/2 \text{ transitions})\,,\end{cases}$$

$$p=1-5(l^2m^2+m^2n^2+n^2l^2)\,,$$

and l, m and n are direction cosines of the external magnetic field with respect to the cubic axes of crystal.

In addition, there will be an interaction between an electron spin of a manganese ion and nuclear spins of six fluorine ions in its neighboring lattice sites. A theory of this interaction has been given by Tinkham[11] and its modification by Clogston *et al.*[3] for $Mn{:}ZnF_2$.

The interaction Hamiltonian is,

$$\mathscr{H}'=g\beta\gamma\beta_N\sum_{i,j}\left[-\frac{\boldsymbol{S}_i\cdot\boldsymbol{I}_j}{r_{ij}^3}+\frac{3(\boldsymbol{r}_{ij}\cdot\boldsymbol{S}_i)(\boldsymbol{r}_{ij}\cdot\boldsymbol{I}_j)}{r_{ij}^5}+\frac{8\pi}{3}\delta(\boldsymbol{r}_{ij})\boldsymbol{S}_i\cdot\boldsymbol{I}_j\right] \tag{3}$$

where r_{ij} is the electron-nucleus distance and i is summed over electrons and j over neighboring six fluorine nuclei.

By taking an expectation value with the orbital wave function of magnetic electron, one can get an effective spin Hamiltonian. Tinkham[11] has chosen the molecular orbitals used by Stevens and Owen[12] for the wave function of magnetic electron, and Clogston *et al.*[3] have moreover taken into account of the electron transfer effect. The spin Hamiltonian can be written in the from,

$$\mathscr{H}'=\sum_j \boldsymbol{S}\cdot A_j^{19}\cdot \boldsymbol{I}_j\,. \qquad (4)$$

The above theories were originally given for an orthorhombic symmetry. In our case of a cubic symmetry, the treatment can be simplified and the shift of the resonance field due to (4) is given by

$$\delta H=A_s\sum_j m_j+(A_p+A_D)\sum_j m_j(3\cos^2\theta_j-1)\,, \qquad (5)$$

where $m_j=+(1/2)$ or $-(1/2)$, θ_j is the angle between the external magnetic field and the σ-bonding axis to the j-th fluorine ion, A_s is a contribution from the admixed fluorine $2s$ orbital, A_D a dipole contribution from the original $3d$ electrons, and A_p a contribution from the admixed fluorine $2p$ orbital and is equal to $(A_{p\sigma}-A_{p\pi})$. Since the two $p\pi$ orbitals are equivalent to each other in the case of cubic symmetry, the term $(A_{p\pi'}-A_{p\pi})$ vanishes. Clogston *et al.* have pointed out the possibility of the $\Delta m=\pm1$ transition, but this anomalous transition has not been found in our spectra.

a) Mn:$KMgF_3$

All observed spectra consisted of six groups, each corresponding to a hfs component of Mn^{55}. Thus, hf interaction constant A^{55} was immediately determined using (2). However, the observed spectra were resolved not completely into the expected components. This is because a and A^{19}'s are comparable in magnitude and so F^{19} hfs components of neighboring fs components overlap each other.

When $H\|[111]$, the splittings due to F^{19} hf interaction should be simplest, but the resolution was not complete. Analysis was therefore made by trial and error. In spite of the incomplete resolution of each component, overall pattern of the spectrum was sensitive to a and A_s. The calculated spectra with $a=8\sim9.5$ Gauss and $A_s=19\sim20$ Gauss resembled closely to the observed spectrum. After the approximate values of parameters had thus been known, the more accurate values could be determined by some particular components. For example, the $m_I=-3/2$ hfs component in the $H\|[110]$ spectrum was expected to have a very small splittings due to fs. The best resolution of F^{19} hfs was therefore expected in this spectrum and really observed as shown in Fig. 2.

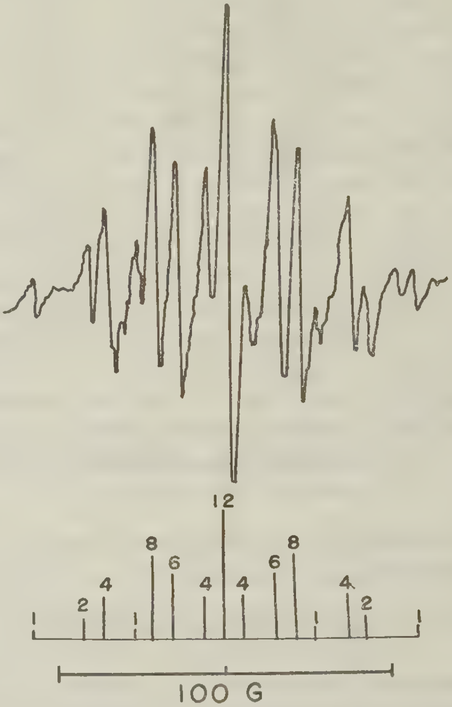


Fig. 2. The observed and calculated F^{19} hfs' in the $m_I=-2/3$ hfs component in the EPR of Mn^{2+}:$KMgF_3$ with $H\|[110]$.

b) Mn:$KCdF_3$ and Mn:$KCaF_3$

In contrast to Mn:$KMgF_3$, the spectra of Mn^{2+} in $KCdF_3$ and $KCaF_3$ has somewhat simpler patterns which were expected from (2) and (5) neglecting the crystalline field term in (2). The resolved spectral lines were however broader than those of Mn:$KMgF_3$; their width being 5∼10 Gauss. This is probably because a is so small that the fs components are not resolved. The upper bound of a was estimated from the width. The parameters other than a could be determined directly from the separations.

c) Mn:K_2MgF_4

As shown in Fig. 1, Mg ions in K_2MgF_4 have very similar environment and nearly the same Mg-F separation to that of $KMgF_3$. The observed spectrum was also very similar.

d) Mn:$NaMgF_3$

The crystal $NaMgF_3$ contains four molecules in unit cell, so four sets of spectra may be in general expected. However, the observed spectra had simple patterns just as seen in

Table II. g-factors, hf interaction constant A^{55}'s, cubic crystalline field splitting parameter a's and F^{19} hf interaction constants A_s's and (A_p+A_D)'s of Mn^{2+} ions in $KMgF_3$, $KCdF_3$, $KCaF_3$, K_2MgF_4 and $NaMgF_3$. The unit of all parameters other than g is 10^{-4} cm^{-1}. Experimentally, only the relative signs were determined; $A^{55}/a<0$ and $(A_p+A_D)/A_s>0$. The negative A^{55} and positive a are now commonly accepted.

Compound	g	A^{55}	a	$\lvert A_s\rvert$	$\lvert A_p+A_D\rvert$
$KMgF_3$	2.000±.002	−91.2±0.9	8.0±1.0	18.1±0.7	4.2±0.5
$KCdF_3$	2.002±.002	−92.6±0.9	$\leqq$4.0	15.8±0.5	2.9±0.5
$KCaF_3$	2.002±.002	−93.1±0.9	$\leqq$4.0	15.5±0.5	2.8±0.5
K_2MgF_4	2.000±.002	−91.5±0.9	8.0±1.0	18.2±0.7	4.2±0.5
$NaMgF_3$	2.001±.002	−92.5±1.5	——	18.1±1.0	3.0±1.5

the cases of $Mn:KCdF_3$ and $KCaF_3$, although the broader line suggested the unresolved splitting due to the four inequivalent Mn^{2+} ions. Since the resolution was poor and the exact atomic arrangement had not been known, the spectrum was analysed for convenience by assuming a pseudo-cubic structure. The values of parameters are therefore less reliable.

All of the parameters thus determined are summarized in Table II.

§ 5. Discussion

a) g and A^{55}

It has been known that g-factor and hf interaction constant are somewhat sensitive to the electronic state of the magnetic electron. When there is some covalency, magnetic electron moves in a somewhat extended orbital. This reduces the electron density near its nucleus and so the magnitude of hf interaction constant. The g-factor is also affected by the change of orbital state. However, if there is no orbital contribution to the total angular momentum as is the case for the ground state of Mn^{2+}, $3d^5\ {}^6S$, g-factor will not change as far as the covalency does not disturb the ${}^6S$ state.

In the crystals studied in our experiment, divalent metal ions have environments of the same symmetry but different separations, except $NaMgF_3$. At larger separation, the electronic state of metal ion should be closer to the state of a free ion and so the A^{55} will increase in magnitude. On the other hand, no change of the multiplicity ${}^6S$ may be expected for the ions with environments of the same symmetry. Therefore, the g-factor will be expected to be constant. Except the case of $Mn:NaMgF_3$ where the atomic arrangement and interatomic distances have not been known, the observed g's and A^{55}'s are in good accordance with the expected tendency, though a slight difference in g's is found within the experimental error. The electron transfer effect[3),13)] which mixes an excited non-${}^6S$ state into the ground state, may possibly account for this difference.

b) Cubic crystalline field splitting parameter a

A cubic crystalline field parameter Dq is proportional to the inverse fifth power of the interatomic distance R. According to the Watanabe's theory[14)], a cubic crystalline field splitting parameter a depends upon Dq as

$$a=(Dq)^2(8.526+0.102(Dq)^2\times10^{-6})\times10^{-10}\ \mathrm{cm}^{-1}.$$

If the small second term is neglected, a is proportional to R^{-10}. Using the values of R listed in Table I, one finds that $a(KCdF_3)/a(KMgF_3)=0.45$ and $a(KCaF_3)/a(KMgF_3)=0.41$. This is consistent with the observed ratios; $a(KCdF_3)/a(KMgF_3)\leqq0.50$ and $a(KCaF_3)/a(KMgF_3)\leqq0.50$.

c) F^{19} hf interaction constants

To separate the p-electron contribution A_p from the observed (A_p+A_D), the contribution from direct dipole-dipole interaction A_D must be subtracted. For that purpose, certain assumptions concerning the inter-ion separation and the distribution of magnetization must be made. If one assumes that the bond length for Mn^{2+} ion is equal to the metal-fluorine distance, R, of the host lattice and that all the Mn^{2+} spin magnetization is contained in a sphere of radius $r<R$, then $A_D=$ 3.2, 2.5 and 2.4×10^{-4} cm^{-1} for Mn^{2+} ions in $KMgF_3$, $KCdF_3$ and $KCaF_3$ respectively. Thus obtained A_p's (1.0, 0.4 and 0.4×10^{-4} cm^{-1}) show a large dependence upon the inter-ion separation, but their accuracy is not so high

that we shall not discuss them and confine ourselves to the *s*-electron contribution A_s.

To see the dependence of A_s upon the Mn^{2+}–F^- distance, the experimental values in this work are plotted against R in Fig. 3 together with the EPR datum of Mn:ZnF_2[3] and the NMR data of MnF_2[6] and $KMnF_3$[15].

Here, it must be emphasized that R in Fig. 3 is the metal-fluorine distance of the host lattice. In the EPR experiment, Mn^{2+} ion is diluted in the host lattice as a substitutional impurity. The true Mn^{2+}–F^- distance is therefore possible to be different from R. Although the same valency and close ionic radius hardly suggest a large distortion of the surrounding fluorine ions, the exact Mn^{2+}–F^- distance cannot be known at present.

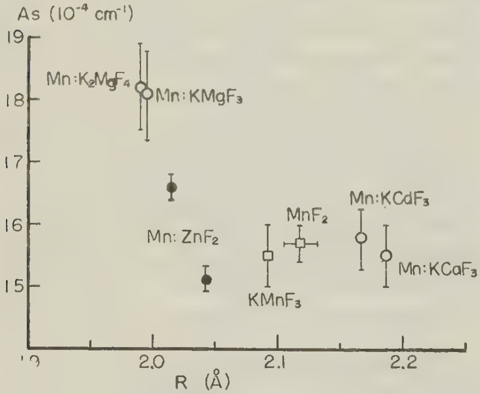

Fig. 3. A_s's plotted against R. The R's for ZnF_2 and MnF_2 are taken from Bauer[16].

Apart from this question, an appreciable variation of the A_s's is seen in Fig. 3. It is interesting that the experimental points can be fitted on a curve which concaves to the R axis rather than a linear line. As Keffer *et al.*[13] and Clogston *et al.*[3] have discussed, the A_s is proportional to $(S_s+\lambda_s)^2$ where S_s is the overlap integral between a manganese 3*d* wave function and a fluorine 2*s* wave function and λ_s is the fraction of the transferred electron from the fluorine 2*s* orbital to the manganese orbital. The wave functions may be expressed by the exponential functions at an outer part of orbital. The S_s may also have an exponential-like dependence upon R. Though it is difficult to know the dependence and the magnitude of λ_s, Keffer *et al.* have estimated S_s and λ_s to be 0.05 and 0.01 respectively for MnF_2. Because of the relative smallness of λ_s, A_s may be supposed to have an exponential-like dependence. This situation explains qualitatively the observed behavior of A_s. It is desired that the "first-principles" calculation as have been done by Mukherji and Das[17] will be carried out at more wide range of interionic separation.

Shulman *et al.*[15] have made the NMR measurement of F^{19} in $KMnF_3$ and determined A_s to be 15.5×10^{-4} cm^{-1}. The Mn^{2+}–F^- distance in $KMnF_3$ is a half of the lattice constant, $a_0=4.186$ Å[8], and lies among the metal-fluorine distances in the crystals studied in the present experiment. Therefore, in spite of the ambiguity of the Mn^{2+}–F^- distances in the host lattices, it can be safely said from our EPR data that the A_s in the dense, magnetic crystal $KMnF_3$ lies between 15.5 and 18.2×10^{-4} cm^{-1}. If a linear interpolation is made, the A_s is 16.7×10^{-4} cm^{-1}, but it will be somewhat close to 15.5×10^{-4} cm^{-1} by reason of the above discussed dependence of A_s upon R, in agreement with the value obtained from NMR with in the the experimental error.

In conclusion, magnetic electrons of the Mn^{2+} ion surrounded by a complete octahedron of fluorine ions with the bond length of 1.99 ∼2.19 Å have 0.58∼0.49% 2*s* character at each Mn^{2+}–F^- bond, or $(S_s+\lambda_s)^2$ in Keffer's notation is $0.58\sim0.49\times10^{-2}$.

§ 6. Summary

1) The Mn^{2+} ions as dilute, substitutional impurities in $KMgF_3$, $KCdF_3$, $KCaF_3$ and K_2MgF_4 surrounded by a complete octahedron of six fluorine ions and that in $NaMgF_3$ by a nearly complete octahedron.

2) The *g*-factors are constant and A^{55}'s increase slightly in magnitude with increasing Mn^{2+}–F^- distance, in accordance with the theoretically expected tendency.

3) The F^{19} hf interaction constant A_s has shown an appreciable dependence upon Mn^{2+}–F^- distance. It should be taken care of this dependence when one deduces the value of F^{19} hf interaction constant in a dense, magnetic crystal from the EPR data of the paramagnetic ion diluted in the host isomorphic diamagnetic crystal. When the dependence is taken into account, both the A_s's obtained from EPR and NMR measurements are in rather good agreement with each other.

Acknowledgements

The author wishes to express his sincere thanks to Professor Y. Yokozawa for his kind encouragement throughout the course of this work, and to Drs. H. Watanabe and T. Asahi for their helpful and stimulating discussions. He is also indebted to Dr. V. Jaccarino for a reprint of his work.

Note added in proof: (1) In a recent paper (Phys. Rev. Letters 4 (1960) 603), Shulman and Knox have reported new value of the A_s in $KMnF_3$ as $(16.26\pm0.5)\times10^{-4}\,cm^{-1}$. The A_s estimated from EPR in the text is now in satisfactory agreement with the NMR result.

(2) Benedek and Kushida (Phys. Rev. **118** (1960) 46) have recently shown the dependence of A_s upon Mn-F distance in MnF_2 by applying hydrostatic pressure while measuring the F^{19} resonance frequency at the antiferromagnetic state of MnF_2. They have shown a satisfactory agreement of their experimental results with those calculated by Marshall and Stuart (quoted in the paper by Benedek and Kushida). Marshall and stuart calculated f_{2s}, the degree of unpairing of the $2s$ fluorine orbital, for the Mn-F distances of 2.10 to 2.14Å at intervals of 0.01Å. If we assume that these calculated values can be applied to Mn^{2+} ions in the crystals studied in our experiment and assume a linear extrapolation to be hold, we can determiee the Mn-F distances in the host crystals of $KMgF_3$, $KCdF_3$, and $KCaF_3$ to be 2.080 2.119, and 2.124Å respectively. The more accurate values of A_s in more wide range of Mn-F distance are desired to be established by theoretical calculations and NMR study of F^{19} in $KMnF_3$ with application of hydrostatic pressure. Then, the A_s obtained from EPR measurement will give us an accurate knowledge of the local distortion arround impurity ion.

The Dipole Moment and End-to-end Length of the Isotactic Vinyl Polymer, I. Mutual Dependence between Dipole Moment and End-to-end Length

By Tsugio Mori

Ôtsu Senior High School, Ôtsu, Shiga-ken, Japan

(Received March 28, 1960)

The formulas for the mean-squared dipole moment and end-to-end length of the isotactic vinyl polymer are derived. The polymer model used in these derivations is similar to Lifson's one[1], but the dependence of these mean-squared quantities on molecular weight of the polymer is considered in the present calculations. The two mean-squared quantities, dipole moment and end-to-end length, are not independent of each other, and it is pointed out that they are connected by a simple expression. On the other hand, the present treatment is useful to see the corrected Staudinger's viscosity rule from a new point of view.

§ 1. Fundamental Notations

The linear polymer discussed in this paper is the polar isotactic vinyl-type one, and is treated in state of an infinitely diluted solution. The molecular formula of this polymer is $(CH_2-CHR)_nCH_2$, where R is a dipolar substituent. The number of skeletal carbon atoms is

$$N=2n+1\,, \tag{1}$$

and we designate these carbon atoms by

$$C_1,\ C_2,\ \cdots,\ C_{2n+1}$$

successively from one end of the skeletal chain. The bond vector from C_k to C_{k+1} is denoted by $\boldsymbol{b}_k$, and lengths of vectors

$$\boldsymbol{b}_1,\ \boldsymbol{b}_2,\ \cdots,\ \boldsymbol{b}_{2n}$$

are assumed to be all equal to b_0. The electric dipole moment vector of the side chain $C_{2i}-R_i$ is denoted by $\boldsymbol{\mu}_i$, and lengths of vectors

$$\boldsymbol{\mu}_1,\ \boldsymbol{\mu}_2,\ \cdots,\ \boldsymbol{\mu}_n$$

are assumed to be all equal to μ_0. The above polymer model and notations are shown in Fig. 1.

Four bonds meeting at a skeletal carbon atom construct a set of tetrahedral angles, which are assumed to undergo no change through internal rotation of the chain.

Then we discuss the internal rotation of the skeletal chain. The angle of two adjoining bond vectors is denoted by γ, which is a constant and equal to the supplement of the bond angle. The vector $\boldsymbol{b}_{j-1}$ may be considered to rotate regarding $\boldsymbol{b}_{j-2}$ as a fixed axis. Here we denote the rotation angle of $\boldsymbol{b}_{j-1}$ by φ_j, and put $\varphi_j=0$ when $\boldsymbol{b}_{j-3}$ and $\boldsymbol{b}_{j-1}$ form the trans type connection holding $\boldsymbol{b}_{j-2}$ between them. Next we define the system of unit vectors $\boldsymbol{i}_j$, $\boldsymbol{j}_j$, $\boldsymbol{k}_j$ attached to the carbon atom C_j according to the following scheme. In the first place, we set $\boldsymbol{k}_j$ in the

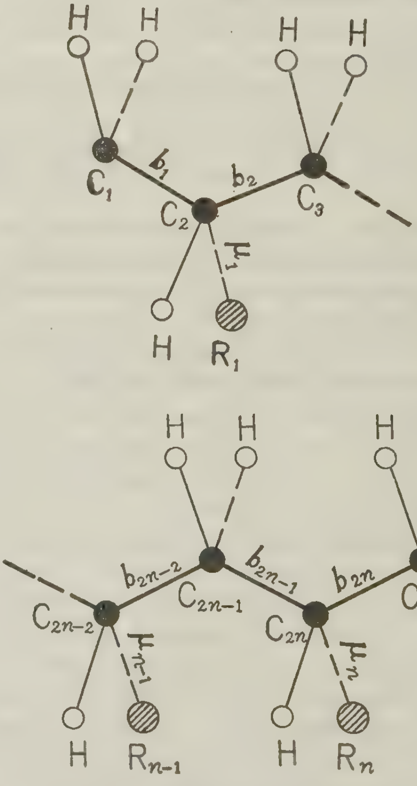

Fig. 1. Isotactic vinyl polymer.

same direction as $\boldsymbol{b}_{j-1}$. Next, let us consider two projected lines both of which start from C_j on the plane determined by three points C_{j-2}, C_{j-1}, C_j and are prependicular to $\boldsymbol{k}_j$. The one of those two projected lines should ntersect the vector $\boldsymbol{b}_{j-2}$ or its extension, and this projection defines the direction of $\boldsymbol{i}_j$. Last of all, $\boldsymbol{j}_j$ is introduced in order to obtain the right-handed orthogonal system formed by $\boldsymbol{i}_j$, $\boldsymbol{j}_j$, $\boldsymbol{k}_j$. These notations are illustrated n Fig. 2.

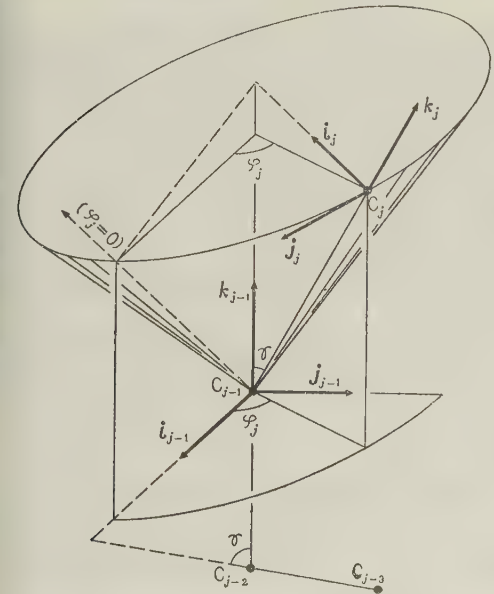

Fig. 2. Internal rotation of skeletal chain.

According to the above discussion, we may consider two sets of components of a vector, namely, components x_j, y_j, z_j in the directions of $\boldsymbol{i}_j$, $\boldsymbol{j}_j$, $\boldsymbol{k}_j$ respectively, and x_{j-1}, y_{j-1}, z_{j-1} n the directions of $\boldsymbol{i}_{j-1}$, $\boldsymbol{j}_{j-1}$, $\boldsymbol{k}_{j-1}$ respectively. Then we have

$$x_j\boldsymbol{i}_j+y_j\boldsymbol{j}_j+z_j\boldsymbol{k}_j=x_{j-1}\boldsymbol{i}_{j-1}+y_{j-1}\boldsymbol{j}_{j-1}+z_{j-1}\boldsymbol{k}_{j-1}\ . \tag{2}$$

We denote the matrix which transforms x_j, y_j, z_j into x_{j-1}, y_{j-1}, z_{j-1} by $\mathbf{D}_j$:

$$\begin{pmatrix} x_{j-1} \\ y_{j-1} \\ z_{j-1} \end{pmatrix}=\mathbf{D}_j\begin{pmatrix} x_j \\ y_j \\ z_j \end{pmatrix}. \tag{3}$$

Let us put, for convenience' sake,

$$\alpha=\cos\gamma\ , \qquad \beta=\sin\gamma\ , \tag{4}$$

and define the matrix $\mathbf{D}$ or $\mathbf{D}(\varphi)$ by

$$\mathbf{D}=\mathbf{D}(\varphi)=\begin{pmatrix} -\alpha\cos\varphi & \sin\varphi & \beta\cos\varphi \\ -\alpha\sin\varphi & -\cos\varphi & \beta\sin\varphi \\ \beta & 0 & \alpha \end{pmatrix}, \tag{5}$$

then the matrix $\mathbf{D}_j$ in Equation (3) is given by

$$\mathbf{D}_j=\mathbf{D}(\varphi_j)\ . \tag{6}$$

The matrix $\mathbf{D}$ has the following natures:

(i) $\mathbf{D}$ is an orthogonal transformation, namely

$$\mathbf{D}^T(\varphi)\mathbf{D}(\varphi)=\mathbf{1}\ , \tag{7}$$

where $\mathbf{D}^T(\varphi)$ is the transposed matrix of $\mathbf{D}(\varphi)$, and $\mathbf{1}$ is the unit matrix.

(ii) The skeletal chain extended to the zig-zag style on a plane is considered as the repetition of trans type connections, namely, parallel bond vectors repeate every two ones is such planar chain. Accordingly we have

$$[\mathbf{D}(0)]^2=\mathbf{1}\ . \tag{8}$$

(iii) In the crystalline state, the skeletal chain is composed of the alternating trans and gauche type connections. Let us consider the unit chain CH_2-CHR being a segment, then three segments complete one period of the chain. Then we have

$$[\mathbf{D}(2\pi/3)\mathbf{D}(0)]^3=\mathbf{1}\ . \tag{9}$$

It is remarked that Eq. (9) is a special case of

$$[\mathbf{D}(2\pi/k)\mathbf{D}(0)]^k=\mathbf{1}\ , \tag{10}$$

where k is an integer.

Although the above natures (i)~(iii) of the matrix $\mathbf{D}$ are self-evident, some authors have given no care upon the confermation test of Eqs. (7)~(9), and used incorrect matrices.

§2. General Formulas for Mean Square of Electric Dipole Moment

The electric dipole moment vector of the polymer, denoted by μ, is given by

$$\mu=\mu_1+\mu_2+\cdots+\mu_n\ . \tag{11}$$

Then the square of the absolute value of μ is given by

$$\mu^2=\left(1+\frac{2}{n}\sum_{i<i}^{n}\sum\cos\omega_{ij}\right)n\mu_0^2\ , \tag{12}$$

where ω_{ij} signifies the angle between μ_i and μ_j, and the double summation is taken for i- and j-values given by

$$i=1,\ 2,\ \cdots,\ n$$

and

$$j=2,\ 3,\ \cdots,\ n$$

but $i<j$. If we take the mean of μ^2, Eq. (12) is replaced by

$$\langle\mu^2\rangle=\left(1+\frac{2}{n}\sum_{i<j}^{n}\sum\langle\cos\omega_{ij}\rangle\right)n\mu_0^2\,, \tag{13}$$

where the notation $\langle\cos\omega_{ij}\rangle$ signifies the mean of $\cos\omega_{ij}$ for all configurations of the polymer chain in an infinitely diluted solution.

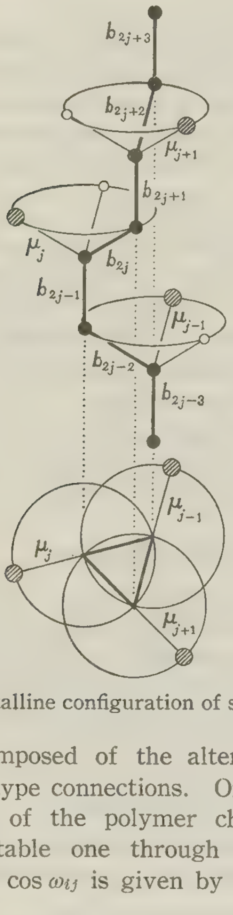

Fig. 3. Crystalline configuration of skeletal chain.

In order to estimate $\langle\cos\omega_{ij}\rangle$, we assume that our polymer chain is most stable in the crystalline configuration illustrated in Fig. 3 which is composed of the alternating trans and gauche type connections. Of course, the configuration of the polymer chain deviates from this stable one through the internal rotation, and $\cos\omega_{ij}$ is given by

$$\cos\omega_{ij}=(001)\mathbf{D}^T\left(\varphi_{2i+1}-\frac{2\pi}{3}\right)\mathbf{D}_{2i+1}\mathbf{D}_{2i+2}\cdots$$
$$\cdots\mathbf{D}_{2j-1}\mathbf{D}_{2j}\mathbf{D}\left(\varphi_{2j+1}-\frac{2\pi}{3}\right)\begin{pmatrix}0\\0\\1\end{pmatrix}, \tag{14}$$

where the notations $\mathbf{D}(\varphi_{2j+1}-2\pi/3)$ and $\mathbf{D}_{2j}$ designate respectively the substitutions of $\varphi=\varphi_{2j+1}-2\pi/3$ and $\varphi=\varphi_{2j}$ in $\mathbf{D}(\varphi)$ defined by (5), and other notations in (14) may also be understood in the similar way. In order to take the mean of (14), we put the second assumption that the rotations of segments as a whole are independent of each other, but in a segment there is a correlation between rotations of two bond vectors. A similar as- sumption has been attempted by Lifson[1]. We devide φ-variables into the following scheme:

$$|\varphi_3\varphi_4|\varphi_5\varphi_6|\cdots|\varphi_{2j-1}\varphi_{2j}|\cdots|\varphi_{2n-1}\varphi_{2n}|\,,$$

and consider that, φ_{2j-1} and φ_{2j} are correlate to each other, but other φ-variables have n correlation to these two variables. In this way, we assume

$$\varphi'=\varphi'(\varphi)\,,\qquad \varphi'(0)=2\pi/3\,, \tag{15}$$

where φ' and φ are abbreviations of φ_{2j-1} and φ_{2j}, respectively. We assume the relations (15) for all φ-pairs commonly. For example, if φ' denotes φ_3, then φ denotes φ_4. The second relation of (15) is concerned with the first assumption which states that the most stable configuration may be realized for $\varphi'=2\pi/3$ and $\varphi=0$.

According to these assumptions we can write

$$\langle\cos\omega_{ij}\rangle=(001)\mathbf{Y}^T\mathbf{X}^{|j-i|}\mathbf{Y}\begin{pmatrix}0\\0\\1\end{pmatrix}, \tag{16}$$

where we put

$$\langle\mathbf{D}_3\mathbf{D}_4\rangle=\langle\mathbf{D}_5\mathbf{D}_6\rangle=\cdots=\langle\mathbf{D}_{2n-1}\mathbf{D}_{2n}\rangle$$
$$=\langle\mathbf{D}(\varphi')\mathbf{D}(\varphi)\rangle=\mathbf{X} \tag{17}$$

and

$$\mathbf{D}\left(\varphi_3-\frac{2\pi}{3}\right)=\cdots=\mathbf{D}\left(\varphi_{2n+1}-\frac{2\pi}{3}\right)$$
$$=\mathbf{D}\left(\varphi'-\frac{2\pi}{3}\right)=\mathbf{Y}\,. \tag{18}$$

Substitution of (16) in Eq. (13) yields

$$\langle\mu^2\rangle=\left\{1+2(001)\mathbf{Y}^T\mathbf{X}\right.$$
$$\left.\times\left(\frac{1}{n}\sum_{i<j}^{n}\sum\mathbf{X}^{j-i-1}\right)\mathbf{Y}\begin{pmatrix}0\\0\\1\end{pmatrix}\right\}n\mu_0^2\,. \tag{19}$$

The summation in this expression should be read

$$\frac{1}{n}\sum_{i<j}^{n}\sum\mathbf{X}^{j-i-1}$$
$$=(\mathbf{1}-\mathbf{X})^{-1}\left\{\mathbf{1}+\frac{1}{n}(\mathbf{1}-\mathbf{X})^{-1}(\mathbf{X}^n-\mathbf{1})\right\}. \tag{20}$$

Let us denote the null matrix by $\mathbf{0}$, then it is evident that

$$\lim_{n\to\infty}\frac{1}{n}[\mathbf{D}(\varphi')\mathbf{D}(\varphi)]^n=\mathbf{0}\,, \tag{21}$$

for the product $\mathbf{D}(\varphi')\mathbf{D}(\varphi)$ is orthogonal*, so is $[\mathbf{D}(\varphi')\mathbf{D}(\varphi)]^n$. However, the formula

$$\lim_{n\to\infty}\frac{1}{n}[\langle\mathbf{D}(\varphi')\mathbf{D}(\varphi)\rangle]^n=\mathbf{0} \quad \text{or} \quad \lim_{n\to\infty}\frac{1}{n}\mathbf{X}^n=0 \tag{22}$$

is not evident, for $\mathbf{X}$ is not orthogonol. Some authors have assumed the formula (22), or treated only the case satisfying (22), and they have reduced (20) to

$$\frac{1}{n}\sum_{i<j}^{n}\sum \mathbf{X}^{j-i-1}\rightarrow(\mathbf{1}-\mathbf{X})^{-1}$$

as $n\rightarrow\infty$, with no study of conditions for the convergence. In this paper, however, we consider that the formula (22) is not satisfied in general, and approximate the formula (20) to

$$\frac{1}{n}\sum_{i<j}^{n}\sum \mathbf{X}^{j-i-1}=\{1+g(n)\}(\mathbf{1}-\mathbf{X})^{-1}\,, \tag{23}$$

where $g(n)$ is a function of n, and it is expected that

$$\lim_{n\to\infty} g(n)\left\{\begin{aligned} &=\infty \text{ (for most chain configurations).}\\ &=\text{a const. (for the random coil).}\end{aligned}\right\} \tag{24}$$

Substitution of (23) in (19) yields

$$\langle\mu^2\rangle=\left[1+\{1+g(n)\}\left(\frac{\langle\mu^2\rangle_0}{n\mu_0^2}-1\right)\right]n\mu_0^2\,, \tag{25}$$

where $\langle\mu^2\rangle_0$ signifies the value of $\langle\mu^2\rangle$ when $g(n)$ is neglected, namely,

$$\langle\mu^2\rangle_0=\left\{1+2(001)\mathbf{Y}^T\mathbf{X}(\mathbf{1}-\mathbf{X})^{-1}\mathbf{Y}\begin{pmatrix}0\\0\\1\end{pmatrix}\right\}n\mu_0^2\,. \tag{26}$$

The details of the function $g(n)$ may be explained later in concerning with the treatment of the mean square end-to-end length of the polymer.

§ 3. General Formulas for Mean Square of End-to-end Length

The vector from C_1 to C_{2n+1}, denoted by R, is given by

$$\boldsymbol{R}=\boldsymbol{b}_1+\boldsymbol{b}_2+\cdots+\boldsymbol{b}_{2n}\,. \tag{27}$$

Then the mean square of the absolute value of R is

$$\langle R^2\rangle=\left(1+\frac{1}{n}\sum_{i<j}^{2n}\sum\langle\cos\theta_{ij}\rangle\right)2nb_0^2\,, \tag{28}$$

where θ_{ij} signifies the angle between two vectors b_i and b_j, and the meaning of $\langle\cos\theta_{ij}\rangle$ is similar to that of $\langle\cos\omega_{ij}\rangle$ in the preceding section. Some differences between (13) and (28) are due to the fact that the double summations extend to $j=n$ and $j=2n$, respectively, in (13) and (28). The formula for $\cos\theta_{ij}$ is given by

$$\cos\theta_{ij}=(001)\mathbf{D}_{i+2}\mathbf{D}_{i+3}\cdots\mathbf{D}_{j+1}\begin{pmatrix}0\\0\\1\end{pmatrix} \tag{29}$$

which differs from $\cos\omega_{ij}$. It is remembered that the number of matrices in (14) is even and there are naturally the division

$$|\mathbf{D}_3\mathbf{D}_4|\mathbf{D}_5\mathbf{D}_6|\cdots|\mathbf{D}_{2n-1}\mathbf{D}_{2n}|\,.$$

Thus $\langle\cos\omega_{ij}\rangle$ is able to reduce to the form as (16). However, the formula (29) has not such regularity, and we need another method in order to estimate $\sum\sum\langle\cos\theta_{ij}\rangle$.

If we put

$$\langle\mathbf{D}_4\rangle=\langle\mathbf{D}_6\rangle=\cdots=\langle\mathbf{D}_{2n}\rangle=\langle\mathbf{D}(\varphi)\rangle=\mathbf{Z} \tag{30}$$

and

$$\langle\mathbf{D}_3\rangle=\langle\mathbf{D}_5\rangle=\cdots=\langle\mathbf{D}_{2n+1}\rangle=\langle\mathbf{D}(\varphi')\rangle=\mathbf{Z}' \tag{31}$$

and use $\mathbf{X}$ defined by (17), we find five kinds of expressions of the mean $\langle\mathbf{D}_{i+2}\mathbf{D}_{i+3}\cdots\mathbf{D}_{j+1}\rangle$ for the combinations of even and odd values of j and i. These expressions are shown in Table I.

Table I.

j	i	$\langle\mathbf{D}_{i+2}\mathbf{D}_{i+3}\cdots\mathbf{D}_{j+1}\rangle$
$2l-1$ (odd)	$2k$ (even)	$\mathbf{Z}\mathbf{X}^{l-k-1}$
$2l-1$ (odd)	$2k-1$ (odd)	$\mathbf{X}^{l-k}$
$2l$ (even)	$2k$ (even)	$\mathbf{Z}\mathbf{X}^{l-k-1}\mathbf{Z}'$
$2l$ (even)	$2k-1$ (odd)	$\mathbf{X}^{l-k}\mathbf{Z}'$
$2l$	$2l-1$	$\mathbf{Z}'$

(for $l>k$)

Accordingly we have

$$\begin{aligned}\sum_{i<j}^{2n}\sum\langle\cos\theta_{ij}\rangle&=(001)\left\{\sum_{k<l}^{n}\sum(\mathbf{Z}\mathbf{X}^{l-k-1}+\mathbf{X}^{l-k}+\mathbf{Z}\mathbf{X}^{l-k-1}\mathbf{Z}'+\mathbf{X}^{l-k}\mathbf{Z}')+n\mathbf{Z}'\right\}\begin{pmatrix}0\\0\\1\end{pmatrix}\\ &=(001)\left\{(\mathbf{Z}+\mathbf{X})\left(\sum_{k<l}^{n}\sum\mathbf{X}^{l-k-1}\right)(\mathbf{1}+\mathbf{Z}')+n\mathbf{Z}'\right\}\begin{pmatrix}0\\0\\1\end{pmatrix};\end{aligned} \tag{32}$$

---

* Eq. (7) yields the relation $[\mathbf{D}(\varphi')\mathbf{D}(\varphi)]^T[\mathbf{D}(\varphi')\mathbf{D}(\varphi)]=\mathbf{D}^T(\varphi)\mathbf{D}^T(\varphi')\mathbf{D}(\varphi')\mathbf{D}(\varphi)=\mathbf{D}^T(\varphi)\mathbf{D}(\varphi)=\mathbf{1}$. Therefore $\mathbf{D}(\varphi')\mathbf{D}(\varphi)$ is orthogonal.

remarking that j and l in double summations run to $2n$ and n, respectively. For further reductions of (32), let us remember the assumption that

$$\frac{1}{n}\sum\sum_{k<l}^{n}\mathbf{X}^{l-k-1}=\{1+g(n)\}(\mathbf{1}-\mathbf{X})^{-1}\,,$$

and replace $\mathbf{Z}+\mathbf{X}$ by $(\mathbf{1}+\mathbf{Z})-(\mathbf{1}-\mathbf{X})$. Then we have

$$\frac{1}{n}\sum\sum_{i<j}^{2n}\langle\cos\theta_{ij}\rangle=\{1+g(n)\}(001)(\mathbf{1}+\mathbf{Z})(\mathbf{1}-\mathbf{X})^{-1}(\mathbf{1}+\mathbf{Z}')\begin{pmatrix}0\\0\\1\end{pmatrix}-g(n)(1+\alpha)-1\,. \tag{33}$$

Substitution of (33) in Eq. (28) yields

$$\langle R^2\rangle=\{1+(1-P)g(n)\}\langle R^2\rangle_0\,, \tag{34}$$

where

$$P=\frac{1+\alpha}{(001)(\mathbf{1}+\mathbf{Z})(\mathbf{1}-\mathbf{X})^{-1}(\mathbf{1}+\mathbf{Z}')\begin{pmatrix}0\\0\\1\end{pmatrix}} \tag{35}$$

and

$$\langle R^2\rangle_0=(001)(\mathbf{1}+\mathbf{Z})(\mathbf{1}-\mathbf{X})^{-1}(\mathbf{1}+\mathbf{Z}')\begin{pmatrix}0\\0\\1\end{pmatrix}2nb_0^2\,. \tag{36}$$

In this way, $\langle R^2\rangle_0$ signifies the value of $\langle R^2\rangle$ when $g(n)$ is neglected.

§ 4. Discussion of $g(n)$ Term

The formula (36) agrees with Lifson's result[1], and the so-called mean square end-to-end lengths treated customarily are mostly of such type, of which the character is to neglect the $g(n)$ term.

In this paper, however, the $g(n)$ term is not negligible, but infinitely large as $n\to\infty$. Now we should estimate the order of infinity of $g(n)$. Let us consider, in the first place, the limit in which the polymer is extended as a rigid straight rod, then $\langle R^2\rangle$ is equal to $(2nb_0)^2$ and is infinity of the order of n^2 while $\langle R^2\rangle_0$ is infinity of the order of n. Therefore we conclude that $g(n)$ is infinity of the order of n from Eq. (34) in the limit of ridid straight polymer. Let us consider, next, another limit that the polymer is in the so-called unperturbed configuration and $\langle R^2\rangle=\langle R^2\rangle_0$. In this limit, $g(n)$ must vanish. According to these considerations, we assume

$$g(n)=K(n^\nu-1)\,, \tag{37}$$

where K and ν are both constants independent of n. In special, ν is limited within the interval

$$0\leqq\nu\leqq1\,. \tag{38}$$

Of course, $\nu=1$ and $\nu=0$ correspond to the ridid straight configuration and the unperturbed one respectively. In principle, the values of K and ν should be estimated through the potential of the internal rotation of the polymer chain. However, the assumption (37) is needed in this stage to avoid difficulties of theoretical treatment of $g(n)$. Then it should be an immediate problem for us, whether we can find the value of ν within the interval (38) or not, through comparison of the assumption (37) with experiments.

If we put

$$\rho=(\langle R^2\rangle/\langle R^2\rangle_0)^{1/2}\,, \tag{39}$$

the parameter ρ is the same as Flory's one introduced in his theory of the effect of excluded volume, namely, the linear expansion ratio of the polymer through that effect. From (34), (39) and (37), we have

$$\rho^2-1=K(1-P)(n^\nu-1)\,, \tag{40}$$

accordingly ρ is an increasing function of n. Therefore we should have a straight line, of which the slope is one, in the plot of $\log(\rho^2-1)$ against $\log(n^\nu-1)$ under suitable choice of ν. It is unavoidable to use experimental values of atactic polymers in place of that values of isotactic ones, because the lack of data of isotactic ones.

Some data of molecular weights and cubes of ρ are shown in Tables II and III, in which the former Table concerns with polyisobutylen-

Table II. Polyisobutylen-cyclohexane (30°C), $M_0=56.104$

M	ρ^3	$n^{0.25}-1$	ρ^2-1
9.5×10^3	1.39	2.61	0.245
5.02×10^4	1.96	4.47	0.565
5.58×10^5	3.10	8.99	1.126
2.72×10^6	4.46	13.8	1.71

Table III. Polystyrene-benzene (20°C), $M_0=104.144$.

M	ρ^3	$n^{0.25}-1$	ρ^2-1
4.45×10^4	1.55	3.55	0.339
6.55×10^4	1.70	4.01	0.423
2.62×10^5	2.54	6.08	0.860
6.94×10^5	3.03	8.03	1.094
2.55×10^6	4.22	11.51	1.61
6.27×10^6	5.73	14.7	2.20

cyclohexane solution, and the latter with polystyrene-benzene solution. These values are taken from Flory's text book[2].

In these Tables, M and M_0 denotes the molecular (or submolecular) weights of the polymer and segment, respectively, and the relation

$$n=M/M_0 \tag{41}$$

is self-evident. The values of $n^\nu-1$ and ρ^2-1 are also shown in these tables, where the value $\nu=0.25$ is chosen. The plots of $\log(\rho^2-1)$ against $\log(n^\nu-1)$ due to Tables II and III are illustrated in Fig. 4.

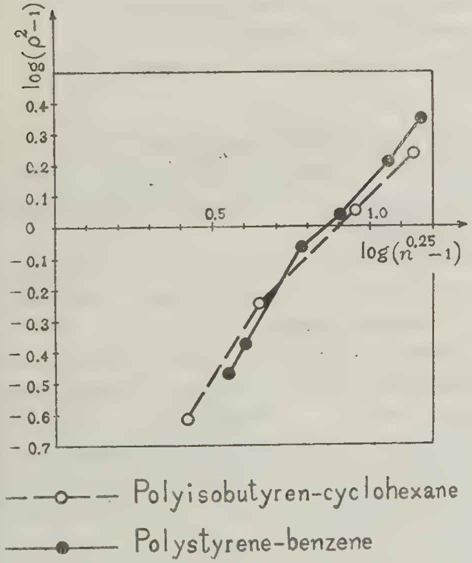

Fig. 4. log-log plots of (ρ^2-1) against $(n^\nu-1)$.

The plots seem nearly straight lines of which each slope is one. Thus the relation (40) is satisfactory beyond such a rough treatment, namely, an experimental foundation has been given to the assumptions (37) and (23).

There is another interest in discussion of the constant ν with the viscosity of solution. If we denote the intrinsic viscosity by $[\eta]$, the Staudinger's rule is written as

$$[\eta]=(\text{const.})M\,.$$

But this rule agrees not always with experiment, and it is corrected to the form

$$[\eta]=(\text{const.})M^{\zeta}\,, \tag{42}$$

where $\zeta=0.5\sim1$ for almost polymers, and $\zeta=2$ for straight rod polymers. Till now, there are two kinds of independent theories, the one of which explains Eq. (42) for $\zeta=2$, although unfortunately the author has no convenience to seek for which paper describes that theory. Another kind of theories[2,3,4] explains Eq. (42) for $\zeta=0.5\sim1$. However, we have an unified treatment that explains Eq. (42) for $\varepsilon=0.5\sim2$ if we combine the relation (40) with Elory's method[2]. According to Flory, we use the relation

$$[\eta]=(\text{const.})M^{1/2}\rho^3\,. \tag{43}$$

From (40) and (41), we write

$$\rho=(\text{const.})n^{\nu/2}=(\text{const.})M^{\nu/2} \tag{44}$$

for large n and ρ. Let us substitute (44) in (43), and compare with (42). Then we have

$$\zeta=(3\nu+1)/2\,. \tag{45}$$

Remembering the interval (38) of ν, we have $\zeta=0.5$ for unperturbed polymer chain, and $\zeta=2$ for straight polymer chain. Thus we have a simple treatment that explains (42) within the interval

$$0.5\leqq\zeta\leqq2\,.$$

§ 5. Mutual Dependence between Electric Dipole Moment and End-to-end Length

In general $g(n)$ relates to $\langle R^2\rangle$ and $\langle R^2\rangle_0$ according to the relation

$$1+g(n)=\frac{\rho^2-P}{1-P}=\frac{\langle R^2\rangle-(1+\alpha)Nb_0^2}{\langle R^2\rangle_0-(1+\alpha)Nb_0^2} \tag{46}$$

which is derived from (34), (35), (36) and $N=2n+1\simeq2n$. Substitution of (46) in (25) yields

$$\frac{\langle\mu^2\rangle}{n\mu_0^2}=1+\frac{\rho^2-P}{1-P}\left(\frac{\langle\mu^2\rangle_0}{n\mu_0^2}-1\right), \tag{47}$$

or

$$\frac{\langle\mu^2\rangle-n\mu_0^2}{\langle\mu^2\rangle_0-n\mu_0^2}=\frac{\langle R^2\rangle-(1+\alpha)Nb_0^2}{\langle R^2\rangle_0-(1+\alpha)Nb_0^2}\,. \tag{48}$$

Therefore $\langle\mu^2\rangle$ and $\langle R^2\rangle$ are dependent on each other through Eq. (48). Numerical calculations of $\langle\mu^2\rangle_0/n\mu_0^2$ and $\langle R^2\rangle_0/Nb_0^2$ may be carried out independently. However, three kinds of values, $\langle\mu^2\rangle_0/n\mu_0^2$, $\langle R^2\rangle_0/Nb_0^2$ and ρ, are needed when we wish to calculate the numerical values of $\langle\mu^2\rangle/n\mu_0^2$. These calculations may be performed in the succeeding paper[5] for a special type of internal rotation.

Magneto-plasma Resonance in Semiconductors (I)

Muneyuki DATE
Department of Physics, Faculty of Science,
Osaka University, Osaka

(Received April 1, 1960)

Theory of the magneto-plasma resonance in semiconductors is developed for the general case where several kinds of free carriers are moving under a static magnetic field. The absorption and dispersion relations are obtained which are applicable to the usual semiconductors such as Si and Ge. It is shown that, under favorable conditions, the resultant plasma frequency can be determined in a way as if there were only one kind of carrier which has the reduced mass of all the carriers concerned. The experimental method to determine the parameter of the magneto-plasma resonance is also discussed.

§ 1. Introduction

As is well known, there have been two important discoveries in the study of the resonance phenomena in semiconductors at microwave frequencies. One is the electron spin resonance of the free carriers or the trapped electrons; the other is the cyclotron resonance. In connection with the experiment of the cyclotron resonance, however, Dresselhaus, Kip and Kittel have pointed out that the magneto-plasma resonance of the free carriers becomes also important when the number of the free carriers is increased.[1] This problem was further discussed by the same authors[2]* for the simplest case in which the effective mass is cubic and when minority carries are concerned. They also observed the magneto-plasma resonance in InSb in the microwave region.

Since then, this problem has not been considered until Wolf came again to discuss the plasma resonance.[3] He considered the possibility of exciting the multi-mode resonance under simple conditions such as those discussed by *DKK*.

In actual semiconductors such as Si and Ge, however, the problem is more complicated. The effective mass has a tensor character and there are several kinds of free carriers which have different effective masses and relaxation times. Accordingly, it is desirable to make a more general treatment of the free carriers for the magneto-plasma resonance. Moreover, this may be necessary for the study of the spin resonance and cyclotron resonance of such substances as Si and Ge in which the magneto-plasma resonance may have an appreciable influence on these resonances. As an example, let us consider the following case. When there are about 10^{14} donors/cc with an excitation energy of 0.01 eV to the conduction band in Ge, the plasma frequency in the spherical specimen will be about 10^{10}/sec at 20°K, namely it comes into the microwave region. Then, it is quite conceivable that the magneto-plasma resonance, whose frequency is of the same order of magnitude as that of the ordinary plasma frequency, is necessarily associated with the observation of the electron spin and cyclotron resonances.

---

* Hereafter we shall call this paper as *DKK*.

Now let us consider the experimental method of studing the magnetoplasma resonance. To investigate the properties of the free carriers at rf-frequencies, it will be convenient to use the device developed by Okamura, Fujimura and the present author4)* for measuring the dielectric constant, permeability and conductivity of ferrites at microwave frequencies. Later, this method was applied to the study of the same sort of measurements on semiconductors.5),6) In this *OFD* method, the resonance shift and the loss of the resonant cavity containing the specimen are measured, and from these quantities the high frequency properties of the free carriers, represented by a complex susceptibility and a complex conductivity are deduced. The loss and shift are related to these quantities in the following way:

$$\frac{1}{Q}=\left(\mathcal{E}''+\frac{\sigma'}{\mathcal{E}_0\omega}\right)\int_{\Delta V}E^2dv\,,$$

$$-2\frac{\Delta\omega}{\omega}=\left(\mathcal{E}'-1-\frac{\sigma''}{\mathcal{E}_0\omega}\right)\int_{\Delta V}E^2dv\,.$$

The first equation represents the loss factor of the cavity and the second is the relation for the resonance shift. In these equations, the dielectric constant and conductivity are defined as

$$\mathcal{E}=\mathcal{E}_0(\mathcal{E}'-i\mathcal{E}'')\,,$$

$$\sigma=\sigma'-i\sigma''\,.$$

The integral $\int_{\Delta V}E^2dv$ over the volume of the specimen must be evaluated, and if the sample is at the place where the microwave electric field is the greatest, its volume becomes $4\cdot\Delta V/V$, where $\Delta V/V$ is the ratio of the volume of the sample to that of the resonant cavity. Thus, if the magneto-plasma resonance of the semiconductor could satisfactorily be represented by an anomaly in the complex conductivity, we can study it experimentally using the *OFD* method. Usually, $\mathcal{E}'$ is known and $\mathcal{E}''$ can be considered as zero.

In the next section, the *DKK* method will be modified in such a way that the magneto-plasma resonance of the simple system is represented by a complex conductivity. In the third section, a similar calculation for the general case where several species of carriers exist in the semiconductor will be made assuming that the carrier density is not very high and the motion of each carrier is determined by the rf-electric field, long range depolarization field and external magnetic field.* Conclusions of these discussions will briefly be described in the last section.

§ 2. The Complex Conductivity in the one-carrier Problem

There are several differences between the plasma oscillations in metals and those in semiconductors. One of the important differences is seen in the boundary conditions. In metals, the plasma wave length is much smaller than the size of the specimen. Accordingly, the boundary effect is unimportant in metals. On the contrary, it is important in semiconductors in which the plasma wavelength is larger than the size of the sample. As was described in the preceding section, Wolf pointed out the possibility of the multi-plasma resonance in semiconductors. But the occurrence of this mode is limitted by severe conditions which are rather exceptional in semiconductors. Accordingly we omit to discuss the magneto-plasma resonance of multi-mode.

The semi-classical equation of motion for the carriers was first proposed by *DKK* and it is as follows:

$$m^*\left(\frac{d\vec{V}}{dt}+\rho\vec{V}\right)=e(\vec{E}-L\vec{P})+\left(\frac{e}{c}\right)\vec{V}\times\vec{H}\,, \qquad (1)$$

where $\vec{V}$ is the velocity of the conduction electrons, m^* their effective mass, $\vec{E}$ the external electric field, L the depolarization factor, $\vec{H}$ the external magnetic fiedld, P the dielectric polarization and ρ the relaxation frequency ($\rho=\tau^{-1}$ where τ is the relaxation time). Starting from Eq. (1), the complex conductivity can be calculated in the following way. Assuming $E\propto e^{i\omega t}$, we obtain from Eq. (1):

---

* Hereafter we shall call this the *OFD* method.

* This case will be called hereafter the n-carrier problem. The case where only one kind of carrier is present, as was discussed by *DKK*, may thus be called the one-carrier problem.

$$(i\omega'+\rho)\vec{V}=\left(\frac{e}{m^*}\right)\vec{E}_i+\vec{V}\times\vec{\omega}_c\,, \tag{2}$$

where $\vec{E_i}$ is the reduced field and was defined by *DKK* as

$$\vec{E}_i=\vec{E}\Big/\left\{1+\frac{L(\mathcal{E}'-1)}{4\pi}\right\}.$$

The definition of the various frequencies is as follows:

ω: external frequency,

$\omega_c=\dfrac{eH}{m^*c}$: cyclotron frequency,

$\omega_p=\sqrt{\dfrac{L_iNe^2}{m^*}}$: plasma frequency,

$\omega'=\omega-\dfrac{\omega_p{}^2}{\omega}$: reduced frequency.

L_i is the reduced depolarization factor defined by *DKK* as

$$L_i=L\Big/\left\{1+\frac{L(\mathcal{E}'-1)}{4\pi}\right\}.$$

Assuming that $\vec{E}_i$ is along the x-axis and $\vec{H}$ along a direction perpendicular to it, the comple conductivity is obtained from Eq. (2) as

$$\sigma=\frac{I_x}{E_{ix}}=\frac{Ne^2}{m^*}\frac{1}{(i\omega'+\rho)+\dfrac{\omega_c{}^2}{(i\omega'+\rho)}}\,. \tag{3}$$

From this equation, the real and imaginary parts of the conductivity can be calculated as follows:

$$\sigma'=\frac{\sigma_0(1+\omega_c{}^2\tau^2+\omega'^2\tau^2)}{(1+\omega_c{}^2\tau^2-\omega'^2\tau^2)^2+4\omega'^2\tau^2}\,, \tag{4}$$

$$\sigma''=\frac{\sigma_0\omega'\tau(1+\omega'^2\tau^2-\omega_c{}^2\tau^2)}{(1+\omega_c{}^2\tau^2-\omega'^2\tau^2)^2+4\omega'^2\tau^2}\,, \tag{5}$$

where $\sigma_0=Ne^2\tau/m^*$. When no magnetic field is present, Eqs. (4) and (5) reduce to

$$\sigma_0'=\frac{\sigma_0}{1+\omega'^2\tau^2}\,, \tag{6}$$

$$\sigma_0''=\frac{\sigma_0\omega'\tau}{1+\omega'^2\tau^2}\,. \tag{7}$$

Eqs. (4) and (6) were first obtained by *DKK*. Eqs. (5) and (7) are our additional results.

Now it will be interesting to see in what way the sign of the imaginary part of the conductivity, σ'', changes with frequency and magnetic field strength. From (5), we see that when $\omega>\omega_p$ (high frequency or low temperature) σ'' is negative for $\omega_c{}^2<\omega'^2+1/\tau^2$ and positive for $\omega_c{}^2>\omega'^2+1/\tau^2$, while the reverse is true when $\omega<\omega_p$ (low frequency or high temperature). Since σ'' appears in the reactance of the sample and behaves as if it were an effective dielectric constant, this change of sign is a convenient measure in the characteric quantities of the semiconductor.

Now it must be noted that by measuring the complex conductivity at $H=0$ and the magnetic fied H_0 at which the sign of σ'' changes, N, τ and m^* can be obtained from the following calculations. Assuming $\omega'\neq0$ in Eq. (5), H_0 must satisfy the following relation:

$$1+\omega'^2\tau^2-\omega_c{}^2\tau^2=0\,. \tag{8}$$

Using Eqs. (6), (7) and the definition of ω_c, τ/m^* can be obtained from Eq. (8) as follows:

$$1+\left(\frac{\sigma_0''}{\sigma_0'}\right)^2=\left(\frac{eH_0}{c}\right)^2\left(\frac{\tau}{m^*}\right)^2. \tag{9}$$

On the other hand, the following relation is obtained from Eqs. (6) and (7):

$$\sigma_0=\frac{Ne^2\tau}{m^*}=\frac{\sigma_0'^2+\sigma_0''^2}{\sigma_0'}\,. \tag{10}$$

Utilizing Eqs. (9) and (10), N can be obtained as

$$N=\frac{H_0}{ec}\sqrt{\sigma_0'^2+\sigma_0''^2}\,. \tag{11}$$

τ and m^* are obtained in the following way. Using Eqs. (6), (7) and the definition of ω_p, we obtain

$$\frac{\sigma_0''}{\sigma_0'}=\tau\left(\omega-\frac{L_iNe^2}{m^*\omega}\right). \tag{12}$$

Then, using Eqs. (9) and (12), τ and m^* can be obtained separately as

$$\tau=\frac{1}{\omega}\left\{\frac{\sigma_0''}{\sigma_0'}+\frac{L_i}{\omega}\,\frac{\sigma_0'^2+\sigma_0''^2}{\sigma_0'}\right\}, \tag{13}$$

$$m^*=\frac{H_0e}{c\omega}\left\{\frac{\sigma_0''}{\sqrt{\sigma_0'^2+\sigma_0''^2}}+\frac{L_i}{\omega}\sqrt{\sigma_0'^2+\sigma_0''^2}\right\}. \tag{14}$$

§ 3. The Complex Conductivity in the *n*-carrier Problem

As was mentioned before, there are several kinds of free carriers in usual semiconductors. In such cases the problem is very difficult to solve rigorously. But when the densities of the carriers are so small that their interaction can be represented by a common long range depolarization force acting on each of them, the problem can be solved as follows. Let us assume that the carrier are all electrons. This is no essential restriction to the theory and if desired, holes can also be included without much altering the treatment. The equation of motion can be written as follows:

$$\begin{aligned}
&(i\omega+\rho_1)V_{1x}-i\alpha\frac{1}{m_1{}^*}\sum_{j=1}^{n}N_jV_{ix}=\frac{e}{m_1{}^*}E_i+V_{1y}\omega_c\ ,\\
&(i\omega+\rho_1)V_{1y}-i\alpha\frac{1}{m_1{}^*}\sum_{j=1}^{n}N_jV_{jy}=-V_{1x}\omega_{c1}\ ,\\
&\cdots\cdots\cdots\cdots\\
&(i\omega+\rho_n)V_{nx}-i\alpha\frac{1}{m_n{}^*}\sum_{j=1}^{n}N_jV_{jx}=\frac{e}{m_n{}^*}E_i+V_{ny}\omega_{cn}\ ,\\
&(i\omega+\rho_n)V_{ny}-i\alpha\frac{1}{m_n{}^*}\sum_{j=1}^{n}N_jV_{jy}=-V_{nx}\omega_{cn}\ ,
\end{aligned}\tag{15}$$

where $\alpha=L_ie^2/\omega$. The second terms in the left-hands of these equations represent the average effect of the other electrons producing a long range polarizing field. The equations reduce to Eq. (2) if we put $N=1$. As before, the magnetic field is along the z-direction and the rf-electric field is along the x-direction. From these equations, we obtain the following relations:

$$V_{jx}=\frac{(i\omega+\rho_j)\dfrac{e}{m_j{}^*}E_i+i(i\omega+\rho_j)\dfrac{\alpha}{m_j{}^*}X+i\dfrac{\alpha}{m_j{}^*}\omega_jY}{(i\omega+\rho_j)^2+\omega_{cj}{}^2}\ ,\tag{16}$$

$$V_{jy}=\frac{-\dfrac{e}{m_j{}^*}\omega_{cj}E_i-i\dfrac{\alpha\omega_{cj}}{m_j{}^*}X+i(i\omega+\rho_j)\dfrac{\alpha}{m_j{}^*}Y}{(i\omega+\rho_j)^2+\omega_{cj}{}^2}\ ,\qquad (j=1,\ 2,\ \cdots,\ m)\tag{17}$$

where X and Y are

$$\left.\begin{aligned}
X&=\sum_{j=1}^{n}N_jV_{jx}\ ,\\
Y&=\sum_{j=1}^{n}N_jV_{jy}\ .
\end{aligned}\right\}\tag{18}$$

Now we obtain the following relations by multiplying Eqs. (16) and (17) by N_j and summing over j:

$$X=\sum_{k=1}^{n}\frac{e\dfrac{N_k}{m_k{}^*}(i\omega+\rho_k)}{(i\omega+\rho_k)^2+\omega_{ck}{}^2}E_i+\sum_{k=1}^{n}\frac{i\alpha\dfrac{N_n}{m_n{}^*}(i\omega+\rho_k)}{(i\omega+\rho_k)^2+\omega_{ck}{}^2}X+\sum_{k=1}^{n}\frac{i\alpha\dfrac{N_k}{m_k{}^*}\omega_{ck}}{(i\omega+\rho_k)^2+\omega_{ck}{}^2}X\ ,\tag{19}$$

$$Y=\sum_{k=1}^{n}\frac{-e\dfrac{N_k}{m_k{}^*}\omega_{ck}}{(i\omega+\rho_k)^2+\omega_{ck}{}^2}E_i-\sum_{k=1}^{n}\frac{i\alpha\dfrac{N_k}{m_k{}^*}\omega_{ck}}{(i\omega+\rho_k)^2+\omega_{ck}{}^2}X+\sum_{k=1}^{n}\frac{i\alpha\dfrac{N_k}{m_k{}^*}(i\omega+\rho_k)}{(i\omega+\rho_k)^2+\omega_{ck}{}^2}Y\ .\tag{20}$$

Solving these Eqs. (19) and (20), one obtains X and Y.

On the other hand, the resultant conductivity is defined by

$$\left.\begin{aligned}
\sigma_x&=\frac{eX}{E_{ix}},\\
\sigma_y&=\frac{eY}{E_{ix}},
\end{aligned}\right\}\tag{21}$$

where σ_x represents the drift conductivity and σ_y the Hall conductivity. With the use of Eqs. (19) and (20), conductivities can be written in another way as

$$\sigma_x=\frac{ie^2}{\alpha}\left(1-\frac{P}{P^2-Q^2}\right),\tag{22}$$

$$\sigma_y=\frac{e^2}{\alpha}\frac{Q}{P^2-Q^2}\ ,\tag{23}$$

where P and Q are defined by

$$P=1-i\sum_{k=1}^{n}\frac{\dfrac{\omega_{pk}{}^2}{\omega}(i\omega+\rho_k)}{(i\omega+\rho_k)^2+\omega_{ck}{}^2}\ ,\tag{24}$$

$$Q=\sum_{k=1}^{n}\frac{\frac{\omega_{pk}^2}{\omega}\omega_{ck}}{(i\omega+\rho_k)^2+\omega_{ck}^2}\,, \tag{25}$$

In this way we obtained the solution. Since it is not easy to obtain from this result separate formulae for σ' and σ'' in the general case, we shall discuss only special but important cases.

(1) $\omega_{ck}=0$ and $\rho_k=0$ (vanishing magnetic field neglecting relation effects).

This is the simplest case, σ_y and σ_x' are zero and σ_x'' is given by

$$\sigma_x''=\frac{e^2\sum_{k=1}^{n}\frac{N_k}{m_k^*}}{\omega_n'}\,, \tag{26}$$

where $\omega_n'=\omega-\sum_{k=1}^{n}\omega_{pk}^2/\omega$ is introduced as the generalized reduced frequency. It is interesting to note that the resonance frequency of this system is determined by the vanishing of the generalized reduced frequency, i.e., $\omega_n'=0$. Furthermore, the resultant reduced mass, μ, defined by

$$\frac{N}{\mu}=\sum_{k=1}^{n}\frac{N_k}{m_k^*}\quad\left(N=\sum_{k=1}^{n}N_k\right), \tag{27}$$

can be used.

(2) $\omega_{ck}=0$ and $\rho_k=\rho$ (vanishing magnetic field with a common relaxation time).

The complex conductivity can be written as

$$\begin{aligned}\sigma_x'&=e^2\sum_{k=1}^{n}\left(\frac{N_k}{m_k^*}\right)\frac{\rho}{\omega_k'^2+\rho^2}\,,\\ \sigma_n''&=e^2\sum_{k=1}^{n}\left(\frac{N_k}{m_k^*}\right)\frac{\omega_k'}{\omega_k'^2+\rho^2}\,,\\ \sigma_y&=0\,.\end{aligned} \tag{28}$$

For other cases, such as the case of $\omega_{ck}=0$ and $\rho_k\neq\rho_{k'}$ (vanishing magnetic field with different relaxation times), where the coherency of the motions of different carriers is spoiled by the difference of their relaxation times, or $\omega_{ck}\neq\omega_{ck'}$ and $\rho_k=0$ (different cyclotron frequencies and neglecting relaxation effect), where the different carriers move with different cyclotron frequencies, no simple expression can be obtained for σ_x', σ_x'', σ_y' and σ_y''.

For Si and *Ge*, the cases (1) and (2) may be realized at liquid helium temperatures in mm wave region. The dynamical motion of the various free carriers can be analyzed by varying the impurity concentration, the measuring temperature and the shape of the sample. It may be interesting to investigate the temperature range where the impurity band conduction begins. Because the accuracy of the α'' measurements can be reduced to the accuracy of the frequency measurement of the resonant cavity, we may be able to detect the fine variation of the phenomena which is not easily observable by *DC*-method.

§ 4. Conclusion

Using this theory of the magneto-plasma resonance of the *n*-carrier problem, we can obtain the following practical informations of the dynamical properties of the free carriers in semiconductors:

(1) The pure magneto-plasma resonance frequency and the relaxation time in Si and Ge etc. using Eqs. (26), (27) and (28).

(2) The carrier density, the effective mass and the relaxation time at microwave frequencies by measuring the loss and shift of the resonant cavity as are shown in Eqs. (11), (13) and (14). The resonance is observed as an anomaly of the complex conductivity.

(3) The resonance phenomena which are observed in association with the cyclotron and spin resonance can be discussed quantitatively as the magneto-plasma resonance.

Proton Magnetic Resonance in Pure and Doped Ice

By Kiyoshi KUME

The Institute for Solid State Physics, University of Tokyo, Tokyo

(Received April 14, 1960)

Basing upon a carefully designed method of measurement in samples showing long T_1, a complete proton magnetic resonance experiment of ice is attempted. First, on a second moment argument in rigid lattice state, the possibility that protons do not lie on the inter-oxygen lines is pointed out, in connection with the neutron diffraction studies. Secondly, from the relaxation time and line-narrowing measurements, the difference between the behaviors of protons in pure and doped ice is discussed, the results of the dielectric and the direct current conductivity measurements by Zürich group being taken into consideration.

§ 1. Introduction

It was established through X-ray analysis(1), that ice crystal belongs to the hexagonal space group D^4_{6h}-$C6/mmm$ under ordinary pressures and temperatures, the oxygen atoms occupying regular lattice points ± (1/3, 2/3, 1/16) and ± (1/3, 2/3, 7/16) as is shown in Fig. 1, each surrounded by the neighboring four atoms approximately tetrahedrally. But as for the positions of hydrogens, the X-ray analysis can tell hardly anything, and the problem has been left for later investigations.

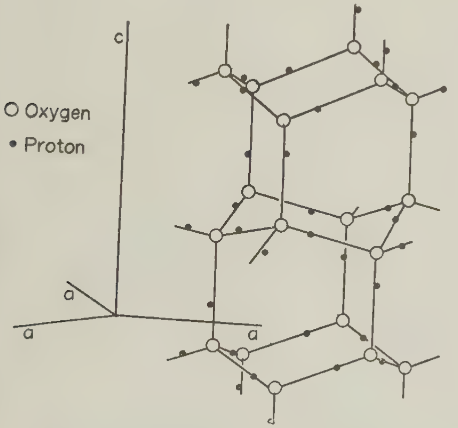

Fig. 1. Crystal structure of ice.

On the other hand, several properties of ice have been discovered, which are considered to have some connection with the arrangement or the rearrangement of protons. First, by specific heat measurement, the residual entropy of 0.82 ± 0.05 cal/deg mole was concluded by Giauque et al at 10°K(2)(3), and this fact was explained by Pauling(4), assuming a disordered arrangement of protons in the ice crystal. According to his model, protons are assumed to obey the following three rules. Namely, first, two protons exist among the four possible positions surrounding each oxygen, secondly, protons lie on the lines connecting two oxygens, and thirdly, no two protons can exist on any one such oxygen-oxygen line. Moreover, as far as these three rules can admit, protons can take any of the possible arrangements at random. The calculated value of residual entropy upon this model is $k \ln (3/2)^N = 0.806$ cal/mol degree, and is considered to agree well with the observed. Next, the dielectric behavior was rather thouroughly examined by Smith-Hitchcock(5), Auty-Cole(6) and other authors(7), and shown to exhibit Debye-type dispersion at rather low frequencies and at relatively high temperatures. The dispersion has naturally been attributed to the reorientation of dipoles associated with water molecules

Recent neutron diffraction studies by Peterson-Levy(8) revealed the positions of protons (actually deuterons) to be consistent with the Pauling model. As for the dynamical behavior of protons, some effort was made to study it by measuring the dielectric behavior, not only of a pure sample but also of a doped one(9)(10). The most systematic attempt of this kind made recently seems to be the dielectric as well as the direct current conductivity measurements on HF doped ice by the school in Zürich(9).

Under these circumstances, we attempted rather complete proton magnetic resonance studies to shed some light on these problems from a somewhat different point of view. The characteristic features of the method exist in that, first, protons are concerned exclusively with it, and secondly, the method is rather microscopic in the sence that only very short range interactions are concerned, and both of these two features are essentially favorable to our studies on ice. In section 2, the quantitative line shape measurements on a rigid lattice at sufficiently low temperatures will be discussed in connection with the positions of protons, at the same time, taking into account the result of the neutron diffraction studies. In sections 3, the experimental result on the temperature dependence of the length of the relaxation time T_1 and of the narrowing of the absortion line in pure as well as in doped specimens, will be interpreted from the standpoint of the dynamical behavior of protons. The arguments should mainly be compared with the results of dielectric measurements(9), which might, however, not entirely be free from the influence of some macroscopic effects like electrode polarization.

The proton magnetic resonance experiment on ice crystals, is not entirely novel. Following the pioneer work by B.B.P.(11), some attempts of refining or extending it were made by the group in Osaka University(12) from the angle of line shape measurements, and by T.E. Turner(13) and others(14) from the angle of relaxation time measurement. Nevertheless, their results were not necessarily satisfactory, as will be mentioned in the following sections, because the proton system in an ice crystal has a longer relaxation time, especially at low temperatures, and consequently the accurate measurements of absorption line shapes as well as of relaxation time is rather difficult; therefore, thus far, no satisfactory result has even been attained. The author has made some effort in improving the measuring technique in case of longer T_1, with much success as is given below. As for specimens, the author used a carefully purified one, as well as one specifically doped with non-paramagnetic ions in order to clarify the mechanism of relaxation.

§ 2. Line Shape of a Polycrystalline Sample in Rigid Lattice State

Although the specimen used in this case is of not so high purity, it has a long T_1 of the order of ten minutes, special precaution being to thus necessary to cut down the r.f. level as low as 40 microgauss to prevent saturation. The detecting system used, is of a bridge type, having sufficiently low noise figure.(23)(24

A recorded derivative of the saturation free absorption line in polycrystalline ice at –180°C is reproduced in Fig. 2. There is seen

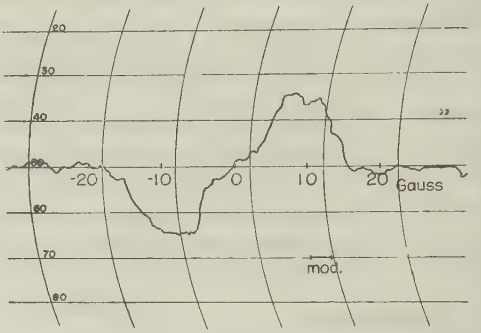

Fig. 2. Derivative of absorption curve of polycrystalline ice.
Sample: Ice polycrystal of not so high purity. See the text for details.
Field: 7060 Gauss.
Field sweep: 2.6 Gauss/min.
Frequency: 30.0 MC.
R. f. field within sample coil: 40 microgauss.
Time constant: 12 sec.
Temperature: 90°K.

somewhat flattened portion at the center, which may be considered to show the two spin character of the proton system, which is much more pronounced in the single crystal experiment(25). It has a maximum-slope-linewidthof $16._0$ Gauss, which is compatible with the data of B.P.P.(11) as well as with that of Osaka Group(12) at higher temperatures. The second moment of the absorption line is found to be 36.7±1.7 Gauss(2), the modulation correction being made after Andrew(16). The second moment shown above is the average of six independent data, together with the standard deviation.

The above measurements are made on a specimen, frozen at a temperature near the melting point at rather a high rate of about one minute, and then cooled to –180°C within 150 minutes and then kept there for about 120 minutes. An independent measurement is made on a specimen at –180°C, after being kept at about –5°C for a few weeks. The latter showed almost the same line shape as above, within the experimental error, although it has a longer T_1 of about 40 minutes. In the line shape measurement in this case, the r. f. field is cut to zero except during short periods for measurements to escape from saturation and the result is rather qualitative in character(27).

Through the second moment arguments in case of the rigid lattice, we shall discuss the stable positions of protons in the crystal lattice as follows. We assume the so-called Pauling rules, which are already mentioned in section 1. Although these rules lay certain restrictions on the arrangement of protons, there still remain some possibilities. According to the orientation of the central water molecule, the protons "0", "1" and "2" are fixed as shown in Fig. 3 through above mentioned rules. The remaining protons of the molecules I, II, III, which are not shown in the figure, as well as the protons of the molecule other than the nearest, cannot be uniquely fixed. In Pauling's disordered model(4), such protons are placed at random, and in other kinds of proposed ordered structures(17), they are fixed with certain regularities. As far as the second moment argument is concerned, however, we cannot discriminate the former from the latter, because the contributions to the proton "0" from protons attatched to molecule I is the same, on whichever O—O line among the possible three they are situated, and furthermore the difference in the contributions from those of II, III or those of the protons of the molecules other than the nearest is too small to influence the total second moment. Actually, the contribution from the molecule II is 0.37 Gauss^2 in case of Pauling model, compared with 0.35 Gauss^2 in case of Bjerrum's ordered structure(17), and that from the molecules III is 0.31 Gauss^2 in the former, compared with 0.29 Gauss^2 in the latter. And in total, the difference between the two models is found to be 0.06 Gauss(2), which value is not so sensitive to the assumed parameters concerning the shape of the water molecule.

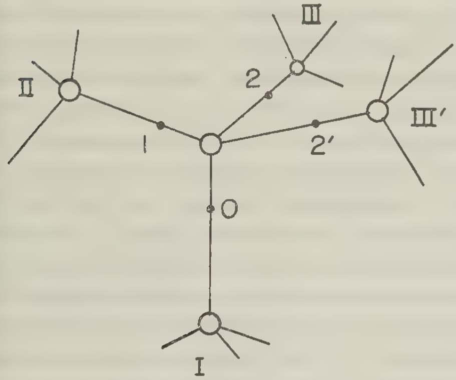

Fig. 3.

The main contribution to the total second moment is determined by the shape of the water molecule, namely the OH length and the HOH angle. Actually, in the powder experiment, only the second moment is available, and this gives a relation between these two unknown parameters. The result is shown graphically in Fig. 4 by the shaded area, the width of which corresponds to the experimental error given above.

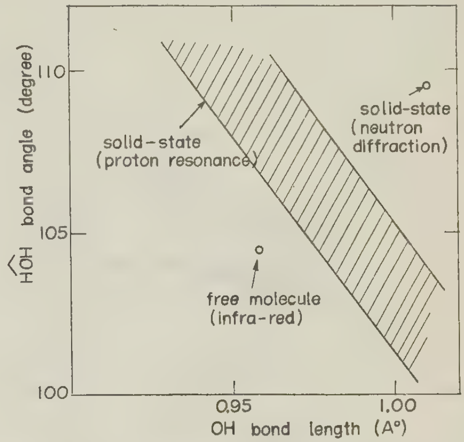

Fig. 4. Shapes of water molecules determined through various methods in free- as well as in solid-state.

First, if we assume the shape of the water molecule to be the same as that of the free molecule(18) (OH = 0.958_4 Å, HOH angle = 104°27′), the calculated second moment is obviously outside of the experimental error (Fig. 4). This suggests that, in a crystalline state, the OH bond is lengthened or/and the HOH angle is more opened, through the influence of the hydrogen bonding between molecules.

On the other hand, the neutron diffraction(8) gives an OH bond length of 1.01 Å as well as the tetrahedral bond angle HOH of 109.5°, the resulting second moment is again outside the experimental error, whereas this bond length is required to have the value of 0.95_5 ±0.01 Å in order to be consistent with the observed second moment, keeping the tetrahedral bond angle. On the contrary, if we assume the OH distance of 1.01 Å, and adjust the bond angle HOH so as to obtain the best fit with the observed second moment, the resulting bond angle will be 102±2 degrees, which is rather close to the bond angle of 104.5 degrees in a free molecule. At first sight, the discrepancy between neutron and resonance studies might seem to be serious, judging from the higher accuracy of the neutron diffraction studies. In Pauling model, however, it is natural to ascribe equal probability to the possible three alternatives as shown in Fig. 5. Because of the restriction imposed upon the arrangement of the protons, this does not violate the validity of Pauling's entropy arguments. According to the neutron diffraction, the contour of the hydrogen is much more elongated in the direction perpendicular to, rather than in the direction parallel to the O—O line. Although we have only a single proton among points H_1, H_2 or H_3 a random spacial configuration results in the contour diagram such as the one observed, as a result of the superposition of the off O—O line positions of hydrogen atoms. The above anisotropy reported by neutron diffraction studies is of the order of magnitude consistent with resonance data, assuming the HOH angle of 104.5 degrees, and hence the bond length of 1.01 Å.

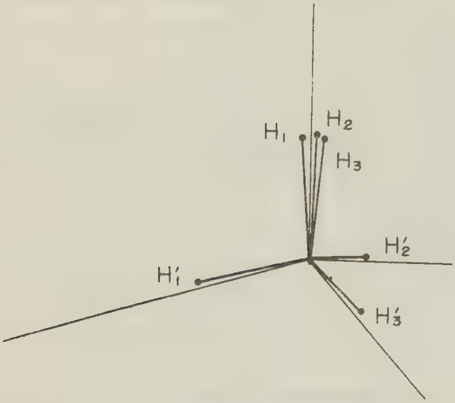

Fig. 5.

Thus the present second moment argument suggests that although the effect of hydrogen bonding distorts molecules appreciably, it is not large enough to pull out the hydrogen, so as to come on the O—O line. This conclusion is compatible with the existing neutron diffraction data on weak O-H---O hydrogen bonds such as in the case of the water of crystallization in sodium sesquicarbonate(19) (O—O length 2.78 Å), and oxalic acid dihydrate (O—O length 2.86 Å)(20), as well as our nuclear resonance data on boric acid (O—O length 2.72 Å)(26).

§ 3. Temperature Dependence of Relaxation Time and Line Width

(a) *Specimen*

For the purpose of T_1 measurements, a highly purified specimen is necessary, because, in the first place, as is well known(21), even the slightest contamination by paramagnetic impurities drastically affects the T_1 value, and at the same time, in connection with the dielectric measurements,(9)(10) even non-paramagnetic impurities may become a cause of certain types of lattice defects, which will also affect the T_1 value appreciably.

The water distilled with an ordinary type metal distillater is further purified through a distillation column of about 1 meter in height, which is filled with a mixture of two kinds of ordinary ion exchange resin, AG Amberlite IR-120 and IRA-400 from the Japan Organo Co. LTD. The water thus purified is shown to have a specific electric conductivity of 1.0~1.5 μ℧/cm, and is sealed in fused-silica ampoules under a nitrogen atmosphere, after being bubbled with nitrogen to get rid of the oxygen gas dissolved in the water, which might affect the value of T_1 owing to its paramagnetic character. The water thus prepared is frozen at about -5°C in the refrigerator. According to Turner's experiment(13), a gradual rise in T_1 value is observed as time elapses after freezing, and finally reaches the stationary value. A similar phenomena has been observed in our preliminary experiment. Therefore, the sample used in the present measurement has all been annealed at -5°C over six months. The specimen thus prepared is considered to be free from alkaline substances, for the operations were made in polyethylene or silica containers, and not in the glass.

Besides the 'pure' specimen, thus prepared, we also measured the T_1 in a "doped" one. 1/1000 N of KOH is added to the pure liquid water, and the liquid is frozen at -10°C and then annealed. If it were assumed that all of the KOH molecules remained in ice, there would exist one KOH molecule per five thousand water molecules. And we also measured the T_1 in two kinds of "pure" specimens, which are supposed to have a different purity from each other.

(b) *Method of measuring longer T_1*

In case of longer T_1 of several hours, it is practically impossible to observe "steady-state" signals. In this case, however, T_1 can be determined by combining the following two informations. One is the height of the "transient" absorption signal, which is given after the appropriate time from the time, at which the magnetization starts to recover from the state of complete saturation. The other is the saturation-free signal, which is, in principle, can be obtained from the measurement, made after the elapse of sufficiently a long time compared with T_1 of the sample to be measured, since the foregoing irradiation of high frequency magnetic field is cut off. This is practically impossible in case of longer T_1. A specimen of ice, which has sufficiently a short T_1 due to added parramagnetic impurities, is therefore made use of, to determine the saturation-free value. The calibrator signals are used for determining the scale, throughout the measurement. The long range stabilities of the magnetic field and the whole detecting system are checked by a field monitor, and a calibrator, respectively, and the balance of the bridge is readjusted just before the transient signal is given. For details of the procedure adopted here, see the separated paper(27). Fig. 6 shows an example of the transient signal.

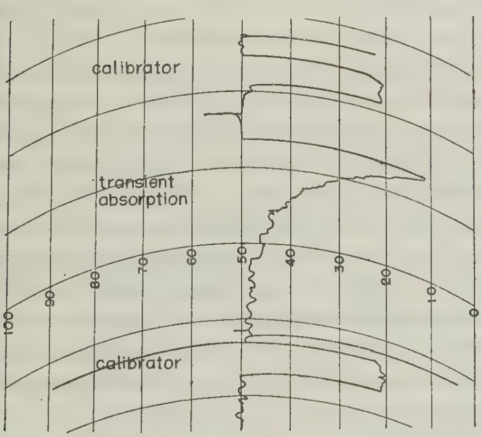

Fig. 6. An example of the transient signal.
Sample: Ice pure "1", see the text for details.
Field: 7060 Gauss.
Field sweep: fixed.
Frequency: 30.0 MC.
R. f. field within sample coil: 1 milligauss.
Time constant: 0.7 sec.
Temperature: 193° K.
Flow rate of the chart: 1 cm/30 sec.

(c) *Results*

In Fig. 7 is shown the temperature dependence of relaxation time T_1. The T_1 shorter than twenty seconds is measured by the saturation method, and the one between ten minutes and twenty seconds is measured by the ordinary direct method. The measurement of a T_1 longer than five minutes is done by the method described in the preceding paragraph. Before each measurement at a certain temperature, the specimen is kept at that temperature for more than 40 minutes in order to obtain thermal equilibrium. In a preliminary experiment, we confirmed that T_1 did not change over 10% during 8 hours at -85°C. Therefore, equilibrium would sufficiently be attained after 40 minutes. It is obvious from Fig. 7 that the curve of the

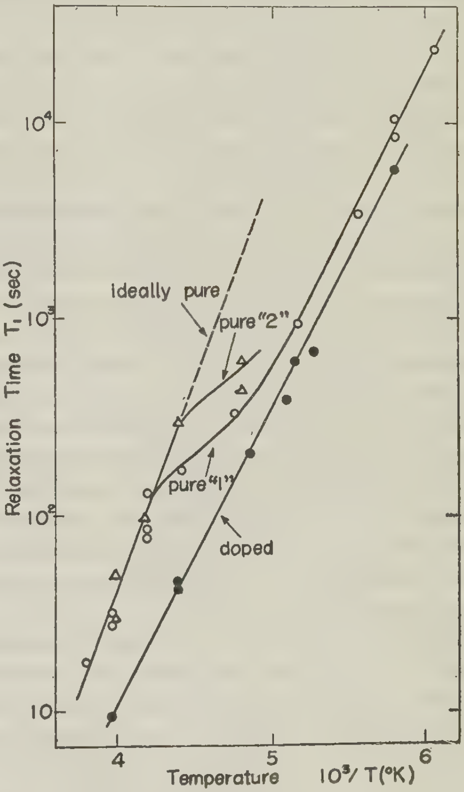

Fig. 7. Temperature depencence of relaxation time T_1 in pure as well as in doped polycrystalline ice.

sample numbered "pure 1" consists of three regions. The first region above -40°C has a maximum slope, which corresponds to the activation energy of 0.44 eV, and the second region between -40°C and -80°C has a minimum slope of about 0.17 eV, and finally the third and the lowest temperature region has a medium slope of 0.30 eV. T_1 versus temperature curve for the "pure 2" has the first region in common with that of "pure 1" at higher temperatures. The second region, however, is different in absolute value, but still has the same slope with that of "pure 1". Compared with these pure samples, the "doped" one has a straight line, whose slope is the same as that of the third region of "pure 1". At first sight, it might appear strange that the "doped" one has a straight line, and the "pure" has a crooked one. The explanation might be as follows. Suppose that the perfectly pure specimen shows a straight line as shown in Fig. 7 with an extrapolated broken line. By adding a small amount of impurities, the curve is bent into three as in the case of "pure", and the second region gradually shifts to the higher temperature side by the further addition of impurities, and then finally in sufficiently doped samples, the curve has only a slope which corresponds to the third region of the "pure" specimen.

The difference between the "pure" and the "doped" ice is also seen in the temperature dependency of the line width (Fig. 8). As the temperature is raised, the absorption line of the "doped" ice becomes narrower more rapidly than that of the "pure" ice. This behavior can be correlated with the difference between the T_1's of the pure and doped ice, in the corresponding regions shorter than one minute. In the corresponding regions longer than one minute, however, the correlation time τ_c, which is related to the observed T_1 through the well-known formula $\tau_c=\frac{<\Delta\nu^2>_{AV}}{\nu^2}T_1$, where $<\Delta\nu^2>_{AV}$ and ν mean the second moment of the absorption line width, and the resonance frequency, respectively, is longer than the reciprocal of the line width in frequency scale, and consequently the line width saturates at a value of so-called "rigid lattice case" and difference between the "pure" and the "doped" also disapears.

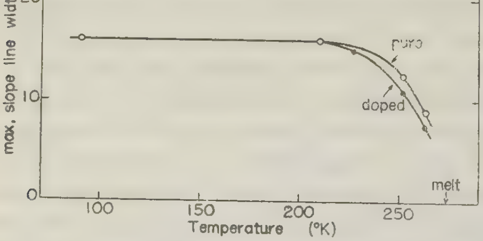

Fig. 8. Narrowing of absorption line in pure as well as in doped polycrystalline ice.

(d) *Discussion*

First, we will comment on the comparison with the previously reported value of T_1 by B.P.P.(11) and Turner(13). B.P.P. measured T_1 only in the higher temperature region above -35°C. Compared with the present results, their results are about three times as short, although the difference in temperature dependency is insignificant. The difference might be attributed to either the difference in purity, of which effect is already obvious from the present work, or perhaps in the difference in thermal treatment. Turner extended B.P.P.'s measurements to lower temperatures. Comparing this again with the present work, his T_1 curve has approximately the same slope as ours in the second region mentioned above, although his results are about twice as long as that of our specimen "pure 2" in absolute value. In the third region, however, his curve deviates gradually from ours to the shorter T_1-side, and finally reaches a constant value of 10^4 seconds. The latter behavior might naturally be considered to be due to the effect of paramagnetic impurities existed in Turner's samples, which are considered to provide a temperature-independent relaxation mechanism(21). Throughout the above comparison, we have ignored the difference in T_1 due to a different external magnetic field.

Secondly, the correlation time τ_c, which is obtained from the observed T_1 through the above-mentioned formula, is compared with the dielectric relaxation time τ reported by the Zürich group(9). The Zürich group has measured the dielectric relaxation time τ as the function of the impurity (HF) content at three fixed temperatures -36°C, -10°C, -3°C. They have found that as the impurity increases, the activation energy decreases from the initial value of 0.58 eV to a minimum value of 0.23 eV, and then increases again to reach the final value of 0.32 eV. This behavior is quite similar to what we have found. If we cut a group of T_1 versus $1/T$ curves in Fig. 7 by a straight line corresponding to a fixed temperature, for example at −60°C, it is readily seen that the activation energy first gets the highest value, then drops to the lowest, and then reaches to a final medium value as the amount of impurities added increases. The comparison between the activation energies in both cases are shown in Table 1. The activation for the dielectric relaxation differs a little from that for the resonance, according to their definitions. Taking this difference into account, the coincidence between the correlation time in proton magnetic resonance and the dielectric relaxation time is considered to be satisfactory. Judging from the experimental results, the difference between species of ionic impurities in their effects on the activation energies is insignificant, as far as they are diamagnetic, because KOH and probably H_2CO_3 too in our work give similar results with the HF impurities in Zürich's experiment. The corresponding behaviors between the proton magnetic and the dielectric relaxation, ensures the fact that the phenomena is based actually upon the microscopic relative motion of protons. If the change in the relaxation time were due to the effect of paramagnetic impurities, it should not be observed in the dielectric measurement. On the other hand, if the change in relaxation were due to any ions other than protons or due to any macroscopic phenomena like the electrode polarization effect, it should not be observed in the proton magnetic resonance experiment.

Table 1. Comparison between various activation energies

	"pure"		"sufficiently doped"
	1st	2nd	3rd
proton magnetic resonance (present work)	0.44	0.17	0.30 eV
dielectric constant (Zürich group)			
Auty-Cole definition	0.58	0.23	0.32
Debye definition	0.51		
Direct current conductivity (Zürich group)			
Au-electrode	0.6		
sandwitch-electrode			0.33

The experimental result shows that, by the addition of small amount of ionic impurities, a new state appears. The state, which is called "third region" in the above description, is considered to be of rather well-defined one. Bacause, once the state has been realized by the addition of a certain small amount of impurities, not only the activation energy, but also the absolute values can be changed little, by further addition of the impurities. This fact is seen by comparing the above data for doped sample which has a considerable amount of impurities with those for "pure", which has only a trace of such impurities. As is obvious from Fig. 7, the T_1 value of pure specimen in the first region is determined by the different mechainsm corresponding to higher activation energy, whereas T_1 in the third region is due to the same mechainsm as is seen in the doped sample, because there is a justice to believe the existence of a trace of impurities in the so-called "pure" specimen. In the following, we shall call the third region as "sufficiently doped" state and the first region, as "pure" state, and give a discussion concerning the difference between the two states, in connction with the Zürich(9) and other(22) results of direct current conductivity. In contrast to the "third region", "the second region" is structure-sensitive, as is readily seen in the above description.

As is well known, the microscopic diffusion constant of protons is deduced through the well-known formula $D_{\mathrm{n.m.r.}}=\frac{<r^2>}{\tau_c}$, where the correlation time τ_c is known from the proton magnetic resonance experiment, and the mean flight distance r is assumed so as to be consistent with the crystal structure. If the diffusion is not localized, it would result in macroscopic conductivity under an applied electric field, and the specific conductitify is related with the diffusion constant through the so-called Einstein relation $D_{\mathrm{n.m.r.}}=\sigma\frac{kT}{Nq^2}$, where N and q mean the number in unit volume and the charge of carriers, respectively.

Actually, the equation does not hold in "pure" state; as is already pointed out by Bradley[(22)]. If we tacitly adhere to the above equation, we are forced to assume too small a value of 0.02 Å for r. In the "sufficiently doped" state, however, the equation is found to hold fairly well, in contrast to the "pure" state, the left and right hand sides of the equation amounting to 2×10^{-12} cm/sec and $2\sim3\times10^{-12}$ cm/sec at 250°K, respectively, under a reasonably assumed value of 1 Å for r. The data of the conductivity in the "sufficiently doped" state which are used in the above discussions, are actually those in "pure ice" with sandwitch-electrodes of HF-doped ice. However, as is reported, the specimen is naturally considered to be a doped one, because the lattice deffects from the electrode flow into the specimen. According to their discussion the conduction is believed to be due to neither electrons nor ions of any kind other than protons.

In general, two kinds of motion of protons are thought to be possible in ice crystals[(17)]. One of them is the motion of protons accompanied by the rotational motion of the water molecule, leaving one of the hydrogen bonds as it is, and only breaking the other. The other is the so-called "proton transfer" along the hydrogen bond without any rotation. As is readily seen from the crystal structure of ice (Fig. 1), these two kinds of proton motion give approximately the same order of magnitude of local magnetic field fluctuations; consequently the arguments on the order of magnitude such as given above, cannot discriminate, which of them is actually resposible for the phenomena observed in the present investigation. Nevertheless, from the facts given above, that the Einstein equation holds in the "sufficiently doped" ice and does not hold in the "pure" ice, we might safely say as follows: In the case of "sufficiently doped" ice, protons move smoothly in the crystal of ice through both of the two kinds of motions. On the contrary, in pure ice, it is rather difficult for protons to move because of the fact, that the motion is of a localized, or that the number of carriers is much smaller. A small number of lattice defects such as hydroxyl ions or oxionium ions produced by the addition of alkaline or acidic impurities would facilitate the motion of protons. The activation energy is expected to be lowered by the presence of the added impurity. This is in agreement with the observation descibed above.

Zürich group attempted interpretations of the two states through dielectric and conductivity measurements, especially through discussions of the static dielectric constant. They attributed the activation energy of 0.58 eV in the pure state to the thermal production of the imperfection as well as the rotation of the water molecule, and that of 0.32 eV in the "sufficiently doped" state to the production of the ion, accompanied by the proton conduction due to the addition of HF. These conclusions seem to be consistent with our results.

The author wishes to express his hearty thanks to Prof. Y. Kakiuchi for suggesting the subject, and also for his kind guidance with deep insight.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 15, No. 8, AUGUST, 1960

Radiation Effects on Dimethyl-diphenyl Siloxane Copolymer. I. Protective Effect of Phenyl Radical on the Cross-linking.

By Mitsuru KOIKE and Akibumi DANNO
Japan Atomic Energy Research Institute, Tokai-mura, Naka-gun, Ibaraki-ken, Japan

(Received March 19, 1960)

The radiation effects both of polydimethyl siloxane and dimetyl-diphenyl siloxane copolymers were studied by the use of gamma rays of cobalt-60 in order to estimate the protective effect due to phenyl radical against the radiation-induced cross-linking. The viscosity of irradiated sample increased with the absorbed dose and finally the sample became gel. The efficiency of cross-linking of copolymers is remarkably reduced with increasing concentration of diphenyl siloxane. The minimum absorbed dose for gel formation, the efficiencies of cross-linking per monomer unit were obtained as a function of the concentration of phenyl radical. It is estimated that the protective effect of diphenyl siloxane may extend over five or six neighbouring monomers of dimethyl siloxane.

§ 1. Introduction.

The effects of ionizing radiation on high polymers have been studied by many workers, and it is well known that polystyrene is the most stable polymer against radiations[1)-6)]. An ordinally polymer needs the absorbed energy of about 20 eV for one cross-linking, whereas polystyrene requires much higher value of about 3,000 eV[1)]. The stability of polystyrene is due to the presence of phenyl radical within the polymer molecule.

In order to obtain polymers of higher radiation stability, several studies on the copolymers containing phenyl group were carried out. For examples, Sisman and Bopp[2)] studied the radiation effect of styrene-butadiene and styrene-acrilonitrile copolymers irradiated in a nuclear reactor. They observed that the change in hardness of the copolymers was much less than that of pure polybutadiene and polyacrilonitrile. Alexander and Charlesby[7] studied the irradiation behavior of copolymer containing various proportions of styrene and isobutyrene, and found that the degradation of isobutyrene was greatly suppressed with increasing content of styrene. They also calculated the degree of protection due to phenyl group assuming a random distribution of styrene and isobutyrene units throughout the copolymer molecule, and came to a conclusion that phenyl group in styrene monomer unit protects about four neighbouring carbon atoms in the main-chain.

The irradiation behavior of polydimethyl siloxane also has been studied by may investigators.[2,3,8-10] They concluded that the cross-linking is formed in the polymer by the irradiation[11-15]. The stabilizing effect of phenyl group, in dimethyl-diphenyl siloxane copolymer, was observed by Warrick[13]. He found that in this copolymer the energy required, for the same order of cross linking formation, was 20 times as that of polydimethyl siloxane. However, his result has not been reported in detail.

In the present work, measurement were carried out on the change of viscosity caused by the irradiation on dimethyl-diphenyl siloxane copolymer, for various concentrations of diphenyl siloxane and also for different initial molecular weight of the copolymers, in order to study the protective effect of phenyl group against the radiation-induced cross-linking of siloxane copolymer. From the experimental results obtained some informations on the protective effect of phenyl group against cross-linking was obtained.

§2. Experimental.

The polydimethyl siloxane and the copolymer of dimethyl siloxane and diphenyl siloxane used in this experiment are transparent and viscous liquid*. The concentration of phenyl group in the copolymer were selected to be 5 and 25 mol%, respectively.

Molecular weight of the polymer was obtained from viscosity measurement using the Stauding's law,

$$\eta = KM^{\alpha}, \tag{1}$$

where η is viscosity, M the molecular weight, K and α constants for a given polymer. In the case of polydimethyl siloxane[11], Eq. (1) applies with bulk viscosity, η, in cs at 25°C; $K=5.3\times10^{-4}$, $\alpha=1.39$ when $M<30{,}000$; and $K=2.7\times10^{-14}$, $\alpha=3.7$ above this molecular weight. The value of M thus obtained should be the weight average[12]. In order to determine the molecular weight of copolymer, the same value as for polydimethyl siloxane were tentatively applied for K and α in Eq. (1), since the value of K and α for the copolymer have not been published. For the calculation of the degree of polymerization of the copolymer, the molar average molecular weight was used as the molecular weight of apparent monomer, assuming that the copolymer consisted hypothetically of one kind of monomers. Data thus obtained are shown in Table I.

Table I. Phenyl radical content, initial bulk viscosity, η_0, initial molecular weight (weight average), M, and initial degree of polymerization, P, of the samples.

content of phenyl radical (mol %)	η_0 (cs)		M	P

	3,000	3.17 〃	4.10 〃	532
25	450	4.42×10^2	1.82 〃	194

Irradiation was carried out with the cylindrical 10 kilo-curie cobalt-60 source[16]. The maximum field strength of 2×10^6 rad/hr was available at the center of the source cylinder. Dose rate of about 2.0×10^6 rad/hr was usually used for irradiation, but sometimes about 5×10^5 rad/hr was also used. The upper limit of absorbed dose for the experiment was 1.4×10^9 rad. A test tube of hard glass of 20 cm in height and 1.8 cm in diameter was filled with sample liquid and plugged with a glass stopper leaving air column of about 2 cm high above the liquid surface. Samples thus prepared were placed inside or outside of the source cylinder and irradiated at room temperature.

---

* The samples were supplied by Shin-etsu Chemical Industry Co., Ltd.

The change in bulk viscosity of irradiated samples was measured by a rotation viscometer of concentric cylinder type at 25°C. This viscometer consists of inner and outer cylinders; the outer cylinder rotates at constant speed and the inner cylinder is suspended vertically by a torsion wire. A sample to be measured is filled in the gap between the inner and the outer cylinders. The bulk viscosity of liquid can be measured from the angular deflection of the torsion wire. Varying the dimensions of the torsion wire and the inner cylinder, it is possible to measure a viscosity change in a wide range.

§ 3. Results of experiment.

The viscosity of copolymers increases more slowly with increasing radiation dose than that of polydimethyl siloxane. The change in viscosity of these polymers by the irradiation depends both on the initial molecular weight and on the concentration of phenyl group. Fig. 1 shows the relationship between these changes in viscosity and the absorbed dose. The initial viscosity of the low molecular sample of polydimethyl siloxane is 0.65 cs. The viscosity change of this low molecular sample was very small even after the irradiation of 1.4×10^9 rad. In other samples, the viscosities increased with increasing absorbed dose and finally samples appeared gel-like. Between the samples having the same phenyl group content, but of different molecular weight, the higher molecular samples required larger absorbed dose than that of the lower molecular weight, for the same amount of viscosity change. On the other hand, between the samples having the same initial molecular weight but containing different amount of phenyl groups. Samples of the higher phenyl group content required larger absorbed dose for the same amount of viscosity change. Further, a similar relation is observed on the minimum absorbed dose for gel formation as mentioned below.

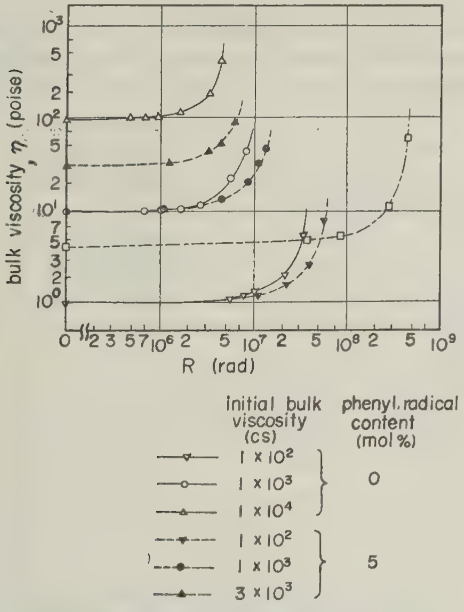

Fig. 1. The change in bulk viscosity by gamma irradiation.

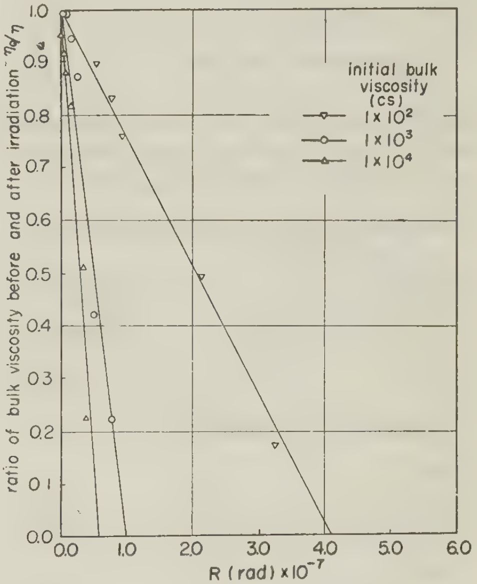

Fig. 2. The relationship between the absorbed dose and the ratio of bulk viscosity before and after irradiation for polydimethyl siloxane.

Figs. 2, 3, and 4 show the relationship between the absorbed dose, R, and the ratio of viscosities, η_0/η, for 0.5 and 25 mol% copolymers, respectively. Setting aside the beginning range where R is small, the linear relationship between η_0/η and R are found both for polydimethyl siloxane and for copolymers. Accordingly, it may be assumed that η_0/η is proportional to R, then the relationship between η_0/η and R can be written, as

$$\eta_0/\eta = 1 - AR \,. \qquad (2)$$

In Eq. (2), A, slope of straight lines in Figs.

2, 3 and 4, is the function of initial molecular weight and the concentration of phenyl radical.

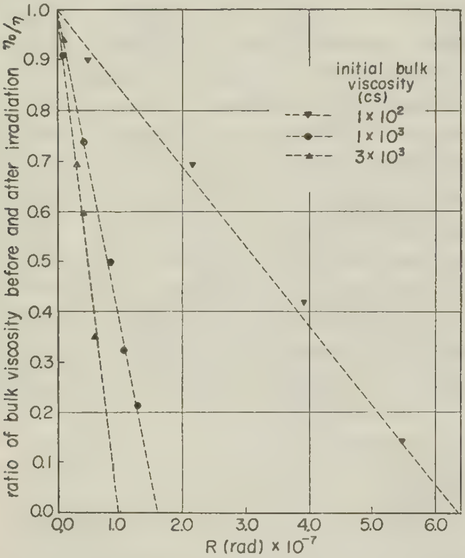

Fig. 3. The relationship between the absorbed dose and the ratio of bulk viscosity before and after irradiation for 5 mol % copolymer.

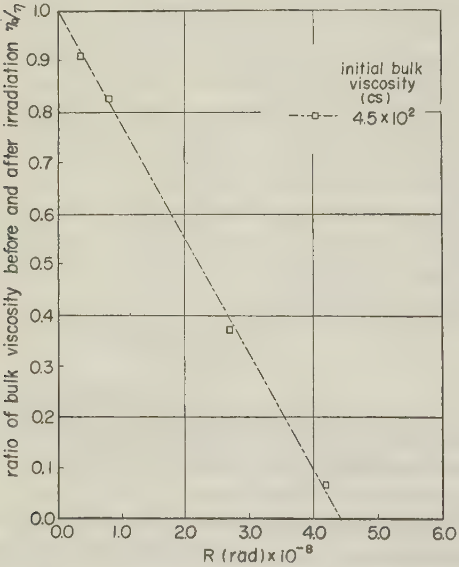

Fig. 4. The relationship btween the absorbed dose and the ratio of bulk viscosity before and after irradiation for 25 mol % copolymer.

The increase in viscosity of irradiated sample is due to the formation of cross-links. When the cross-linked monomer in the molecule is formed to some extent, sample becomes gel. Theoretically, the first gel formation occurs at an absorbed dose of R_g which is needed to produce one cross-linked monomer unit per weight average molecule[17]. Experimentally R_g can be obtained as the dose corresponding to $\eta \to \infty$[18],[19], or $\eta_0/\eta=0$ in Figs. 2, 3 and 4, because η_0/η decreases linearly with the absorbed dose, R, as shown in Eq. (2). The values of R_g obtained in this way are shown in Table II.

Table II. Minimum absorbed dose needed for gel formation, R_g, and the product of R_g and initial molecular weight, M.

content of phenyl radical (mol %)	η_0 normal (cs)	R_g (rad)	$R_g \times$ M (rad)	
0	100	4.1×10^7	2.7×10^{11}	$3\ 0\times10^{11}$
	1,000	9.8×10^6	3.0 〃	
	10,000	5.9 〃	3.3 〃	
5	100	6.3×10^7	4.3 〃	4.3×10^{11}
	1,000	1.6 〃	4.7 〃	
	3 000	9.8×10^5	4.0 〃	
25	450	4.4×10^8	8.0×10^{2}	

Fig. 5 shows the relation between η_0/η and *PR*. In this figure, it is seen that the plots for samples containing the same amount of phenyl groups fall on a straight line independently of the initial molecular weights. Therefore, the relation between η_0/η and *PR* can be expressed as follows;

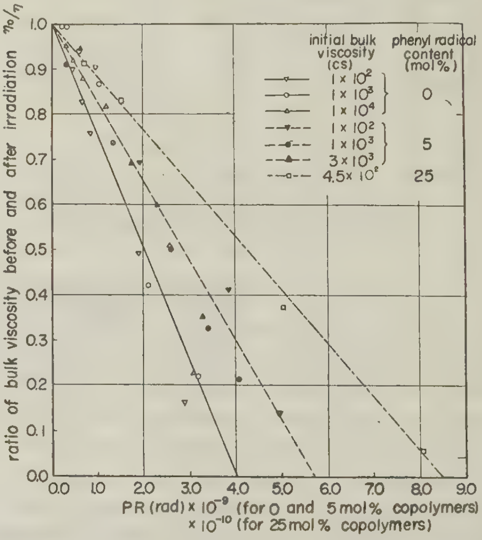

Fig 5. The relationship between η_0/η and *PR*.

$$\eta_0/\eta = 1 - \varepsilon_p PR\ , \tag{3}$$

where ε_p denotes the slope of each line shown in Fig. 5. Suffix p represents the concentration of phenyl group. $\mathcal{E}_p$ signifies the efficiency of cross-linking of any given monomer unit in the molecule per unit absorbed dose in rad. It depends not on the initial molecular weight but only on the concentration of phenyl group.

Eq. (3) may be extended to gel point. As η_0/η is zero and R is R_g at the gel point, Eq. (3) gives ;

$$\mathcal{E}_p=1/(PR_g) \qquad (4).$$

So far as Eq. (4) is satisfied at the gel point, the product PR_g, and hence the product MR_g must be constant for the copolymer containing the same amount of phenyl group. Fig. 6 shows the relationships $\log R_g$ *vs* $\log M$ for each phenyl radical content as a parameter. A linearity is seen between $\log R_g$ and $\log M$, and the slope of this line is nearly one. Furthermore, the line for polydimethyl siloxane was parallel to the line for 5 mol% copolymer. Accordingly, a relationship of $R_g \times M$=constant is obtained and this relation agrees with Charlesby's result for a pure silicone oil[11]. As shown in Table II, the mean values of product $R_g \times M$ for 0, 5 and 25 mol% copolymers are 3.0×10^{11}, 4.3×10^{11} and 8.0×10^{12} rad, respectively.

In general, the efficiency of cross-linking of a given monomer unit, $\mathcal{E}$, for each copolymer can be obtained as $1/(PR_g)$ using Eq. (4). The values of $\mathcal{E}$ obtained in this way are shown in Table III. The energy absorbed per cross-linked unit is defined by reciprocal of $\mathcal{E}$. Since the value of energy absorption to produce one ion pair in air, W, is 34 eV and the electron density of silicone is very similar to that of water, the absorbed energy in eV per cross-linked unit is

$$\frac{6.1\times10^{13}\,\text{eV}\times\text{molecular weight of monomer}}{6.0\times10^{23}\times\mathcal{E}}.$$

The energy absorbed per cross-linking (corresponding to two cross-linked units), E, is twice the above value, and the G-value of cross-link formation becomes $100\,\text{eV}/E$. The values of E and G for each irradiated sample are also shown in Table III.

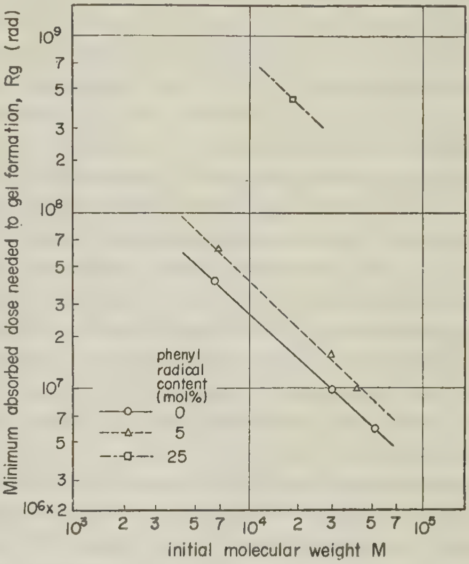

Fig. 6. The relationship between the minimum absorbed dose for gel formation, R_g, and the initial molecular weight, M, for each phenyl radical content as a parameter.

Table III. Efficiency of cross-linking of monomer per one rad, $\mathcal{E}$, absorbed energy per cross-linking, E, and G-value of cross-linking.

§ 4. Discussion of the result.

The efficiency of formation of cross-links in dimethyl-diphenyl siloxane copolymers by the irradiation of gamma rays depends not on the initial molecular weight but on the concentration of phenyl group in the copolymer as stated above. Recently, Watanabe[19] pointed out from the theoretical consideration that the relationship η_0/η *vs* R was represented not always by a linear function but by a function involving the parameter α appeared in Eq. (1). The theoretical curve is shaped S. Our observed curve is considered to be a straight line within the experimental error for samples of low molecular weight and approaches the theoretical curve of $\alpha=3.7$ for high molecular weight samples. Therefore, the slight deviation from straight line in our observed curves may be explained by his theory. However, we treated the observed curve as a straight line in first apploximation.

As shown in Table III, E for polydimethyl siloxane is 62 eV. This value is considerably larger than the value of 32 eV given by Charlesby[12] for the same polymer irradiated in a nuclear reactor. When Charlesby calculated the absorbed energy, however, the value adopted for W was 29 eV. The latest value of W is 34 eV, and his value of E, 32 eV, should be modified to 38 eV. His experiment of gamma irradiation gave 40 eV as the value of E to the same polymer. The discrepancy between the value of present authors and that of Charlesby may be attributed to three factors; (1) the presence of air, (2) different dose rate and (3) the different ways of the determination for R_g. Concerning the third, it may be considered that the values of R_g, or E, determined from a straight line between η_0/η and R will be somewhat larger than that could be determined from the theoretical curve shaped S.

Moreover, in 5 and 25 mol% copolymers the values of E are 9.0×10 and 1.6×10^3 eV, respectively. The increase of E with the increasing concentration of phenyl group, is due to the increment of a ratio of dimethyl siloxane monomer units which is protected by phenyl group to the total number of its monomers. Even in 25 mol% copolymer, however, the protective effect by phenyl group is not sufficient compared with that in the case of polystyrene in which E is 3,000–5,000 eV[1]. On the other hand, even after the absorotion of 1.4×10^9 rad, the low molecular sample of 0.65 cs initial bulk viscosity did not show any appreciable change in viscosity as far as we have explored.

Based on the assumption of random distribution of dimethyl siloxane and diphenyl siloxane units throughout the copolymer molecule, a calculation was carried out on the range of protection of phenyl group according to the reasoning of Alexander and Charlesby[7]. They deduced the range of protection from the reduced degradation rate, but the present authors from the reduced cross-linking efficiency. For this purpose let M represent a dimethyl siloxane and P a diphenyl siloxane unit. Let f denote the probability that any given monomer unit is M. The numerical values of f are given in Table IV for 5 and 25 mol% of phenyl group.

Let us now assume that any given dimethyl siloxane unit **M** is only protected by P unit against cross-linking, if its nearest neighbour unit is a diphenyl siloxane unit P. The probability of such an arrangement as M**M**M, of which only such **M** unit is able to cross-link, is given by f^2. Therefore the ratio of such **M** units to the total number of units in the specimen is given by f^3. In general, it is assumed that P unit protects n-units of M successibly arranged in the nearest neighbour of P unit. Then the ratio of M units possible to cross-link to the total number of units is given by f^{2n+1}. Now, the ratio of cross-linked monomer units to the total number of units under the protection of phenyl group is defined as the degree of protection. The numerical values of f^{2n+1} for given f and n are shown in Table IV.

Table IV. Comparison of theoretical and observed values of the degree of protection.

		degree of protection	
content of phenyl radical		5 mol %	25 mol %
probability of dimethyl siloxane, f		0.975	0.875
theoretical values			
f^{2n+1}	$n=1$	0.93	0.67
	4	0.80	0.30
	5	0.76	0.23
	6	0.72	0.18
	7	0.68	0.13
observed values			
$\mathcal{E}_p/\mathcal{E}_0$		0.74	0.05

On the other hand, the observed degree of protection is obtained as the ratio of cross-linking efficiency of copolymer, $\mathcal{E}_p$, and that of polydimethyl siloxane, $\mathcal{E}_0$. It was calculated as follows,

$\mathcal{E}_p/\mathcal{E}_0=1.82\times10^{-10}/2.45\times10^{-10}=0.74$ for 5 mol%

$\mathcal{E}_p/\mathcal{E}_0=1.17\times10^{-11}/2.45\times10^{-10}=0.05$ for 25 mol%

These ratios are also summarized in Table IV.

The degree of protection observed is 0.74 for 5 mol% copolymer and 0.05 for 25 mol% copolymer, respectively. Comparison of the degree of protection observed with f^{2n+1} calculated, makes clear that in the case of 5 mol% copolymer the observed value, 0.74, is placed between the calculated, 0.76 for $n=5$ and 0.72 for $n=6$. In the case of 25 mol%, however, the observed value, 0.05, is smaller than the value of 0.18 calculated using $n=6$. The value of $\mathcal{E}_p$ for 5 mol% copolymer is the mean value for three samples having different molecular weight and it is more reliable than that for 25 mol% copolymer. Therefore, it may be considered that the protection by single diphenyl siloxane unit extended over five or six monomer units of dimethyl siloxane on the average.

For the vinyl polymer, copolymer of isobutylene and styrene, Alexander and Charlesby reported that the range of protection by phenyl group extends over four main-chain carbon atoms[7]. However, there is a considerable difference in the range of protection by phenyl group between vinyl copolymer and siloxane copolymer. This difference of the range of protection between two kinds of the copolymers may be regarded as due to the difference in the number of phenyl radicals in monomer unit, and the difference in the main-chain structure. The copolymer used by Alexander and Charlesby has only one phenyl group in one styrene monomer unit. However, the copolymer used in the present work has two phenyl groups in one diphenyl siloxane monomer unit.

Provided that the excitation or ionization of π electron in phenyl group has no chemical effects on cross-linking or degradation, diphenyl siloxane monomer unit will be able to dissipate more energy by the existence of two phenyl groups than styrene monomer unit will. Secondary, we may consider the difference in main-chain structure between vinyl copolymer and siloxane copolymer. Vinyl copolymer consists of *–C–C–* and siloxane copolymer of *–Si–O–*. In the latter, silicon and oxygen atoms have more electrons content than carbon atom has. Moreover, oxygen atom has movable lone pair electrons in its $2p$ orbit. Therefore electron may be more easily movable in *–Si–O–* chain than in *–C–C–* chain. It is assumed that electron in molecule is excited or ionized by radiation and the transition of its excited or ionized state can occur by electron migration through the main-chain into phenyl groups and its energy is dissipated by the resonance strcture of phenyl radical. The mechanism of protective effect in the copolymer under consideration may be explained by above mentioned assumption. It may be reasonable that the siloxane copolymer in which the electron migrates easily through the main-chain *–Si–O–* is protected more notably by phenyl groups than the vinyl copolymer is protected.

Therefore, it may be reasonably concluded that the range of protection by phenyl radical in the diphenyl siloxane can extend over five or six monomer units of dimethyl siloxane.

Interpretation of Exciton Induced Luminescence in KI/Tl

By Masao TOMURA

Department of Applied Physics, Osaka City University, Osaka

(Received April 23, 1960)

Details of the exciton induced luminescence in KI/Tl1) are discussed. It is pointed out that the absorption coefficient at the long wavelength tail of the first characteristic absorption band of a single crystal of KI is much smaller than that of an evaporated polycrystalline film of KI, and then the complex shapes of excitation spectra of the exciton induced luminescences from Tl^+ ion and a certain impurity are explained. Furthermore, a new weak absorption band is found in the long wavelength tail of the first exciton absorption band, which is infered to be due to the triplet-like state of the exciton.

Some discussions are given on the problem of migration of excitons and the life time of the exciton is estimated to be much longer than 10^{-8} sec.

§1. Introduction

In the preceding work1) the exciton induced luminescences (being denoted as E.I.L. in the following) from single crystals of KI/Tl have been measured at various temperatures for specimens of several concentrations of Tl^+ ion. It was concluded that excitons migrate through the crystal and transfer their energies to Tl^+ ions as well as to certain impurities, giving rise to their own luminescences. The excitation spectra for both E.I.L. were not simple and different from each other in shape. The absorption coefficient of the exciton absorption band is so large ($\sim 10^6\,cm^{-1}$) that almost all of excitons are created just near the surface of the crystal and may decompose under the influence of the surface in some ways. Then the shapes of the excitation spectra should be analysed in connection with the absorption coefficient of the exciton absorption band.

In the next place, concerning the life time of the exciton, it has been believed that the exciton should have the life time corresponding to dipole radiation, that is, 10^{-8} sec in the order of magnitude2). On the other hand, Takeuti3) has shown from his theoretical calculation that there are singlet and triplet states of the exciton band. Then if the singlet exciton which can be created with irradiation of ultra-violet light would drop into the triplet state in the course of migration through the crystal, it might obtain a rather longer life time because of its forbidden nature in transition to the original ground state.

In the present paper, some discussions will be given on the above two problems as well as on the temperature-dependence of E.I.L which was observed in the preceding work1).

§ 2. Exciton absorption band of KI

The absorption coefficient of the first characteristic absorption band of KI has been measured by several authors[4]. At liquid nitrogen temperature, it has values of about $1\times10^5\,\text{cm}^{-1}$ at the peak of the band, that is, 214 mμ, and about $1\times10^5\,\text{cm}^{-1}$ at 216 mμ, and the shape of the absorption band seems to be symmetric at least in the middle region of the band. However, these measurements were carried out for thin polycrystalline films which were evaporated on appropriate substrates.

On the other hand, a few measurements have been carried out for single crystals only in the region of the long wavelength tail of the absorption band[5]. Although the values of absorption coefficient in this region differ from specimen to specimen, they do not seem to exceed $10^2\,\text{cm}^{-1}$ in the order of magnitude at about 216 mμ. Some examples of the absorption coefficients are shown in Fig. 1.

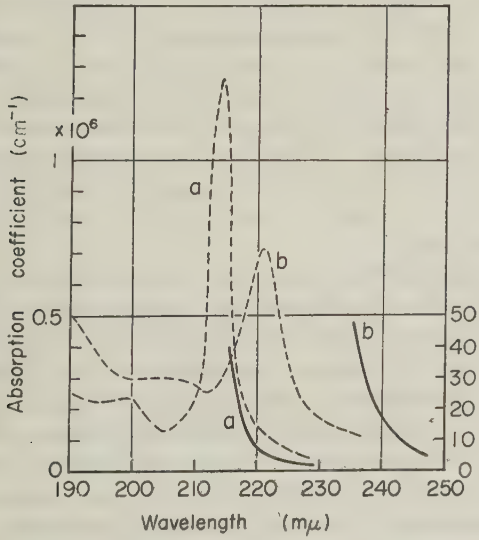

Fig. 1. The absorption coefficients of a single crystal (solid line) and thin polycrystalline film (broken line) of KI. a : at liquid nitrogen temperature and b: at room temperature. The left and right ordinate scales are for the broken and solid lines respectively. The magnitude of the left one was estimated roughly.

It is remarkable that the absorption coefficient of a single crystal in the long wavelength tail is smaller than that of a thin polycrystalline film by the order of 10^3 or so. In the wavelength region shorter than the peak of exciton absorption band, the absorption coefficient of a single crystal was so high* that it could not be measured. Perhaps its value might be larger than $10^3\,\text{cm}^{-1}$ at least.

The absorption coefficients of alkali halides have been usually obtained for thin polycrystalline films of 100∼1000 Å in thickness. Heller and Marcus[6] have pointed out that the dipole-dipole interaction which is the most important in the configuration-interaction of excitons in alkali halides is very sensitive to the size of the crystal. If the crystal has dimensions smaller than the spread of the exciton wave packet, the exciton may alter its nature, making the position and shape of the exciton absorption band to be changed. In the case of KI, the position of the exciton absorption band actually varies with the thickness of the specimen[7].

In view of these facts, the shape of the excitation spectra of E.I.L. which were measured in a single crystal shall be analysed on the stand point of very small absorption coefficients in the long wavelength tail of the exciton absorption band.

§ 3. Excitation spectra of E.I.L.

Examples of the excitation spectra of E.I.L. are shown in Fig. 5 in the preceding paper[1]. In the present paper, the excitation spectra of E.I.L. near the peak of the exciton absorption band which were measured with a fine

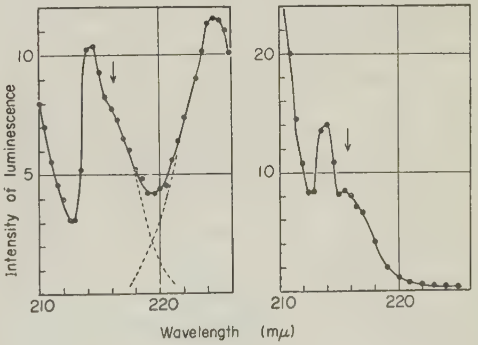

Fig. 2. The excitation spectra of E.I.L. from Tl^+ ion (left figure) and a certain impurity (right figure) at -210°C. Tl^+ ion concentration is $1\times10^{16}/\text{cm}^3$. Band pass is 6 Å at 220 mμ. The step pointed by an arrow corresponds to the weak absorption band discussed in §7. The maximum at 224 mμ in the left figure is due to the localized exciton around a Tl^+ ion.

---

* The present author is indebted to Dr. T. Onaka for this measurement.

band pass of 6 Å at 220 mμ are shown in Fig. 2.

The dominant properties of the excitation spectra are as follows. There is a minimum at the position of the peak of the exciton absorption band, that is 214 mμ* at liquid oxygen temperature. With increase of temperature, the position of the minimum moves to the longer wavelength side along with the peak of the absorption band. Further, a step is seen at about 202 mμ which may correspond to the second weak absorption band at 200 mμ in Fesefeldt's measurement[4]. The position of the first maximum, that is about 216 mμ*, lies in the region of the long wavelength tail of the exciton absorption band where the absorption coefficient is as small as 10^2 cm^{-1} as mentioned in § 2. As for the second maximum in the excitation spectra, its position corresponds to the region of the minimum in the exciton absorption bands, that is about 206 mμ. (See Fig. 1.)

In the present measurement the thickness of the specimen is about 2 mm, so that almost all of the incident light is absorbed in the crystal when the absorption coefficient exceeds about 30 cm^{-1}. Then if the quantum yield of E.I.L. is constant the shape of excitation spectrum should be flat in the middle region of the exciton absorption band. However, the higher is the absorption coefficient, the smaller is the intensity of E.I.L.; so it is inferable that the exciton decomposes preferentially in the vicinity of the surface of the crystal just as in the case of Apker and Taft's experiment[8]. In the region of the long wavelength tail where the absorption coefficient is smaller than 10^2 cm^{-1}, the intensity of E.I.L. may be proportional to the absorption coefficient, resulting a maximum in the excitation spectrum between the regions of very small and large absorption coefficients. The first maximum in the excitation spectrum which lies at about 216 mμ corresponds to the above maximum.

As shown in Fig. 2 a flatted top is seen at the above maximum point. Therefore, almost all of the incident light is absorbed at this wavelength, and the exciton is created deep in the interior of the crystal, being freed from decomposition under the influence of the surface of the crystal. In the preceding paper we have employed the intensity of luminescence at this wavelength as the intensity of E.I.L. This choice seems to be right in order to obtain the proper yield for E.I.L.

As for the excitation spectrum for E.I.L. from the unknown impurity (being denoted as *D* impurity in the following), it is different from that from Tl$^+$ ion in shape. The position of its first maximum lies at a little shorter wavelength than that for the latter and the intensity at its second maximum is higher than that at the first maximum in contrast to the case of E.I.L. from Tl$^+$ ion. On the stand point that the exciton migrates through the crystal, eventually meeting both Tl$^+$ ion as well as *D* impurity, the above facts are only understood by assuming that *D* impurities exist preferentially near the surface of the crystal in constrast with Tl$^+$ ion which distributes uniformly in the crystal. If the absorption coefficient is large, the exciton is created for the most part near the surface of the crystal, while in the case of smaller absorption the exciton is created deep in the interior of the crystal. Therefore, the relative probability of the exciton to meet a Tl$^+$ ion and *D* impurity differs according to the absorption coefficient.

In Fig. 3* the ratios of the intensities of E.I.L. from Tl$^+$ ion to that from *D* impurity are shown. In the larger absorption region, that is, the shorter wavelength region than the peak of the exciton absorption band, the ratio is rather weakly dependent of wavelength. Accordingly, we may infer that the absorption coefficients in this region are roughly unchanged in the order of one or two, coinciding with the results of measurements on thin polycrystalline films mentioned in § 2.

In the case of 2.7×10^{19}/cm^3 Tl$^+$ ion concentration the ratio is nearly unity at the wavelength of 212.5 mμ where the absorption coefficient is about 1×10^6 cm^{-1}, so the mean concentration of *D* impurity in the depth of 10^{-6} cm from the surface of the crystal may be equal as the concentration of Tl$^+$ ion, that is 10^{19}/cm^3 in the order of magnitude. With decrease of the absorption coefficient the value of the ratio increases and then the concentration of D impurity decreases towards the interior of the crystal. As mentioned in the preceding paper, at the wavelength of the first maximum in the excitation spectrum the intensity of D emission is roughly equal to that of Tl^+ emission in the specimen of $10^{16}/cm^3$ Tl^+ ion concentration. In the other words, the apparent concentration of D impurity is $10^{16}/cm^3$ in the order of magnitude in the deep interior of the present crystal.

---

* At about 60°K, the position of the exciton absorption peak moves to about 212.5 mμ and that of the first maximum in the excitation spectrum to about 214 mμ.

* Fig. 3, 4 and 5 are obtained from the measurements reported in the preceding paper.

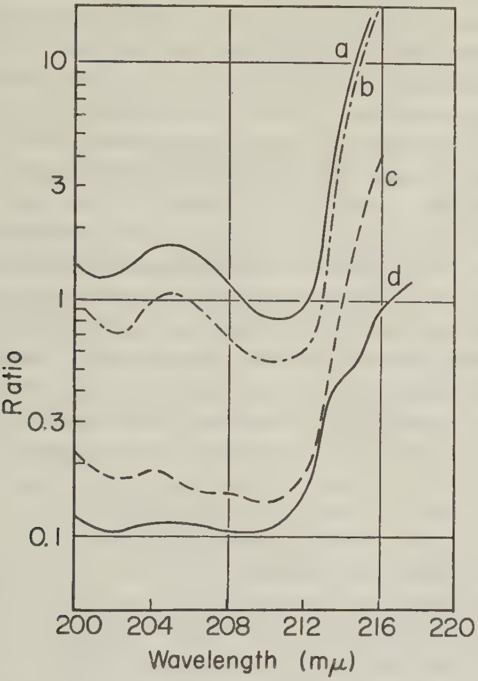

Fig. 3. The ratios of the intensities of E.I.L. from Tl^+ ion to that from D impurity at about −215°C. Tl^+ ion concentrations are a: $2.7\times 10^{19}/cm^3$, b: $5.7\times 10^{18}/cm^3$, c: $7\times 10^{17}/cm^3$ and d: $4.2\times 10^{16}/cm^3$.

Recently Teegarden and Weeks[9] have reported that D impurities are to be attributed to F centers which are created by the exciton from negative ion vacancies near the surface of the crystal. Their conclusion is just coincident with the present result.

Furthermore, the step in the excitation spectrum for E.I.L. at 202 mμ may be perhaps attributed to a kind of the exciton absorption band and not to an absorption band due to band to band transition. The induced luminescence at this wavelength shows no distinct properties other than those of E.I.L. at the longer wavelength region.

§ 4. Further discussions on the shape of the exciton absorption band

The ratio of both intensities of E.I.L. mentioned in § 3 increases abruptly towards the long wavelength region. (See Fig. 3.) In view of the difference between the distributions of Tl^+ ion and D impurity, we can infer from the above result that the absorption coefficient at low temperatures varies from $10^6\,cm^{-1}$ to $10^2\,cm^{-1}$ corresponding to just a little change of wavelength from 212.5 mμ to 214 mμ. This conclusion is coincident with the new information concerning the absorption coefficient of the exciton absorption band obtained in § 2. Thus the shape of the exciton absorption band of a single crystal seems to be completely asymmetric. Although measurements of absorption coefficients are rather difficult when the crystal is luminescent, the small absorption coefficient in the tail of the exciton absorption band observed by Teegarden and other authors[5] is confirmed by the above measurements of E.I.L. The asymmetry of the shape of the excitation spectrum near the region of its minimum shown in Fig. 2 also supports this conclusion, because the magnitude of the absorption coefficient corresponds to the intensity of E.I.L. in the opposite direction.

Toyozawa[10] has analysed the shape of the exciton absorption band of KI by using the data for thin polycrystalline films obtained by Fischer[4] and concluded that the lowest exciton band had its minimum at $K \neq 0$. (K is the wave number vector of the exciton.) From the present analysis, however, the minimum of the exciton band should lie at $K=0$ or $K\approx 0$. Then the absorption in the shorter wavelength region than the peak of the exciton absorption band may be caused by indirect transition.

In the next place, the influence of polishing the surface of the crystal was examined. Fig. 4 shows the ratio of the intensity of E.I.L. in a crystal of which surface is polished with a sand paper to that in a annealed crystal. The value of the ratio increases at the positions of the maxima of the exciton absorption band, that is, 212.5 and 202 mμ; while it decreases at about 206 mμ where the absorption coefficient is rather small. As before mentioned, E.I.L. in the high absorption region has the smaller yield for the higher absorption coefficient, so these results may mean that by the procedure of polishing the magnitudes of the absorption coefficients at the maxima decrease and that at the minimum increases with eventual increasing and decreasing of the intensity of E.I.L. respectively.

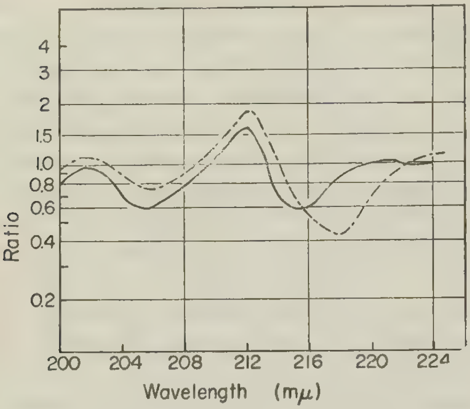

Fig. 4. The ratios of the intensities of E.I.L. in a crystal of which surface is polished with a sand paper to that in a annealed crystal for one hour at 400°C. Tl$^+$ ion concentration is $4.2 \times 10^{16}/\mathrm{cm}^3$ and temperature is -208°C. The solid and chained lines ane for E.I.L. from Tl$^+$ ion and D impurity respectively.

Blackney and Dexter[11)] have calculated increase of the edge absorption of alkali halides due to dislocations on the stand point that the deformation potential due to dislocations alters the energy of the exciton state to larger and smaller values, resulting increase and decease of absorption coefficients at the tails and the peak of the absorption band respectively.

In view of the above facts, in a perfect crystal which has no dislocations the absorption coefficient at the peak of exciton absorption band may be much larger than in an evaporated polycrystalline film. Differences between the shapes of the exciton absorption band of a single crystal and thin polycrystalline film are very interesting. The long range interaction such as dipole-dipole interaction may have a dominant role in the configurational interaction of excitons in alkali halides and then the surface of the crystal will have influences on tne electronic structure of the exciton.

§ 5. Temperature-dependence of E.I.L.

The temperature-dependence of E.I.L. has been described already in the preceding report. In the region of strong absorption, the larger is the absorption coefficient, the smaller is the intensity of E.I.L. as mentioned in § 3, therefore real properties of the temperature-dependence of E.I.L. can not be obtained from the intensities of E.I.L. at the positions of the minimum and second maximum of the excitation spsctrum. Thus the intensity of E.I.L. at the first maximum should be taken in order to discuss its temperature-dependence. Although both E.I.L. from Tl$^+$ ion and *D* impurity must be considered simultaneously in the discussion on the temperature-dependence of E.I.L. because of energy-transfer of the exciton to both centers, only E.I.L. from Tl$^+$ ion will be analysed easily, because Tl$^+$ ion distributes uniformly in the crystal.

According to Teegarden and Weeks[9)] the the origin of *D* impurities may be attributed to incipient negative ion vacancies in the host crystal. Therefore, though E.I.L. from *D* impurity quenches thoroughly at room temperature, the exciton itself may collide with the impurity, dissipating its energy even at higher temperatures. Then in the discussion of the temperature-dependence of E.I.L. from Tl$^+$ ion, the amount of energy which is dissipated to *D* impurities should be considered even at higher temperatures.

The E.I.L. from Tl$^+$ ion decreases with temperature especially in cases of lower Tl$^+$ ion concentrations, while that from *D* impurity seems to increase with temperature, if the nature of thermal quenching is subtracted. (See Fig. 6 in the preceding report.) Concidering these results, the sum of energies which are transfered to Tl$^+$ ion and *D* impurity seems to show no temperature-dependence even in the case of lower concentration of Tl$^+$ ion. In other words, the total amount of energy of the exciton which should be transfered to imperfections does not depend on temperature, though the intensity of E.I.L. from Tl$^+$ ion appears to depend on temperature.

In the case of higher concentration of Tl$^+$ ion such as $10^{19}/\mathrm{cm}^3$ where *D* impurities have no role because of smaller density, E.I.L. from Tl$^+$ ion shows actually a weak temperature-dependence. At the wavelength of the first maximum of the excitation spectrum, the absorption band due to the exciton and that due to the localized exciton around Tl$^+$ ion overlap a little with each other and the amount of overlapping becomes greater with increase of temperature, because both absorption bands show broadening with increase of temperature. Then the intensity of E.I.L. from Tl^+ ion decreases with increase of temperature through decreasing of absorption due to the exciton.

On the other hand, the above overlapping of both absorption bands is negligible in the case of lower concentration of Tl^+ ion, so the temperature-dependence of E.I.L. from Tl^+ ion must be explained by other reason.

As the migration of the exciton in the crystal of KI has been concluded in the preceding work, the exciton may be considered to become thermalized in the course of wandering through the crystal. The yield of E.I.L. from Tl^+ ion η may be shown as

$$\eta=\frac{f_{Tl}}{t_{Tl}+f_D+f_I}.$$

Here, f_{Tl}, f_D and f_I are frequencies of collision of the exciton with Tl^+ ion, D impurity and other imperfections such as dislocation, the surface of the crystal and etc. These frquencies should be represented as $v\sigma n$ where v is the velocity of the thermalized exciton, σ the cross section of collision between the exciton and the above defects at which the exciton dissipates its energy and n the densities of these defects.

when an exciton comes to an I^- ion next to a Tl^+ ion, it may be trapped around the Tl^+ ion after emitting some phonons* or move to the next I^- ion. The former process will need a duration of about 10^{-13}** sec and the latter 10^{-14} sec. Therefore, the probability of trapping of the exciton around a Tl^+ ion may be about one tenth of that of moving to the next I^- ion. The trapped exciton will transfer its energy to the Tl^+ ion through two center Auger transition of which the probability is about 10^{12}/sec after calculation by Dexter and Heller[12].

On the other hand, the trapped exciton around a Tl^+ ion might become a moving one through a kind of activation process of which the probability will be represented as $pe^{-E/kT}$. Here p is frequency factor of 3×10^{12}/sec* and E is the difference of energy between the states of the moving exciton and the trapped exciton around the Tl^+ ion. Thus σ_{Tl}, the cross section of excitation of Tl^+ ion by the moving exciton, is

$$\sigma_{Tl}=\sigma_0\frac{\nu_{Tl}}{\nu_{Tl}+pe^{-E/kT}}$$

where σ_0 is the product of trapping probability of the exciton around a Tl^+ ion mentioned before and the area covering the lattice spacing, that is, about $10^{-16}\,\mathrm{cm}^2$; and ν_{Tl} the probability of the above two center Auger transition.

Accordingly, η may be shown as

$$\eta=\frac{1}{1+\frac{n'\sigma'+n''\sigma''}{n\sigma_0}+\frac{n'\sigma'+n''\sigma''}{n\sigma_0}\cdot\frac{p}{\nu_{Tl}}e^{-E/kT}}.$$

The singly and doubly primed notations are for D impurity and the other imperfections respectively. Thus the yield of E.I.L. from Tl^+ ion has a similar nature to that of thermal quenching of normal luminescent materials. As $n'\sigma'$, $n''\sigma''$ and $n\sigma_0$ are all equal in the order of magnitude and E is estimated as 0.04 eV from the measurement in the case of $10^{16}/\mathrm{cm}^3$ Tl^+ ion concentration, η may show the temperature-dependence in the range of temperature in the present experiments. (See Fig. 5)

The Greek bands due to Tl^+ ion and F center lie at 224 and 238 mμ respectively, so the difference of energy between the exciton and these localized excitons are 0.25 and 0.58 eV respectively. As will be mentioned in the next section, considering the triplet-like exciton band through which the exciton migrates, the energy-differences between the electronic states of the moving exciton and the localized ones become much smaller. Further, the optical energy difference might be large than the thermal one, so the activation energy of 0.04 eV might be assumed to be the thermal energy difference. The electronic state of the localized exciton around a *F* center (being denoted as *D* impurity in this paper) is deeper than that around a Tl^+ ion, so σ' may be considered to be insensitive to temperature in the region of the present measurement.

---

* In the preceding work, it was shown that the spectral distribution of E.I.L. from Tl^+ ion is the same as that of the emission in the Greek band due to Tl^+ ion and is different from that of emission in the absorption bands at 233 and 244 mμ due to Tl^+ ion itself. Then the moving exciton may be assumed to become trapped around a Tl^+ ion before it transfers its energy to the Tl^+ ion.

** The broadening of the exciton absorption band, that is 0.1 eV, at liquid nitrogen temperature, was assumed to be caused by the interaction of the exciton with phonons.

* The residual absorption of KI lies at 102 μ.

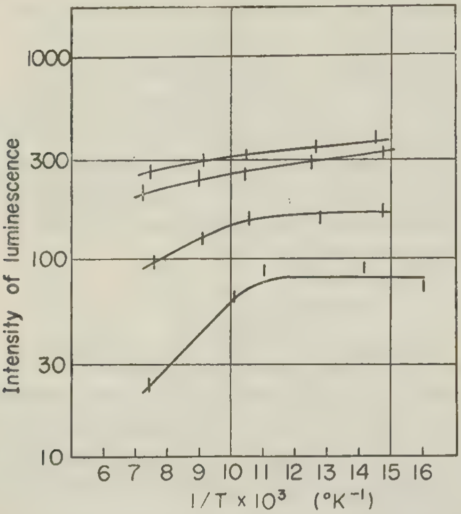

Fig. 5. The temperature dependence of the intensity of E.I.L. from Tl^+ ion. Tl^+ ion concentrations are $2.7\times10^{19}/cm^3$, $5.7\times10^{18}/cm^3$, $7\times10^{17}/cm^3$ and $4.2\times10^{16}/cm^3$ in order from the upper side.

If the yield of E.I.L. from Tl^+ ion decreases with increase of temperature, the yield of E.I.L. from *D* impurity may show the reverse temperature-dependence, because the total energy of the exciton to be transfered to imperfections is independent of temperature as mentioned before. However, the latter yield also decreases at higher temperature because of its nature of thermal quenching.

§6. Quantum yield of E.I.L. and life time of a moving exciton

As shown in Fig. 5 in the preceding report, in the case of lower concentrations of Tl^+ ion such as $10^{16}\sim10^{17}/cm^3$, the sum of the intensities of E.I.L. from Tl^+ ion and *D* impurity at the second maximum of the excitation spectrum attains quantum yield of nearly unity, while that at the first maximum is smaller about two or three times than the former. Although the exciton is created deep in the interior of the crystal under irradiation at the wavelength of the first maximum, there may exist some impurities at which the exciton dissipates its energy, the amount of which is estimated to be about $10^{16}/cm^3$ in the order of magnitude in refering to the concentration of Tl^+ ion. The fact that the yield at the second maximum is very high inspite of the possibility of destruction of the exciton near the surface of the crystal should be attributed to the localization of *D* impurities near the surface of the crystal.

Thus the intensity of E.I.L. from Tl^+ ion is reduced by the overlapping of the exciton absorption band with the absorption band at 224 mμ in the case of very high concentration of Tl^+ ion and by the presence of the other imperfections in the case of lower concentration of Tl^+ ion, so the observed value of the yield of E.I.L. from Tl^+ ion, that is 40%, seems to be apropriate for the migration of the exciton.

As the original reagent of KI involves a little amount of Tl^+ ion, the present single crystal of KI contains already $5\times10^{14}/cm^3$ of Tl^+ ion without intentional adding of TlI. The E.I.L. from Tl^+ ion can be observed even in these crystals. Then the frequency of the interaction between the exciton and Tl^+ ion $v\sigma n$ can be estimated to be of the order of 10^5/sec by assuming the effective mass of the moving exciton to be the free electron mass and σ to be $10^{-16}/cm^2$. The corresponding life time of the thermalised exciton, that is 10^{-5} sec, is much longer than the one which has been convinced to be 10^{-8} sec for the exciton[2].

It has not been found that the exciton in KI does emit its own edge luminescence after annihilation. The above conclusion may well explain this fact. After creation of an exciton, it may drop into the triplet like state which has a very small transition probability to go back to the original ground state.

On the other hand, it has been known that the exciton in CdS does emit its edge luminescence[13]. The exciton in this case is of hydrogen like type, so the energy difference between the singlet and triplet states may be very small against the case of KI, because of a rather small exchange energy. Then the population of the exciton in the singlet state may be large, eventually leading a large transition probability to go back to the ground state through emitting normal dipole radiation. These explanation may be the reason for the exciton whether it emits own edge luminescence or not.

§ 7. A new exciton absorption band of KI.

In Fig. 2 steps at about 216 mμ are found in the excitation spectra for E.I.L. from Tl$^+$ ion and *D* impurity. As they appeare in the tail of the exciton absorption band where the absorption coefficient is small, they might be due to an impurity of some kind. The step, however, is observed in both excitation spectra, so the excitation at the step seems to show transfer of excitation energy to Tl$^+$ ion as well as to *D* impurity. Furthermore, the spectral distribution of the emission at the step is the sames as the one at the first maximum of the excitation spectrum of E.I.L. as shown in Fig. 6.

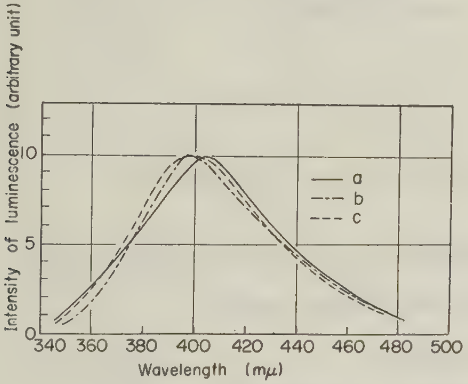

Fig. 6. The spectral distributions of emission bands under irradiation of lights 218 (a), 216 (b) and 214 mμ (c) at −204°C. Tl$^+$ ion concentration is 5×10^{15}/cm^3. These emission bands are composed of E.I.L. from Tl$^+$ ion as well as D impurity.

Accordingly, the step should not be attributed to an particular impurity. However, the most probable kind of impurities in KI such as Na$^+$ ion might be the cause of this weak absorption band, because the localized exciton around Na$^+$ ion might become the moving one in some cases. Fig. 7 shows the excitation spectra for E.I.L. from *D* impurity in pure KI and KI/NaI single crystals. In the case of 2×10^{-2}mol NaI concentration, another minimum appeares in the excitation spectrum at 215.5 mμ in addition to the minimum which corresponds to the peak of the exciton absorption band lying at 212.5 mμ. The former minimum corresponds to the absorption due to the localized exciton around Na$^+$ ion. On the other hand, the peak of the exciton aborption band of pure NaI lies at 222 mμ[4]. Accordingly, in the case of the present KI single crystal which may contain Na$^+$ ion by the amount of $10^{17}\sim10^{18}$/cm^3 the absorption due to Na$^+$ ion will not lie at the region of 216 mμ where the new weak absorption has appeared, but may lie at a shorter wavelength. Therefore, the new weak absorption band might correspond to a transition to a kind of exciton bands. As seen in Fig. 2, the intensity of E.I.L. at the step is a fraction of the intensity at the first maximum of excitation spectrum, so the order of the value of absorption coefficient of the new absorption band is estimated to be 10^2 cm^{-1}. In viewing of such a small absorption coefficient, the new absorption band might be attributed to a transition to the triplet like exciton band.

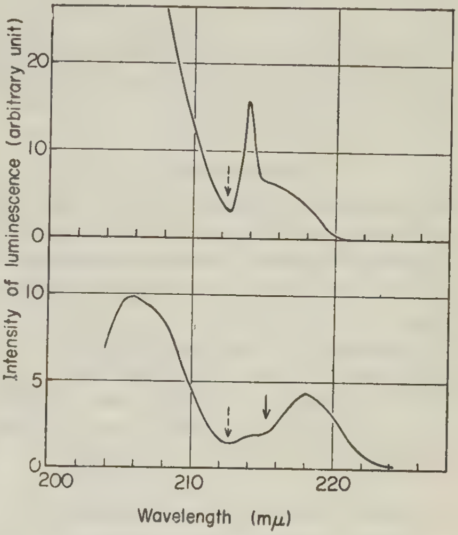

Fig. 7. The excitation spectra for E.I.L. from D impurity in KI (upper figure) and KI/NaI of 2×10^{-2} mol Na$^+$ ion (lower figure) at −205°C. The dotted and solid arrows point the wavelengths corresponding to the peak of the exciton absorption band of KI and that of the absorption band due to the localized exciton around a Na$^+$ ion respectively. Band pass is 6 Å at 220 mμ.

Considering the spin-orbit coupling in the calculation of exciton bands in KI, singlet and triplet states will not be obtained as good quantum states. However, singlet like and triplet like states might be obtained. Goodman and Oen[14] has calculated the electronic states of excitons in alkali halides considering the spin-orbit coupling, and obtained an absorption band of very small absorption coefficient at a wavelength a little longer than the familiar strong absorption band. The new weak absorption band might correspond to the above absorption band calculated by Goodman and Oen.

The author thanks Prof. T. Muto for his interests in this work and Dr. Y. Toyozawa for his discussions, and is also indebted to Messrs. Y. Kaifu and M. Yamakawa for their helps in the measurements.

Jets of a Perfectly Conducting Inviscid Gas in the Presence of a Magnetic Field parallel to the Stream

By Shigeki MORIOKA

Department of Aeronautics, Faculty of Engineering,
Kyoto University

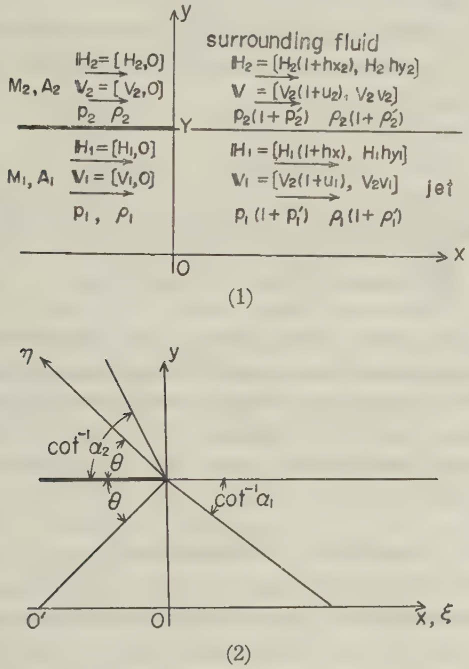
(Received March 14, 1960)

The two-dimensional and the axially symmetrical jets of a perfectly conducting inviscid gas in the presence of a magnetic field parallel to the stream are investigated on the basis of the linearized theory, when the jets are governed by the supersonic hyperbolic equation. To this approximation, the fundamental equations and the boundary conditions are found to agree in their forms with those in the ordinary gasdynamic case, except for some parameters. Therefore, it is possible to obtain the solutions at once by making suitable substitution of the parameters in the well-known solutions for the gasdynamic case.

However, when the surrounding flow is governed by the subsonic hyperbolic equation, the circumstance is somewhat different from the gasdynamic case because disturbances in the surrounding flow propagate along the upstream characteristics. The structure of such a jet in the two-dimensional case is re-examined from the view point of reflection and refraction of a weak plane shock wave incident upon an interface between two streams.

§1. Introduction

Let a jet issue as a uniform, parallel stream from a nozzle of a semi-width (or radius in axially symmetrical jet) Y with Mach number M_1, velocity U_1, density ρ_1, and pressure p_1; let it issue into a fluid at rest or into a uniform stream in the same direction as the jet, with Mach number M_2, velocity U_2, density ρ_2, and pressure p_2. (see Fig. 1) In this paper, we shall only be concerned with the case in which the governing equation is of supersonic hyperbolic type in the domain of the jet, so that the external disturbance does not propagate upstream into the nozzle. The motion is supposed to be steady, and heat conduction as well as viscosity are neglected. The jet and the surrounding fluid are assumed to be an ideal gas with the ratio of the specific heats γ, permeability μ, and infinite conductivity. In the following, we consider two cases; (1) a magnetic field parallel to the stream is imposed on the jet only and (2) a magnetic field parallel to the stream is imposed on both the jet and the surrounding fluid. The difference of the total pressures in the uniform streams q_1-q_2 is assumed to be small compared with q_1, where $q=p+(\mu H^2/8\pi)$, p and H denote respectively the gasdynamic pressure and the intensity of the magnetic field. (Suffices 1 and 2 refer respectively to the jet and to the surrounding fluid.)



(1)

(2)

Fig. 1.

In addition, we assume that the flow and the magnetic field are nearly uniform, so that we may linearize the fundamental equation as well as the boundary conditions on account of small perturbations. The resulting equations are found to have the same forms as those for the gasdynamic case (with no magnetic field), except for some constant parameters. Since the corresponding gasdynamic problems have already been investigated by several writers,[2),3)] we can obtain the solution of the present problem at once by making suitable substitution (or interpretation) of the parameters in the previous investigations.

However, when the surrounding flow is governed by the subsonic but hyperbolic equation, the circumstance is different from the ordinary gasdynamic case in that the disturbance there propagates along the upstream characteristics. In order to clarify the character of such a jet in the two-dimensional case, the reflection and refraction of the magneto-gasdynamic shock wave incident upon the interface of two streams are also investigated.

§ 2. Fundamental Equations and Boundary Conditions

The fundamental equations for the present problem may be written in the forms:

$$\left.\begin{aligned}
&\operatorname{div}(\bar\rho\boldsymbol{v})=0\\
&\operatorname{div}\boldsymbol{H}=0\\
&\operatorname{rot}(\boldsymbol{v}\times\boldsymbol{H})=0\\
&(\boldsymbol{v}\operatorname{grad})\boldsymbol{v}=-\frac{1}{\bar\rho}\operatorname{grad}\bar p+\frac{\mu}{4\pi\bar\rho}\operatorname{rot}\boldsymbol{H}\times\boldsymbol{H}\\
&\frac{d\bar p}{d\bar\rho}=\frac{\gamma\bar p}{\bar\rho}
\end{aligned}\right\}\tag{1}$$

where $\boldsymbol{v}$, $\boldsymbol{IH}$, $\bar p$ and $\bar\rho$ are velocity, intensity of magnetic field, pressure, and density, respectively.

In Eqs. (1), writing $\boldsymbol{v}=[U(1+u), Uv]$, $\boldsymbol{IH}=[H(1+h_x), Hh_y]$, $\bar\rho=\rho(1+\rho')$, $\bar p=p(1+p')$, and $x/Y\to x$, $y/Y\to y$, we assume that u, v, h_x, h_y, p', and ρ' are all small compared with unity, and we neglect squares and products of these quantities, thus obtaining the equations:

$$\left.\begin{aligned}
&h_x=(1-M^2)u \qquad h_y=v\\
&\rho'=-M^2u \qquad p'=\gamma\rho'
\end{aligned}\right\}\tag{2}$$

$$\left.\begin{aligned}
&\frac{A^2-1}{M^2+A^2-1}\frac{\partial v}{\partial x}-\frac{\partial u}{\partial y}=0\\
&(M^2-1)\frac{\partial u}{\partial x}-\frac{\partial v}{\partial y}=\frac{\sigma v}{y}
\end{aligned}\right\}\tag{3}$$

where $A=U(\mu H^2/4\pi\rho)^{-1/2}$ denotes Alfvén number and the index σ takes the values 0 or 1 according as the jet is two-dimensional or axially symmetrical. The relations (2) show that the magnetic field is frozen in the fluid, Introducing the potential ϕ of the disturbance velocity, defined as

$$u=\frac{A^2-1}{M^2+A^2-1}\frac{\partial\phi}{\partial x}\,,\qquad v=\frac{\partial\phi}{\partial y} \tag{4}$$

we obtain from (3) the fundamental equation for the present problem:

$$\frac{(M^2-1)(A^2-1)}{M^2+A^2-1}\frac{\partial^2\phi}{\partial x^2}-\frac{\partial^2\phi}{\partial y^2}=\frac{\sigma}{y}\frac{\partial\phi}{\partial y}\,. \tag{5}$$

This is nothing but the Sears-Resler equation[1]. The field of flow is of elliptic or of hyperbolic character according as $(M^2-1)(A^2-1)/(M^2+A^2-1)$ is negative or positive. Change of the type of the flow field is shown in Fig. 2.

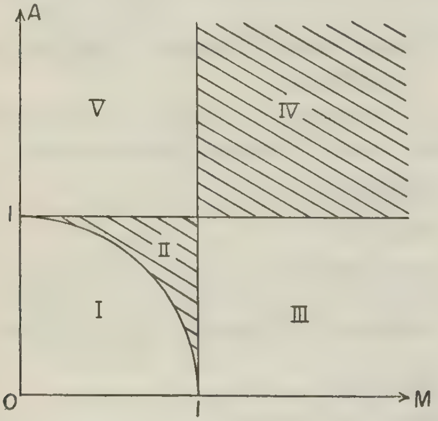


Fig. 2. Change of the type of Eq. (5). Blank and shaded areas are respectively elliptic and hyperbolic.

Since the flow is symmetrical about the axis of the jet, it is sufficient to consider only the upper half of the flow and magnetic fields.

The boundary conditions for the present problem then are expressed as follows.

1) The y-component of the velocity vanishes on the axis of the jet:

$$\frac{\partial\phi_1}{\partial x}=0 \qquad \text{for} \quad y=0\,. \tag{6}$$

2) The total pressure is continuous across the boundary of the jet:

$$q_1-\rho_1U_1^2u_1+\frac{\mu H_1^2}{4\pi}h_{x1}=q_2-\rho_2U_2^2u_2+\frac{\mu H_2^2}{4\pi}h_{x2}$$
$$\text{for} \quad x>0,\ y=1 \tag{7}$$

where q_1 and q_2 are the total pressures in the uniform streams. Since $q_1\simeq q_2$, we may obtain

$$\frac{\rho_2U_2^2}{\rho_1U_1^2}\simeq\frac{M_2^2A_2^2(\gamma M_1^2+2A_1^2)}{M_1^2A_1^2(\gamma M_2^2+2A_2^2)}\,.$$

Inserting this relation together with (2), (4) into Eq. (7), we get

$$\frac{\partial\phi_1}{\partial x}-\frac{M_2^2(A_2^2-1)(\gamma M_1^2+2A_1^2)}{M_1^2(A_1^2-1)(\gamma M_2^2+2A_2^2)}\frac{\partial\phi_2}{\partial x}$$
$$=\frac{A_1^2}{A_1^2-1}\frac{q_1-q_2}{q_1U_1^2} \qquad \text{for} \quad x>0,\ y=1\,. \tag{7'}$$

3) The direction of the flow is continuous across the boundary of the jet:

$$\frac{\partial\phi_1}{\partial y}=\frac{\partial\phi_2}{\partial y} \qquad \text{for} \quad x>0,\ y=1\,. \tag{8}$$

4) As the condition at the exit of the nozzle, we assume undisturbed, uniform flow:

$$\frac{\partial\phi_1}{\partial x}=\frac{\partial\phi_1}{\partial y}=0 \qquad \text{for} \quad x=0,\ 0\leq y<1\,. \tag{9}$$

5) For the conditions at infinity, if the surrounding stream obeys an elliptic type equation, the disturbance should vanish there:

$$\frac{\partial\phi_2}{\partial x} \quad \text{and} \quad \frac{\partial\phi_2}{\partial y}\to 0 \qquad \text{for} \quad y\to\infty\,. \tag{10}$$

On the other hand, if it obeys a hyperbolic type equation, any small disturbance propagates along the characteristics and there should be no disturbance in front of the leading characteristic starting at the edge of the nozzle wall.

§ 3. Formulae of the Substitution

The results obtained in the preceding section differ from the ordinary gasdynamic case in three points: the definition of the velocity potential (4), the equation of flow (5), and the condition (7′) for the continuity of the total pressure across the boundary of the jet.

In order to contrast the magneto-hydrodynamic and gasdynamic cases, we shall adopt the following abbreviations:
for the jet,

$$\alpha_1^2\frac{\partial^2\phi_1}{\partial x^2}-\frac{\partial^2\phi_1}{\partial y^2}=\frac{\sigma}{y}\frac{\partial\phi_1}{\partial y}$$
$$\alpha_1^2=\frac{(M_1^2-1)(A_1^2-1)}{M_1^2+A_1^2-1} \tag{11}$$

for the surrounding fluid,

$$\pm\alpha_2^2\frac{\partial^2\phi_2}{\partial x^2}-\frac{\partial^2\phi_2}{\partial y^2}=\frac{\sigma}{y}\frac{\partial\phi_2}{\partial y}$$
$$\alpha_2^2=\left|\frac{(M_2^2-1)(A_2^2-1)}{M_2^2+A_2^2-1}\right| \tag{12}$$

(where signs ± are taken according as

$(M_2^2-1)(A_2^2-1)/(M_2^2+A_2^2-1)\gtrless 0)$, and for the condition of continuity of total pressure across the boundary of the jet,

$$
\begin{aligned}
&\frac{\partial\phi_1}{\partial x}-\beta\frac{\partial\phi_2}{\partial x}=\varepsilon\\
&\beta=\frac{M_2^2(A_2^2-1)(\gamma M_1^2+2A_1^2)}{M_1^2(A_1^2-1)(\gamma M_2^2+2A_2^2)} \qquad (13)\\
&\varepsilon=\frac{A_1^2}{A_1^2-1}\frac{q_1-q_2}{\rho_1U_1^2}\,. \qquad (14)
\end{aligned}
$$

All these reduce of course to the expressions in the ordinary gasdynamic case by taking the limit $A\rightarrow\infty$ $(H\rightarrow 0)$. Namely, in the gasdynamic case,

$$
\left.\begin{aligned}
&\alpha_1^2=M_1^2-1\,\cdot \qquad && \pm\alpha_2^2=M_2^2-1\\
&\beta=\frac{M_2^2}{M_1^2}\,, && \varepsilon=\frac{p_1-p_2}{\rho_1U_1^2}\,.
\end{aligned}\right\} \qquad (15)
$$

Then, it will be seen that we can obtain at once the solution for the present problem by substituting the generalized expressions (11) ~(14) for the corresponding parameters (15) in the ordinary gasdynamic solution. Since α_1^2 as given by (11) is assumed to be positive in the present paper, various values of M_2^2-1 and $(p_1-p_2)/\rho_1U_1^2$ considered in the gasdynamics may cover the possible values of $\pm\alpha_2^2$ and ε in the present problem. As to β, on the other hand, there occurs only the case $\beta>0$ in the gasdynamics. In the present problem, however, the case $\beta<0$ may also occur. This is peculiar to the magneto-gasdynamic jet.

§ 4. Main Results

In this section, we summarize the main results obtained by making use of the formulae for the substitution stated in the preceding section. To do this, we shall designate, for shortness, as "Case I" the case in which the magnetic field is imposed only on the jet: and as "Case II" the case in which the magnetic field is imposed on both the jet and the surrounding fluid. We also designate as E_{sub}, H_{sub}, E_{sup}, and H_{sup} respectively the subsonic elliptic regions (I) and (V), the subsonic hyperbolic region (II), the supersonic elliptic region (III), and the supersonic hyperbolic region (IV) in Fig. 2.

Two-dimensional jet

1) *Jet issuing into a fluid at rest*

Case I The jet has a periodic structure. If we express the boundary of the jet by $y=Y[1+F(x)]$ ($F(x)$ has the same meaning in the following)

$$F(x)=\alpha_1^2\varepsilon H(x;\,4\alpha_1) \qquad (16)$$

where $H(x;\,2T)=\begin{cases}x & (0\leq x\leq T)\\ 2T-x & (T\leq x\leq 2T)\end{cases}$ is a triangular wave function. The amplitude a and the wave length λ are given by

$$
\left.\begin{aligned}
&a=\alpha_1^2\varepsilon=\frac{(M_1^2-1)A_1^2}{M_1^2+A_1^2-1}\frac{q_1-q_2}{\rho_1U_1^2}\,,\\
&\lambda=4\alpha_1=4\sqrt{\frac{(M_1^2-1)(A_1^2-1)}{M_1^2+A_1^2-1}}\,.
\end{aligned}\right\} \qquad (17)
$$

Case II The boundary of the jet is given by

$$F(x)=\alpha_1^2\varepsilon\left\{1-\sum_{n=0}^{\infty}(-1)^nC_n\sin\delta\cdot\cos\frac{\delta+n\pi}{\alpha_1}x\right\} \qquad (18)$$

where C_n must satisfy the equation

$$\sum_{n=0}^{\infty}C_n(\delta+n\pi)\cos(\delta+n\pi)y=1$$

and $\delta=\tan^{-1}\alpha_1/\beta$. In this case the jet has almost periodic structure, which is similar to a supersonic jet issuing into a uniform subsonic stream in the ordinary gasdynamics.[2] As a first approximation, the wave length of this (almost periodic) jet is given by

$$\lambda\simeq\frac{2\pi\alpha_1}{\delta}\,. \qquad (19)$$

2) *Jet issuing into a uniform subsonic stream*

Case I The jet has almost periodic structure.

Case II When (M_2, A_2) is a point in E_{sub}, the jet has almost periodic structure.

When (M_2, A_2) is a point in H_{sub}, the circumstance is somewhat different from the ordinary gasdynamic case. Namely, the disturbance in the surrounding stream propagates in this case along the upstream characteristics. (The reason for this phenomenon is described in § 5.) However, we may adopt the method of solution similar to that given in Ref. 3 (a supersonic jet in a uniform supersonic stream in the ordinary gasdynamics) by using the new coordinate system (see Fig. 1-(2));

$$
\left.\begin{aligned}
&\xi=x-\cot\theta\cdot(y-1)\,, && \eta=\operatorname{cosec}\theta\cdot y\\
& && \text{for}\quad 0\leq y\leq 1\\
&\xi=x+\cot\theta\cdot(y-1)\,, && \eta=\operatorname{cosec}\theta\cdot y\\
& && \text{for}\quad y\geq 1
\end{aligned}\right\} \qquad (20)
$$

where we must take θ as $\cot\theta>\alpha_2$. In this case, we may define the reflection factor R as the ratio of the amplitude of the reflected wave (the coefficient of the third term in ϕ_1) to that of the incident wave (the coefficient of the first term in ϕ_1), and the transmission factor T as the ratio of the amplitude of the transmitted wave (the coefficient of the second term in ϕ_2) to that of the incident wave. These factors are calculated to be

$$R=\frac{\beta+(\alpha_2/\alpha_1)}{\beta-(\alpha_2/\alpha_1)}\,,\qquad T=\frac{2}{\beta-(\alpha_2/\alpha_1)}\,. \tag{21}$$

Here, we may notice that $\beta<0$ and hence $|R|<1$. Putting $t=x/\alpha_1$, the boundary of the jet is given by

$$F(x)=\frac{\alpha_1\alpha_2\mathcal{E}}{(\alpha_2/\alpha_1)-\beta}\times\left\{t-(1-R)\sum_{n=1}^{\infty}R^{n-1}(t-2n)\cdot u(t-2n)\right\} \tag{22}$$

where $u(t-t_0)=\begin{cases}0 & (t<t_0)\\ 1 & (t>t_0)\end{cases}$ is the unit step function. Thus, for $R>0$ the jet experiences monotonous expansion or contraction, attaining asymptotically another uniform state in the downstream passage; and for $R<0$ it experiences a damped oscillation.

3) *Jet issuing into a uniform supersonic stream*

Case I The structure of the jet is similar to that of a supersonic jet in a uniform supersonic stream in the ordinary gasdynamics. The reflection factor R and the transmission factor T are given as follows:

$$R=\frac{\beta-(\alpha_2/\alpha_1)}{\beta+(\alpha_2/\alpha_1)}\,,\qquad T=\frac{2}{\beta+(\alpha_2/\alpha_1)}\,. \tag{23}$$

Here, it may be noted that $\beta>0$ and $|R|<1$. The boundary of the jet is given by

$$F(x)=\frac{\alpha_1\alpha_2\mathcal{E}}{(\alpha_2/\alpha_1)+\beta}\times\left\{t-(1-R)\sum_{n=0}^{\infty}R^{n-1}(t-2n)\cdot u(t-2n)\right\} \tag{24}$$

Thus, the jet experiences expansion or contraction, which damps out steadily or in oscillation according as $R>0$ or $R<0$.

Case II If (M_2, A_2) belongs to E_{sup}, the jet has the almost periodic structure. If (M_2, A_2) belongs to H_{sup}, it experiences expansion or contraction damping steadily or in oscillation.

Axially symmetrical jet

1) *Jet issuing into a fluid at rest*

The boundary of the jet, interpreting the gasdynamic case[2)], is expressed as

$$F(x)=\frac{\alpha_1{}^2\mathcal{E}}{2}\left\{1-4\sum_{n=0}^{\infty}\frac{1}{(\alpha_1k_n)^2}\cos k_nx\right\} \tag{25}$$

where k_n is the root of the following equation:

$$\alpha_1K_1(\alpha_2k_n)J_0(\alpha_1k_n)-\alpha_2\beta K_0(\alpha_1k_n)J_1(\alpha_1k_n)=0\,. \tag{26}$$

2) *Jet issuing into a uniform subsonic stream*

In *Case I* always and in *Case II*, if (M_2, A_2) belongs to E_{sub}, the jet has similar structure as 1).

In *Case II*, if (M_2, A_2) belongs to H_{sub}, using the coordinate system given by Eq. (20), we can follow the procedure given in Ref. 3 for treating the jet surrounded by a uniform supersonic stream (in the ordinary gasdynamics). Thus, putting $x/\alpha_1=t$, $\alpha_2/\alpha_1=\alpha$, and $\alpha/\beta=k$, the asymptotic form of the boundary may be expressed as

$$\left.\begin{aligned}F(x)&=\frac{\alpha_1{}^2\mathcal{E}}{2}\left\{1+\frac{\alpha}{2kt^2}-\frac{3\alpha^2}{k^2}(1-k\alpha)\frac{\ln t}{t^4}+\cdots\right\}\quad\text{for}\quad t\to\infty\\ F(x)&=\alpha_1{}^2\mathcal{E}k\left\{\frac{1}{1+k}\,t+\frac{1-k\alpha}{4\alpha(1+k)^2}t^2-\frac{(1-k\alpha)^2+3k(1+\alpha)^2}{48\alpha^2(1+k)^3}t^3+\cdots\right\}\quad\text{for}\quad t\to0\,.\end{aligned}\right\} \tag{27}$$

Here, it may be noted that $\beta<0$ and $k<0$.

3) *Jet issuing into a uniform supersonic stream*

In *Case I* always and in *Case II*, if (M_2, A_2) belongs to H_{sup}, the jet is similar to the supersonic jet surrounded by a uniform supersonic stream in the ordinary gasdynamics[3)]. The asymptotic form of the boundary may be given by Eq. (27), with $k>0$.

In *Case II*, if (M_2, A_2) belongs to E_{sub}, the jet will have similar structure to 1).

§ 5. Reflection and Refraction of a Weak Plane Shock Wave at the Interface between Two Streams, and the Structure of the Two-Dimensional Jet of a New Type

In order to obtain deeper understanding of the structure of the new type jet which appears when the field is two-dimensional and the surrounding flow is governed by the subsonic hyperbolic equation, we shall study the problem of reflection and refraction of a weak plane shock wave incident upon the interface between two streams. For this purpose, we first solve the magneto-gasdynamic shock relations on the basis of a weak shock approximation.

The conditions for an oblique shock wave in a perfectly conducting gas in the presence of a magnetic field are given, with the system of reference in which the shock is at rest and the streamlines are parallel to the lines of force, as follows:[4)]

$$\left.\begin{aligned}
&H\sin\alpha=H'\sin\beta\\
&\rho v\sin\alpha=\rho' v'\sin\beta\\
&p+\rho v^2\sin^2\alpha+\frac{\mu H^2}{8\pi}\cos^2\alpha\\
&\qquad=p'+\rho' v'\sin^2\beta+\frac{\mu H^2}{8\pi}\cos^2\beta\\
&\left(\rho v-\frac{\mu H^2}{4\pi}\right)\sin\alpha\cos\alpha\\
&\qquad=\left(\rho' v'-\frac{\mu H^2}{4\pi}\right)\sin\beta\cos\beta\\
&\frac{\gamma}{\gamma-1}\frac{p}{\rho}+\frac{1}{2}v^2=\frac{\gamma}{\gamma-1}\frac{p'}{\rho'}+\frac{1}{2}v'^2
\end{aligned}\right\}\qquad(28)$$

where α is the angle between the shock and the stream toward the shock and β is the angle between the shock and the stream behind the shock, and the quantities behind the shock are denoted by primes. If we put

$$x\equiv\frac{\tan\beta}{\tan\alpha}\qquad(29)$$

we obtain, after some calculation, the following equation for x:

$$\begin{aligned}
&(\gamma+1)(A^2-1)^2M^2x^3+(A^2-1)\{(\gamma+1)M^2\\
&\quad-2A^2-(\gamma-1)M^2A^2-(\gamma M^2+2A^2)\cot^2\alpha\}x^2\\
&\quad-\{(\gamma-1)+(2-\gamma)A^2\}M^2\cot^2\alpha x\\
&\qquad\qquad-M^2\cot^2\alpha=0\,.
\end{aligned}\qquad(30)$$

Once x is found, the other quantities may easily be determined by the following relations:

$$\left.\begin{aligned}
&\frac{H'^2}{H^2}=\frac{\sin^2\alpha}{\sin^2\beta}=\frac{x^2+\cot^2\alpha}{(1+\cot^2\alpha)x^2}\\
&\frac{A'^2}{A^2}=\frac{1}{A^2}+\frac{A^2-1}{A^2}x\\
&\frac{M^2}{M'^2}=\left(1+\frac{\gamma-1}{2}M^2\right)\frac{A^4}{A'^4}\frac{\sin^2\beta}{\sin^2\alpha}-\frac{\gamma-1}{2}M^2\\
&\frac{p'}{p}=\frac{M^2}{M'^2}\frac{A'^2}{A^2}\frac{\sin^2\alpha}{\sin^2\beta}\\
&\frac{\rho'}{\rho}=\frac{A^2}{A'^2}\,.
\end{aligned}\right\}\qquad(31)$$

In addition to the above we must consider the condition that the entropy of the fluid must increase in passing through the shock; $s'-s=\{R/(\gamma-1)\}\cdot\ln\{(p_2/p_1)(\rho_1/\rho_2)^\gamma\}>0$. It is found from this condition that the shock originated at a concave corner must be inclined to the upstream direction in case when the flow is governed by the subsonic hyperbolic equation (Fig. 3). This suggests that any small disturbance propagates into fluid along the upstream characteristic in this circumstance. Moreover, K. Tamada pointed out[5)] that the stationary wave front in the subsonic hyperbolic flow may be interpreted as an envelope of the unsteady wavefronts of the so-called magneto-gasdynamic slow wave emanated from a point source at successive time intervals and this envelope is nothing other than an upstream characteristic. This peculiar property of the wave field in subsonic hyperbolic flow may yield new types of jet in the present problem.

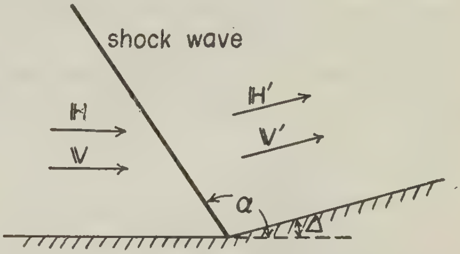

Fig. 3. Oblique shock at concave corner.

Now, in Eq. (30), $x=1$ is seen to be a root for $\cot^2\alpha=(M^2-1)(A^2-1)/(M^2+A^2-1)$. Also, let $x=1+\delta$ be the root corresponding to $\cot^2\alpha=(M^2-1)(A^2-1)(1-\varepsilon)/(M^2+A^2-1)$, where δ, ε are supposed to be sufficiently small. Then, with such a weak shock approximation, Eq. (30) reduces to

$$\delta=\frac{2(M^2-1)(M^2+A^2-1)}{M^2\{3(M^2-1)+(\gamma+1)(A^2-1)\}}\varepsilon\qquad(32)$$

and Eqs. (31) reduce to

$$\left.\begin{aligned}
&\frac{H'^2}{H^2}=\frac{\sin^2\alpha}{\sin^2\beta}=1+\frac{2(M^2-1)(A^2-1)}{M^2A^2}\delta\\
&\frac{A'^2}{A^2}=1-\frac{A^2-1}{A^2}\delta\\
&\frac{M'^2}{M^2}=1-\frac{(A^2-1)\{2+(\gamma-1)M^2\}}{M^2A^2}\delta\\
&\frac{p'}{p}=1+\frac{\gamma(A^2-1)}{A^2}\delta
\end{aligned}\right\}\qquad(33)$$

$$\left.\begin{aligned}\frac{\rho'}{\rho}&=1+\frac{A^2-1}{A^2}\delta\\ \frac{q'}{q}&=1+\frac{2\gamma(A^2-1)(M^2+A^2-1)}{A^2(\gamma M^2+2A^2)}\delta\,.\end{aligned}\right|$$

Using these results, we can examine how a weak plane shock wave reflects and refracts at the interface between two streams. Since the shock is assumed to be so weak that the entropy change across it can be neglected, we need not distinguish the transitions by shock and by expansion waves.

Let us consider a shock configuration as shown in Fig. 4. The conditions on the interface are that the total pressure as well as the stream deflection are continuous across it. Hence

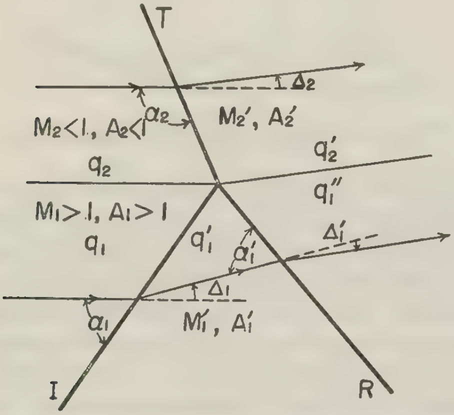

Fig. 4. Shock reflection and refraction at an interface of two streams.

$$\frac{q_2'}{q_2}=\frac{q_1''}{q_1}\,,\qquad \Delta_2=\Delta_1-\Delta'_1\,. \tag{34}$$

Using Eq. (33) and $\Delta=\delta/(\cot\alpha+\tan\alpha)$, these become as follows

$$F_2\delta_2-F_1\delta_1'=F_1\delta_1\,,\quad -G_1\delta_2+G_2\delta_1'=G_2\delta_1 \tag{35}$$

where $F\equiv(M^2-1)(M^2+A^2-1)/A^2(\gamma M^2+2A^2)$ and $G\equiv M^2A^2/\{(M^2-1)(A^2-1)(M^2+A^2-1)\}^{1/2}$. Hence, putting $(F_2G_2+F_1G_1)/(F_2G_2-F_1G_1)\equiv R'$ and $2F_1G_2/(F_2G_2-F_1G_1)\equiv T'$, we get

$$\delta_1'=R'\delta_1\,,\qquad \delta_2=T'\delta_1\,. \tag{36}$$

Thus, we are able to distinguish the four different shock configurations for various values of $M_1>1$, $A_1>1$; $M_2<1$, $A_2<1$ (c.f. Fig. 5).

The reflection factor R and transmission factor T, given by Eqs. (21), are related to the factors R' and T' in Eqs. (36) as follows:

$$R\equiv R'\,,\qquad T\equiv\frac{M_1{}^2A_1{}^2(M_2{}^2+A_2{}^2-1)}{M_2{}^2A_2{}^2(M_1{}^2+A_1{}^2-1)}T'\,. \tag{37}$$

As expected, R is equal to R', while T has the same sign as T' since (M^2+A^2-1) is positive for the present case (subsonic hyperbolic). Thus, when M_1, A_1 (>1), M_2, A_2 (<1) and hence R are given, we can find the structures of the two-dimensional jet of new type according to the considerations on the shock configuration stated above. They are shown schematically in Fig. 5.

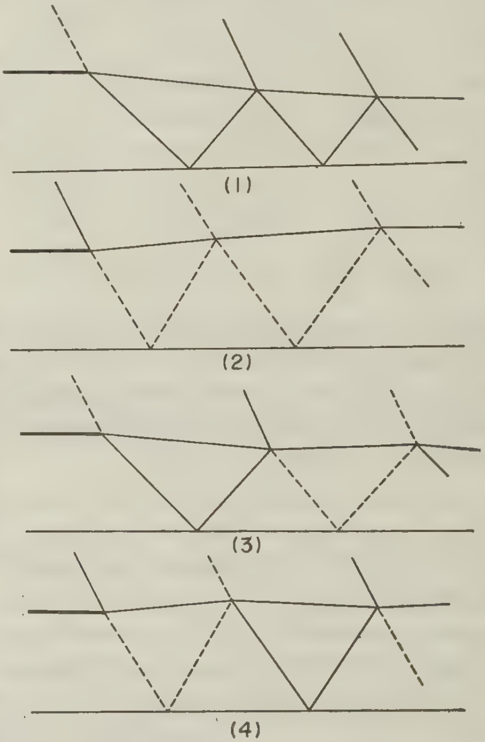

Fig. 5. Structure of the two-dimensional jet of new type. (1) and (2) for $R>0$, (3) and (4) for $R>0$. Full and broken lines represent respectively shocks and expansion waves.

The writer wishes to express his hearty thanks to Prof. K. Tamada for valuable discussion and kind inspection of the manuscript, and to Dr. T. Sakurai for valuable discussion.

Some Remarks on the Magnetogasdynamic Linearized Theory

By Shigenori ANDO

Engineering Division, Gifu Seisakusho, Kawasaki Aircraft Co.

(Received March 29, 1960)

The general theory of magnetogasdynamic linearized flow is extended to cover the case of unsteady flow in an arbitrary direction with respect to the magnetic field. This theory is also valid in the case when the frame is "body axes" slightly inclined against the free stream direction. For the case of steady flow, quadratic expression for the pressure disturbance is derived. Some problems when weak electromagnetic interaction exists are solved for illustration of the application.

§ 1. Introduction

In a previous paper[1] the author presented the magnetogasdynamic linearized theory for steady flow. Resler and McCune[2] derived the linearized equations written in terms of electric current for unsteady flow. As pointed out by them the unsteady flow equations are very useful, because, the stability of the flow can also be investigated. Although Resler and McCune did not explicitly show the procedure of appliation of their equations, their method seems to be more complicated than the present author's method. First, they give an equation for the electric current. When the current has been obtained, then other variables must be found by *integration of the differential equations* for them. Second, their equation for the three-dimensional case is written in a vector form, which adds many inconveniences in solving problems. On the other hand, the present author's equation is written in a scalar form even for the three-dimensional case. Once only one parametric function is obtained, the other quantities can be obtained by *differentiation* only.

As illustration of the present author's technique, some problems when weak electromagnetic interaction exists are solved, namely for a two-dimensional thin wing and for an axisymmetric body. These problems have been solved by previous authors, Sakuai[3] and Kusukawa[4] in their own ways.

Kusukawa has given a quadratic expression for the pressure disturbance on the surface of a slender body[4]. In this paper the more general formula will be derived.

§ 2. Symbols

The symbols used in the present paper are the conventional ones and almost the same as those in reference[1] unless otherwise stated.

§ 3. Extension of the Linearized Theory

3.1 *Extension of the theory*

In the present paper the general theory of magnetogasdynamic linearized flow will be established under the following assumptions.

1) The usual magnetohydrodynamic assumptions are valid.
2) The flow is inviscid and thermally non-conducting.
3) The fluid is a perfect gas.
4) The electrical conductivity or the magnetic Reynolds number is arbitrary.
5) The body which is either two- or three-dimensional makes small disturbance in the flow-and the electromagnetic-field. The undisturbed fields are uniform, where no electric current exists.
6) The applied magnetic field may have all three components $(\bar{B}_{\infty x}, \bar{B}_{\infty y}, \bar{B}_{\infty z})$.
7) Slightly unsteady motion with small angle of attack may be involved. The reference frame $S(0\text{-}\ \bar{x}, \bar{y}, \bar{z})$ is considered as the "body axes" moving with the average velocity (nearly constant) of the body.

Fig. 1. Configuration and Symbols.

It is noted that the last two assumptions differ from the ones used in the previous work[1].

The basic equations are written in dimensionless form as follows:

$$\operatorname{rot} \boldsymbol{E}_* = -\partial \boldsymbol{B}_*/\partial t \tag{1}$$

$$\operatorname{div} \boldsymbol{E}_* = \rho_{e*} \tag{2}$$

$$\operatorname{rot} \boldsymbol{B}_* = R_m \boldsymbol{J}_* \tag{3}$$

$$\operatorname{div} \boldsymbol{B}_* = 0 \tag{4}$$

$$\boldsymbol{J}_* = \boldsymbol{E}_* + \boldsymbol{q}_* \times \boldsymbol{B}_* \tag{5}$$

$$\frac{\partial \rho_*}{\partial t} + \operatorname{div}(\rho_* \boldsymbol{q}_*) = 0 \tag{6}$$

$$\rho_* \left[\frac{\partial}{\partial t} + (\boldsymbol{q}_* . \nabla)\right] \boldsymbol{q}_* = -\nabla p_* + R_m S(\boldsymbol{J}_* \times \boldsymbol{B}_*) \tag{7}$$

$$(\gamma-1)^{-1} \rho_* \left[\frac{\partial}{\partial t} + (\boldsymbol{q}_* . \nabla)\right] T_* = -p_* \nabla . \boldsymbol{q}_* + R_m S \boldsymbol{J}_*^2 \tag{8}$$

$$p_* = \rho_* T_* \tag{9}$$

where $t_* \equiv t = \bar{t}/(L\bar{u}_\infty^{-1})$, $R_m \equiv \mu_e \sigma \bar{u}_\infty L$ and $S \equiv \bar{B}_\infty^2/\mu_e \bar{\rho}_\infty \bar{u}_\infty^2$. All the other quantities marked with asterisk are dimensionless. On the other hand, the ones marked with bar are physical quantities having dimensions. The reference speed $\bar{u}_\infty$ used in the present paper is the average speed (nearly constant) of the body. R_m is called magnetic Reynolds number and S is pressure number. As the electromagnetic unit, MKS rationalized system is used.

All the quantities marked with asterisk are divided into two parts as follows.

$$\left.\begin{array}{l}
\text{Flow velocity:} \quad \bar{\boldsymbol{q}}/\bar{u}_\infty = \boldsymbol{q}_* = \boldsymbol{i} \cos\alpha + \boldsymbol{j} \sin\alpha + \boldsymbol{v} \doteqdot \boldsymbol{i} + \alpha \boldsymbol{j} + \boldsymbol{v}\,, \qquad \boldsymbol{v}(u, v, w) \\
\text{Magnetic flux density:} \quad \bar{\boldsymbol{B}}/\bar{B}_\infty = \boldsymbol{B}_* = \boldsymbol{B}_\infty + \boldsymbol{b}\,, \qquad \boldsymbol{B}_\infty(B_{\infty x}, B_{\infty y}, B_{\infty z}), \quad \boldsymbol{b}(b_x, b_y, b_z) \\
\text{Pressure:} \quad \bar{p}/\bar{\rho}\bar{u}_\infty^2 = p_* = p_\infty + p \quad (\text{The pressure coefficient } C_p \equiv 2p) \\
\text{Density:} \quad \bar{\rho}/\bar{\rho}_\infty = \rho_* = 1 + \rho \\
\text{Temperature:} \quad R\bar{T}/\bar{u}_\infty^2 = T_* = T_\infty + T \\
\text{Current density:} \quad \bar{\boldsymbol{J}}/\sigma \bar{u}_\infty \bar{B}_\infty = \boldsymbol{J}_* = 0 + \boldsymbol{J}\,, \qquad \boldsymbol{J}(J_x, J_y, J_z) \\
\text{Electric field:} \quad \bar{\boldsymbol{E}}/\bar{u}_\infty \bar{B}_\infty = \boldsymbol{E}_* = -(\boldsymbol{i} + \alpha \boldsymbol{j}) \times \boldsymbol{B}_\infty + \boldsymbol{E}\,, \qquad \boldsymbol{E}(E_x, E_y, E_z) \\
\quad \alpha;\ u, v, w;\ b_x, b_y, b_z;\ p, \rho, T;\ J_x, J_y, J_z;\ E_x, E_y, E_z \approx 0(\varPhi)
\end{array}\right\} \tag{10}$$

where $\varPhi$ is a parametric function of very small magnitude to be difined later. α is the angle between the free stream direction and the x-direction. Our assumptions give

$$(\boldsymbol{q}_* . \nabla) = \partial/\partial x + \alpha(\partial/\partial y) + \boldsymbol{v} . \nabla \approx \partial/\partial x$$

In what follows D/Dt stands for $\partial/\partial t + \partial/\partial x$. Linearization reduces Eq. (1)–(9) to the following forms.

The induction equation:

$$R_m \left\{ -\frac{D\boldsymbol{b}}{Dt} + (\boldsymbol{B}_\infty . \nabla)\boldsymbol{v} - \boldsymbol{B}_\infty \operatorname{div} \boldsymbol{v} \right\} + \nabla^2 \boldsymbol{b} = 0 \tag{11}$$

The momentum equation:

$$\frac{D\boldsymbol{v}}{Dt} = -\nabla p - S\boldsymbol{B}_\infty \times \operatorname{rot} \boldsymbol{b} \tag{12}$$

The continuity equation:

$$\frac{D\rho}{Dt} + \nabla . \boldsymbol{v} = 0 \tag{13}$$

The isentropic relations:

$$p = \gamma(\gamma-1)^{-1} T\,, \qquad \rho = (\gamma-1)^{-1} \frac{T}{T_\infty}\,, \qquad p = \gamma p_\infty \rho = \frac{\rho}{M^2} \tag{14}$$

where M represents the free stream Mach number.

From Eqs. (11)-(14), we can derive the fundamental equations in rather refined way than in reference[1]. By elimination of p in Eq. (12) using (13) and (14), we have the generalized continuity equation:

$$\left(\nabla^2 - M^2\frac{D^2}{Dt^2}\right)\operatorname{div}\boldsymbol{v} = SM^2\nabla^2\frac{D}{Dt}(\boldsymbol{B}_\infty.\boldsymbol{b}) \tag{15}$$

From Eq. (12) we have

$$\frac{D}{Dt}\operatorname{rot}\boldsymbol{v} = S(\boldsymbol{B}_\infty.\nabla)\operatorname{rot}\boldsymbol{b} \tag{16}$$

Let us introduce a scalar function φ defined by

$$\frac{D\boldsymbol{v}}{Dt} = S(\boldsymbol{B}_\infty.\nabla)\boldsymbol{b} + \frac{D}{Dt}\nabla\varphi$$

to represent $\boldsymbol{v}$ in terms of φ and $\boldsymbol{b}$. Then we can write down Eqs. (11) and (15) in terms of φ and $\boldsymbol{b}$ only. Now introduce another scalar function Φ in order for Eq. (11) to be satisfied automatically:

$$\left.\begin{aligned} \varphi &= \left(\nabla^2\frac{D}{Dt} - R_m\frac{D^2}{Dt^2} + R_mS\frac{\partial^2}{\partial\eta^2}\right)\Phi \\ \boldsymbol{b} &= -R_m\frac{D}{Dt}\left(\frac{\partial}{\partial\eta}\nabla - \boldsymbol{B}_\infty\nabla^2\right)\Phi \end{aligned}\right\}, \tag{17}$$

Then Eq. (15) gives the fundamental equation for Φ as follows:

$$\left[\left(\nabla^2 - M^2\frac{D^2}{Dt^2}\right)\left(R_m\frac{D^2}{Dt^2} - \nabla^2\frac{D}{Dt}\right) + R_mS\left(M^2\frac{D^2}{Dt^2} - \frac{\partial^2}{\partial\eta^2}\right)\nabla^2\right]\Phi = 0 \tag{18}$$

or

$$\mathscr{L}_F[\Phi] = 0 \tag{18$'$}$$

where

$$\frac{\partial}{\partial\eta} \equiv (\boldsymbol{B}_\infty.\nabla) \equiv B_{\infty x}\frac{\partial}{\partial x} + B_{\infty y}\frac{\partial}{\partial y} + B_{\infty z}\frac{\partial}{\partial z}$$

$\boldsymbol{b}$ and $\boldsymbol{v}$ are expressed in terms of Φ:

$$\boldsymbol{b} = -R_m\left(\frac{\partial}{\partial\eta}\nabla - \boldsymbol{B}_\infty\nabla^2\right)\frac{D\Phi}{Dt} \equiv \mathscr{L}_b[\Phi] \tag{19a}$$

$$\boldsymbol{v} = \left[\left(\nabla^2\frac{D}{Dt} - R_m\frac{D^2}{Dt^2}\right)\nabla + R_mS\boldsymbol{B}_\infty\nabla^2\frac{\partial}{\partial\eta}\right]\Phi \equiv \mathscr{L}_v[\Phi] \tag{19b}$$

The expression for p can be derived as follows. From Eq. (12), we have

$$\operatorname{grad}\left[p + \frac{D\varphi}{Dt} + S(\boldsymbol{B}_\infty.\boldsymbol{b})\right] = 0$$

and hence

$$p = -\frac{D\varphi}{Dt} - S\boldsymbol{B}_\infty.\boldsymbol{b} = \left(-\nabla^2\frac{D}{Dt} + R_m\frac{D^2}{Dt^2} - R_mS\nabla^2\right)\frac{D\Phi}{Dt} \equiv \mathscr{L}_p[\Phi] \tag{19c}$$

Eqs. (18)-(19) are the fundamental relations.

3.2 *Some remarks on fundamental relations*

Comparison of Eqs. (18)-(19) with Eqs. (31)-(33) in reference[1] shows that $\partial/\partial x$ in the latters is replaced by D/Dt.

Equation (18) contains the four important parameters such as the magnetic Reynolds number R_m, the interaction number R_mS, the free stream Mach number M and the direction of applied magnetic field ($B_{\infty x}$, $B_{\infty y}$, $B_{\infty z}$). Although particular selections of these parameters may reduce Eq. (18) to a simple form, this paper will not be concerned with the reduction procedure in detail except for the two cases $R_m=0$ or $S=0$. When σ or R_m is zero,

$$\mathscr{L}_b=0\,,\qquad \mathscr{L}_v=\nabla\left(\nabla^2\frac{D}{Dt}\right),\qquad \mathscr{L}_p=-\nabla^2\frac{D^2}{Dt^2}$$

and

$$\mathscr{L}_F=\left(M^2\frac{D^2}{Dt^2}-\nabla^2\right)\nabla^2\frac{D}{Dt}\,.$$

Let us put

$$\Phi'\equiv\nabla^2\frac{D\Phi}{Dt}\,.$$

Then the new Φ' is nothing but the velocity potential in pure gasdynamics. In the second case when $\bar{\boldsymbol{B}}_\infty$ or S is zero,

$$\mathscr{L}_b=-R_m\left(\frac{\partial}{\partial\eta}\nabla-\boldsymbol{B}_\infty\nabla^2\right)\frac{D}{Dt}\,,\qquad \mathscr{L}_v=\left(\nabla^2\frac{D}{Dt}-R_m\frac{D^2}{Dt^2}\right)\nabla\,.$$

$$\mathscr{L}_p=-\left(\nabla^2\frac{D}{Dt}-R_m\frac{D^2}{Dt^2}\right)\frac{D}{Dt}$$

and

$$\mathscr{L}_F=-\left(\nabla^2-M^2\frac{D^2}{Dt^2}\right)\left(\nabla^2\frac{D}{Dt}-R_m\frac{D^2}{Dt^2}\right).$$

Put

$$\Phi'\equiv\left(\nabla^2\frac{D}{Dt}-R_m\frac{D^2}{Dt^2}\right)\Phi$$

where

$$\left(\nabla^2-M^2\frac{D^2}{Dt^2}\right)\Phi'=0\,.$$

Then we have $v=\mathrm{grad}\,\Phi'$ and $p=-D\Phi'/Dt$ which are again the well-known relations in pure gasdynamics.

Eqs. (19) give the order of magnitude of various disturbances (in the physical quantities) as follows:

$$\left.\begin{aligned}
&\bar{\boldsymbol{B}}-\bar{\boldsymbol{B}}_\infty=\bar{B}_\infty\cdot O(R_m\Phi)\\
&\bar{\boldsymbol{J}}=\sigma\bar{u}_\infty\bar{B}_\infty\cdot O(\Phi)=\bar{B}_\infty\mu_e^{-1}L^{-1}\cdot O(R_m\Phi)\\
&\bar{\boldsymbol{q}}-\bar{\boldsymbol{q}}_\infty=\bar{u}_\infty\cdot\{O(\Phi)+O(R_m\Phi)+O(R_mS\Phi)\}\\
&\overline{\mathrm{rot}}\,\bar{\boldsymbol{q}}=\bar{u}_\infty L^{-1}\cdot O(R_mS\Phi)\\
&\bar{p}-\bar{p}_\infty=\bar{\rho}_\infty\bar{u}_\infty^2\cdot\{O(\Phi)+O(R_m\Phi)+O(R_mS\Phi)\}
\end{aligned}\right\}\tag{20}$$

When $R_m\leqq O(1)$, in the momentum equation

$$O\left\{\frac{\text{Lorentz force}}{\text{inertia force}}\right\}\sim R_mS\tag{21}$$

that is the reason why R_mS is termed interaction factor[5]. In the energy equation

$$O\left\{\frac{\text{Joule heating}}{\text{convection energy}}\right\}\sim O\left\{\frac{(\bar{B}_\infty\mu_e^{-1}L^{-1}R_m\Phi)^2\sigma^{-1}}{C_v\bar{\rho}_\infty(R^{-1}\bar{u}_\infty^2\Phi)(\bar{u}_\infty L^{-1})}\right\}\sim R_mS\Phi\tag{22}$$

which implies the isentropic relations to be valid. On the other hand, when $R_m \gg 1$, all the operator $\mathscr{L}_F$, $\mathscr{L}_b$, $\mathscr{L}_v$ and $\mathscr{L}_p$ are multiplied by R_m and so we can define new Φ' by the relation $\Phi' = R_m \Phi$. Thus all quantities on the left-hand side of Eq. (20) are of $O(\Phi')$, and so we have

$$O\left\{\frac{\text{Joule heating}}{\text{convection energy}}\right\} \sim S R_m^{-1} \Phi' \tag{23}$$

From above considerations we may think that the isentropic relations and the perturbation theory are valid in the both cases, especially even when $R_m \gg 1$, at least if the body is reasonably thin or slender. Eqs. (20) also suggest that when $R_m \gg 1$ the reasonable reference of electric current would be $\bar{B}_\infty \mu_e^{-1} L^{-1}$ as pointed out by I. Imai[7], although the present method leads to the correct result from another reference $\sigma \bar{u}_\infty \bar{B}_\infty$. The electric current will remain in the same order of magnitude as the other quantities, without becoming infinitely large even when $\sigma \to \infty$.

It is noteworthy that the fundamental equation (18) can be satisfied by many physical quantities. For example, Eq. (19a) gives

$$\operatorname{rot} \boldsymbol{b} = -\frac{D}{Dt} \nabla^2 R_m \boldsymbol{B}_\infty \times \nabla \Phi \equiv \mathscr{L}_{\operatorname{rot} \boldsymbol{b}}(\Phi) .$$

Let us operate $\mathscr{L}_{\operatorname{rot} \boldsymbol{b}}$ on Eq. (18); then

$$\mathscr{L}_{\operatorname{rot} \boldsymbol{b}} \mathscr{L}_F(\Phi) = \mathscr{L}_F \mathscr{L}_{\operatorname{rot} \boldsymbol{b}}(\Phi) = \mathscr{L}_F(\operatorname{rot} \boldsymbol{b}) = 0 .$$

In a similar manner we have also

$$\mathscr{L}_F(\boldsymbol{v}) = 0 , \qquad \mathscr{L}_F(\boldsymbol{b}) = 0 , \qquad \mathscr{L}_F(p) = 0 , \qquad \mathscr{L}_F(\operatorname{rot} \boldsymbol{v}) = 0$$

and so on.

The fact that $\mathscr{L}_F$ is a "scalar" operator with constant coefficients gives such many advantages. Resler and McCune[2] presented the fundamental equation in terms of rot $\boldsymbol{b}$ which contains a vector operator for the three-dimensional case. For the two-dimensional case their equation can be written in a scalar form and agrees with Eq. (18). They also suggested that once the equation for rot $\boldsymbol{b}$ is solved, then it is substituted into the other *differential equations* in order to obtain the remaining quantities. On the other hand, in the present method, we have only to define the parametric function Φ satisfying Eq. (18), since the other quantities can be obtained simply by *differentiation*. (See examples in section 5)

§ 4. The Expression of Pressure Distrubance in Quadratic Form

As is well known in pure gasdynamics, the linearized expression of the pressure disturbance like Eq. (19c) is not satisfactory to give the pressure distribution on the surface of the slender body. Kusukawa[4] derived a quadratic expression for the case of aligned magnetic field. In this section the present author derives the expression for the more general case.

In the case of steady flow Eq. (7) reduces to

$$\nabla p = \rho_* \left[-\nabla\left(\frac{1}{2} q_*^2\right) + \boldsymbol{q}_* \times \operatorname{rot} \boldsymbol{v} \right] - S(\boldsymbol{B}_\infty \times \operatorname{rot} \boldsymbol{b} + \boldsymbol{b} \times \operatorname{rot} \boldsymbol{b})$$

Remenbering $\rho_* = 1 + M^2 p + \cdots$ and $\rho_* \boldsymbol{q}_* = \boldsymbol{i} + \boldsymbol{v} + \alpha \boldsymbol{j} + M^2 p \boldsymbol{i} + \cdots$, we have

$$\nabla p = -\nabla\left(\frac{1}{2} q_*^2\right) - M^2 p \nabla\left(\frac{1}{2} q_*^2\right) + \boldsymbol{i} + \boldsymbol{v} + \alpha \boldsymbol{j} + M^2 p \boldsymbol{i}) \times \operatorname{rot} \boldsymbol{v} - S(\boldsymbol{B}_\infty \times \operatorname{rot} \boldsymbol{b} + \boldsymbol{b} \times \operatorname{rot} \boldsymbol{b}) \tag{24}$$

When the second order small terms are omitted, Eq. (24) is integrated to give

$$p = -u - S(\boldsymbol{i} \times \boldsymbol{B}_\infty) . \int_{-\infty}^{x} \operatorname{rot} \boldsymbol{b} dx \tag{25}$$

Substituting p from Eq. (25) into the right-hand side of Eq. (24) and then integrating, we have the quadratic expression of pressure disturbance as follows (all the terms of $O(u\cdot\Phi)$ have been omitted):

$$p=-u-S(\boldsymbol{i}\times\boldsymbol{B}_\infty).\int_{-\infty}^{x}\operatorname{rot}\boldsymbol{b}dx-\frac{v^2+w^2}{2}+\int_{-\infty}^{x}[(\boldsymbol{i}\times\boldsymbol{v}+\alpha\boldsymbol{k}).\operatorname{rot}\boldsymbol{v}-S(\boldsymbol{i}\times\boldsymbol{b}).\operatorname{rot}\boldsymbol{b}]dx \tag{26}$$

$$=\Big(\underset{O(\Phi)}{-\nabla^2\frac{\partial}{\partial x}}+\underset{O(R_m\Phi)}{R_m\frac{\partial^2}{\partial x^2}}-\underset{O(R_mS\Phi)}{R_mS\nabla^2}\Big)\frac{\partial\Phi}{\partial x}-\underset{O(\cdots\Phi^2)}{\frac{v^2+w^2}{2}}+\int_{-\infty}^{x}[\underset{O(R_mS\Phi^2)}{(\boldsymbol{i}\times\boldsymbol{v}+\alpha\boldsymbol{k}).\operatorname{rot}\boldsymbol{v}}-\underset{O(R_m{}^2S\Phi^2)}{S(\boldsymbol{i}\times\boldsymbol{b}).\operatorname{rot}\boldsymbol{b}}]dx \tag{27}$$

Of course the quadratic expression will be complete when all $\boldsymbol{v}$ and $\boldsymbol{b}$ in Eq. (27) are replaced by $\mathscr{L}_v[\Phi]$ and $\mathscr{L}_b[\Phi]$ respectively.

§ 5. Applications of the General Theory

For illustrative purpose, some problems with parallel magnetic field for the case of weak interaction ($R_m\approx 0$ and $R_mS\equiv K\ll 1$) will be solved for two-dimensional and for axisymmetric flow. It may be mentioned that the former has been solved by Sakurai[3] and the latter by Kusukawa[4] with the aid of their own methods. The assumption $R_m=0$ makes great simplifications, together with another assumption that the permeability of the body is equal to that of the gas μ_e. Eq. (19a) shows $\boldsymbol{b}=0$ for this case, which satisfies all requirements such as

i) the magnetic field, Eq. (19a), in the gas,
ii) the electro-magnetic equations in the body,
iii) the electro-magnetic condition on the interface between the gas and the body (all components of the magnetic field should be continuous.)

Thus we may consider the boundary conditions for the flow field only.

When $R_m\approx 0$, $B_{x\infty}\approx 1$, $B_{y\infty}=\delta\ll 1$ and $B_{\infty z}=0$, the fundamental relations (18)-(19) and (27) reduce to the forms:

$$\left[\frac{\partial^2}{\partial x^2}\pm\frac{1}{|1-M^2|}\left(\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right)+K\frac{\partial}{\partial x}\pm\frac{2K\delta}{|1-M^2|}\frac{\partial}{\partial y}\right]\Phi=0 \qquad \text{for} \quad M\lesseqgtr 1 \tag{28}$$

$$\boldsymbol{v}=\left[\frac{\partial}{\partial x}\nabla+\boldsymbol{i}K\frac{\partial}{\partial x}+K\delta\left(\boldsymbol{j}\frac{\partial}{\partial x}+\boldsymbol{i}\frac{\partial}{\partial y}\right)\right]\Phi \tag{29}$$

$$p=-\left(\frac{\partial}{\partial x}+K\right)\frac{\partial\Phi}{\partial x}-\frac{1}{2}(v^2+w^2) \tag{30}$$

$$\boldsymbol{b}\approx 0$$

5.1 *Steady flow past a two-dimensional symmetric wing with sharp edges.* $\boldsymbol{B}_\infty=\boldsymbol{i}+\delta\boldsymbol{j}$

5.1.1 Subsonic flow

In this case, Eqs. (28)-(30) give the relations:

$$\left.\begin{aligned}
&u=\left[\frac{\partial^2}{\partial X^2}+K\frac{\partial}{\partial X}+K\beta\delta\frac{\partial}{\partial Y}\right]\Phi\\
&v=\frac{\partial}{\partial X}\left[\beta\frac{\partial}{\partial Y}+K\delta\right]\Phi\,, \qquad p=-\left(\frac{\partial}{\partial X}+K\right)\frac{\partial\Phi}{\partial X}\\
&X\equiv x\,, \qquad Y\equiv\beta y\,, \qquad \beta\equiv\sqrt{1-M^2}\\
&\Phi_n\equiv\exp\left[-\frac{K}{2}X-\frac{K\delta}{\beta}Y\right]K_n\left(\frac{c}{2}r\right)e^{in\theta}\\
&\left(\frac{c}{2}\right)^2=\frac{K^2}{4}+\frac{K^2\delta^2}{\beta^2}\,, \qquad r^2=X^2+Y^2\,, \qquad \theta=\tan^{-1}\frac{Y}{X}
\end{aligned}\right\} \tag{31}$$

Φ_n being a particular solution. We try to construct the solution satisfying the boundary condition on the wing surface using Φ_0 only, which is one-valued and converges at infinity. Putting, with approximation

$$K_0\left(\frac{c}{2}r\right) \doteqdot -\ln\frac{c}{4}r - \Gamma$$

for small $(c/2)r$,

$$\Phi(X,\ Y) \equiv \int_0^1 f(\mu) \exp\left[-\frac{K}{2}(X-\mu) - \frac{K\delta}{\beta}Y\right]\left[\ln\frac{c}{4}\sqrt{(X-\mu)^2+Y^2} + \Gamma\right] d\mu \tag{32}$$

($\Gamma = 0.5772\cdots$ being Euler's constant) and substituting it into Eq. (31), we have the boundary condition as follows:

$$v(Y=\pm 0) = \pm\frac{df_B(X)}{dX} = \pm\frac{\partial}{\partial X}\int_0^1 f(\mu)\beta e^{-(K/2)(X-\mu)} \frac{|Y|d\mu}{(X-\mu)^2+Y^2} = \pm\frac{d}{dX}[\pi\beta f(X)]$$

where $y = \pm f_B(x)$ is the contour of the wing. Thus we have

$$f(x) = \frac{1}{\pi\beta} f_B(x) \tag{33}$$

We now substitute $f(x)$ into Φ, and in turn Φ into u; then we have u at $Y \approx \pm 0$ as follows:

$$u = \frac{1}{\pi\beta} C.\int_0^1 \frac{f_B'(\mu)}{X-\mu} d\mu + \frac{K}{2\pi\beta}\int_0^1 f_B'(\mu) \ln|X-\mu| d\mu \pm K\delta f_B(X) \tag{34}$$

where $C.\int$ means Cauchy's principal value. The signs ± are assigned, in accordance with the antisymmetry in δ, for the upper and lower surfaces respectively. Eq. (34) is just the one derived by Sakurai in reference 3).

It is noteworthy that in this method only one function $f(x)$ is used instead of two functions in Sakurai's method. The only one function $f(x)$ may be supplemented by the differential operators $\mathscr{L}_u$ and $\mathscr{L}_v$ having $K\delta$ terms.

5.1.2 Supersonic flow

In this case Eqs. (28)–(30) give the relations:

$$\left.\begin{aligned}
&u = \left[\frac{\partial^2}{\partial X^2} + K\frac{\partial}{\partial X} + KB\delta\frac{\partial}{\partial Y}\right]\Phi \\
&v = \frac{\partial}{\partial X}\left[B\frac{\partial}{\partial Y} + K\delta\right]\Phi, \qquad p = -\left(\frac{\partial}{\partial X} + K\right)\frac{\partial\Phi}{\partial X} \\
&X \equiv x, \qquad Y \equiv By, \qquad B \equiv \sqrt{M^2-1} \\
&\Phi \equiv e^{-(K/2)X-(K\delta/B)Y}\cdot\phi, \qquad \phi_{XX} - \phi_{YY} = \frac{K^2}{4}\left(1-\frac{4\delta^2}{B^2}\right)\phi \equiv \frac{L^2}{4}\phi
\end{aligned}\right\} \tag{35}$$

To solve the telegraph equation in ϕ we use the Laplace transform, which saves labour of calculation in comparison with other (say, Riemann's) method. Assuming $\phi = \partial\phi/\partial X = 0$ for $X \leqq 0$, the Laplace transformation of the above telegraph equation leads to

$$\frac{d^2\bar{\phi}}{d^2y} - \left(s^2 - \frac{L^2}{4}\right)\bar{\phi} = 0, \qquad \bar{\phi} = \int_0^\infty e^{-sX}\phi(X,\ Y,\ Z)dX$$

which is integrated to give

$$\bar{\phi} = A(s)\exp\left(-\sqrt{s^2-\frac{L^2}{4}}|Y|\right)$$

The formula of inverse Laplace transform[6):

$$\mathscr{L}^{-1}[(s^2-\alpha^2)^{-1/2}\exp(-b\sqrt{s^2-\alpha^2})]=u(X-b)I_0(\alpha\sqrt{X^2-b^2})$$

$$b>0\,,\qquad u(X)=\begin{cases}0 & X<0\\ 1 & X>0\end{cases}$$

and the convolution formula give the expression:

$$\phi=\int_0^X f(\mu)u(X-\mu-|Y|)I_0\left(\frac{L}{2}\sqrt{(X-\mu)^2-Y^2}\right)d\mu=\int_0^{X-|Y|}f(\mu)\,I_0\left(\frac{L}{2}\sqrt{(X-\mu)^2-Y^2}\right)d\mu \tag{36a}$$

which is symmetric in Y. The antisymmetric solution in Y can be constructed by differentiation of the symmetric solution with respect to Y. Thus we have for $Y\lesseqgtr 0$,

$$\mp f(X-|Y|)-\frac{LY}{2}\int_0^{X-|Y|}\frac{f(\mu)I_1[(L/2)\sqrt{(X-\mu)^2-Y^2}]}{\sqrt{(X-\mu)^2-Y^2}}d\mu \tag{36b}$$

In general the solution is given as a combination of the symmetric and the antisymmetric ones. Assume that the terms of $O(L^2)$ are negligible and thus $\phi_\pm=f(X-|Y|)\pm g(X-|Y|)$ for $Y\gtrless 0$. The boundary condition on the wing surface can be written as follows:

$$v(Y=\pm 0)=\frac{d}{dX}(f_B{}^c(X)\pm f_B{}^t(X))=\left[\frac{\partial}{\partial X}\left(B\frac{\partial}{\partial Y}+K\delta\right)\Phi\right]_{Y=\pm 0}$$

where $y=f_B{}^\pm(X)=f_B{}^c(X)\pm f_B{}^t(X)$ represent the upper and lower wing surfaces respectively. Necessary substitution for Φ gives

$$f'(X)=-B^{-1}\exp\left(\frac{K}{2}X\right)f_B{}^t(X)$$

and

$$g'(X)=-B^{-1}\exp\left(\frac{K}{2}X\right)f_B{}^c(X)$$

Then we have

$$\Phi=-\frac{1}{B}\exp\left(-\frac{K\delta}{B}Y\right)\left\{\int_0^{X-|Y|}\exp\left[\frac{K}{2}(\mu-X)\right]f_B{}^t(\mu)d\mu\pm\int_0^{X-|Y|}\exp\left[\frac{K}{2}(u-X)\right]f_B{}^c(\mu)\,d\mu\right\}$$

$$u(Y=\pm 0)=\mp\frac{1}{B}\,\frac{df_B{}^\pm(X)}{dX}\pm\frac{K}{2B}f_B{}^\pm(X)+K\delta f_B{}^\pm(X) \tag{37}$$

Alternatively if we treat each half space $Y\gtrless 0$ independently using symmetric ϕ only, then we can obtain the same final expression for u. The expression for the particular case of a symmetric wing agrees with Sakurai's result.[8]

5.2 *Steady flow past a slender axisymmetric body with pointed nose and tail,* $\boldsymbol{B_\infty=i}$.

5.2.1 Subsonic flow

Eqs. (28)–(30) give the relations:

$$\left.\begin{aligned}&u=\left(\frac{\partial}{\partial x}+K\right)\Phi\,,\qquad v_r=\frac{\partial\Phi}{\partial r}\,,\qquad v_\theta=0\\ &p=-u-\frac{1}{2}v_r{}^2\,,\qquad r=\beta\sqrt{y^2+z^2}\\ &\Phi=-e^{-(K/2)x}\int_0^\infty d\lambda\int_{-\infty}^\infty f(\mu)\cos\lambda(x-\mu)K_0\left(r\sqrt{\lambda^2+\frac{K^2}{4}}\right)d\mu\end{aligned}\right\} \tag{38}$$

The boundary condition on the body surface determines the unknown function $f(\mu)$ as follows:

$$\begin{aligned}v_r(r=r_B)&=\frac{dr_B}{dx}=\left.\frac{\partial\Phi}{\partial r}\right|_{r=r_B}\\ &=e^{-(K/2)x}\left[\int_{-\infty}^\infty f(\mu)d\mu\int_0^\infty K_1\left(r\sqrt{\frac{K^2}{4}+\lambda^2}\right)\sqrt{\lambda^2+\frac{K^2}{4}}\cos\lambda(x-\mu)d\lambda\right]_{r=r_B}\end{aligned}$$

Now make use of the formula[6)]

$$\int_0^\infty K_\nu[\alpha(x^2+\beta^2)^{1/2}](x^2+\beta^2)^{(1/2)\nu}\cos(xy)dx$$
$$=2^{-1/2}\pi^{1/2}\alpha^{+\nu}\beta^{(1/2)+\nu}(y^2+\alpha^2)^{-(1/2)\nu-1/4}K_{-\nu-(1/2)}[\beta(y^2+\alpha^2)^{1/2}]$$
$$R\alpha>0\,,\qquad R\beta>0$$

and

$$K_{-3/2}(z)=\sqrt{\frac{\pi}{2z}}\left(1+\frac{1}{z}\right)e^{-z}\approx\sqrt{\frac{\pi}{2}}\,z^{-3/2}\qquad\text{for}\quad z\ll 1$$

Then we have

$$\frac{dr_B}{dx}=\frac{\pi}{2}e^{-(K/2)x}\int_{-\infty}^{\infty}\frac{r_Bf(\mu)d\mu}{[(x-\mu)^2+r_B{}^2]^{3/2}}$$

Noting that for small r_B

$$\int_{-\infty}^{\infty}\frac{f(\mu)r_Bd\mu}{[(x-\mu)^2+r_B{}^2]^{3/2}}\cong\frac{f(x)}{r_B}\int_{-\infty}^{\infty}\frac{d(\mu/r_B)}{\{1+[(\mu-x)/r_B]^2\}^{3/2}}=\frac{2f(x)}{r_B}$$

we obtain

$$f(x)=\frac{1}{2\pi^2}\exp\left(\frac{K}{2}x\right)F'(x)\tag{39}$$

where $F(x)=\pi r_B{}^2$ represents the cross-sectional area of the body. It should be noted that the approximations

$$K_0(z)\approx-\ln\frac{z}{2}-\Gamma\quad\text{and}\quad K_1(z)\approx\frac{1}{z}\qquad\text{for}\quad z\ll 1$$

are not valid under the integral sign $\int_0^\infty\cdots d\lambda$. Substitution from (39) into Φ and thence use of the formula[6)]

$$\int_0^\infty K_0(\alpha\sqrt{x^2+\beta^2})\cos xydx=\frac{\pi}{2}\,\frac{\exp(-\beta\sqrt{y^2+\alpha^2})}{\sqrt{y^2+\alpha^2}}$$
$$R\alpha>0\,,\qquad R\beta>0$$

leads to the expression:

$$\Phi=\frac{1}{4\pi}\left[-\int_0^1F'(\mu)[(x-\mu)^2+r^2]^{-1/2}d\mu+KF(x)\right]+O(K^2)$$
$$=\frac{1}{2\pi}\left[F'(x)\ln\frac{r}{2}+\frac{1}{2}\int_0^1F''(\mu)\frac{\mu-x}{|\mu-x|}\ln|\mu-x|\,d\mu\right]+\frac{K}{4\pi}F(x)\tag{40}$$

In the above derivation we have made use of the relation:

$$\omega(r,\,x;\,\mu)\equiv\frac{\mu-x}{|\mu-x|}\ln\frac{|\mu-x|+\sqrt{(x-\mu)^2+r^2}}{r}\equiv\sinh^{-1}\frac{\mu-x}{r}$$
$$\frac{\partial\omega}{\partial\mu}=[(x-\mu)^2+r^2]^{-1/2}$$

Thus we have

$$u=-\frac{1}{4\pi}\int_0^1\frac{F''(\mu)d\mu}{\sqrt{(x-\mu)^2+r^2}}+\frac{K}{4\pi}\left[F'(x)-\int_0^1\frac{F'(\mu)d\mu}{\sqrt{(x-\mu)^2+r^2}}\right]$$
$$=-\frac{1}{4\pi}\left[F''(1)\ln(1-x)+F''(0)\ln x+2F''(x)\ln\frac{2}{r}-\int_0^1F'''(\mu)\frac{\mu-x}{|\mu-x|}\ln|\mu-x|\,d\mu\right]$$
$$+\frac{K}{4\pi}\left[F'(x)+2F'(x)\ln\frac{r}{2}+\int_0^1F''(\mu)\frac{\mu-x}{|\mu-x|}\ln|\mu-x|\,d\mu\right]\tag{41}$$

Now the drag coefficient is given by

$$C_D=2\int_0^1 F'(x)\left[-u-\frac{1}{2}\left(\frac{dr_B}{dx}\right)^2\right]dx\equiv C_{DO}+C_{DK}$$

where C_{DO} is pure gasdynamic one and C_{DK} represents the magnetogasdynamic effect. Simple calculations show that

$$\left.\begin{aligned} C_{DO}&=2\int_0^1 F'(x)\left[\frac{1}{4\pi}\int_0^1\frac{F''(\mu)d\mu}{\sqrt{(x-\mu)^2+r_B^2}}-\frac{1}{2}\left(\frac{dr_B}{dx}\right)^2\right]dx=0\\ C_{DK}&=\frac{K}{2\pi}\left[\int_0^1\int_0^1\frac{F'(x)F'(\mu)}{\sqrt{(x-\mu)^2+r_B^2}}dxd\mu-\int_0^1[F'(x)]^2dx\right]\\ &=\frac{K}{2\pi}\left[-\int_0^1\int_0^1 F'(x)F''(\mu)\frac{\mu-x}{|\mu-x|}\ln|\mu-x|d\mu dx+\int_0^1\{F'(x)\}^2\left(2\ln\frac{2}{r_B}-1\right)dx\right]\end{aligned}\right\}\tag{42}$$

It seems to be difficult to prove that C_{DK} is positive.

5.2.2 Supersonic flow

In this case we put $\Phi=e^{-(K/2)X}\phi$ and have

$$\phi_{XX}-\phi_{YY}-\phi_{ZZ}-\frac{K^2}{4}\phi=0\tag{43}$$

where

$$X\equiv x\,,\qquad Y\equiv By\,,\qquad Z=Bz\qquad\text{and}\qquad B\equiv\sqrt{M^2-1}$$

With the Laplace transform of ϕ, we obtain for small r,

$$\bar{\phi}=-A(s)K_0\left(r\sqrt{s^2-\frac{K^2}{4}}\right)\doteq A(s)\left(\ln\frac{r}{2}+\Gamma\right)+\frac{A(s)}{2}s\left[\frac{\ln(s-(K/2))}{s}+\frac{\ln(s+(K/2))}{s}\right]$$

where

$$r=\sqrt{Y^2+Z^2}\qquad\text{and}\qquad\bar{\phi}\equiv\int_0^\infty e^{-sX}\phi(X,Y,Z)dx\,.$$

By the inverse transform, we have

$$\phi(X,r)=f(X)\ln\frac{r}{2}-\int_0^X f'(\mu)\ln|X-\mu|d\mu+O(K^2)$$

The unknown function $f(X)$ is determined by the boundary condition as

$$f(X)=\frac{1}{2\pi}\exp\left(\frac{K}{2}X\right)F'(X)$$

Then we have

$$\begin{aligned}\Phi&=\frac{1}{2\pi}\left[F'(X)\ln\frac{r}{2}-\int_0^X F''(\mu)\ln(X-\mu)d\mu+\frac{K}{2}F(X)\right]\\ &=\frac{-1}{2\pi}\int_0^{X-r}\frac{F'(\mu)d\mu}{\sqrt{(X-\mu)^2-r^2}}+\frac{K}{4\pi}F(X)\end{aligned}$$

In the above derivation we have made use of the relations:

$$\bar{\omega}(r,X;\mu)\equiv-\ln\frac{|X-\mu|+\sqrt{(X-\mu)^2-r^2}}{r}\equiv-\cosh^{-1}\frac{X-\mu}{r}$$

$$\frac{\partial\bar{\omega}}{\partial\mu}=[(X-\mu)^2-r^2]^{-1/2}$$

We also have

$$\left.\begin{aligned} u&=\frac{-1}{2\pi}\frac{\partial}{\partial X}\int_0^{X-r}\frac{F'(\mu)d\mu}{\sqrt{(X-\mu)^2-r^2}}+\frac{K}{4\pi}\left[F'(X)-2\int_0^{X-r}\frac{F'(\mu)d\mu}{\sqrt{(X-\mu)^2-r^2}}\right]\\ &=\frac{1}{2\pi}\left[F''(X)\ln\frac{r}{2}-\frac{d}{dX}\int_0^X F''(\mu)\ln(X-\mu)d\mu\right]\\ &\quad+\frac{K}{2\pi}\left[F'(X)\ln\frac{r}{2}-\int_0^X F''(\mu)\ln(X-\mu)d\mu+\frac{1}{2}F'(X)\right] \end{aligned}\right\}\tag{45}$$

$$\left.\begin{aligned} C_D&=C_{DO}+C_{DK}\\ C_{DO}&=-\frac{1}{2\pi}\int_0^1\int_0^1 F''(X)F''(\mu)\ln|X-\mu|dXd\mu>0\\ C_{DK}&=\frac{K}{2\pi}\left\{2\int_0^1 F'(X)\,dX\int_0^{X-r}\frac{F'(\mu)}{\sqrt{(X-\mu)^2-r^2}}d\mu-\int_0^1[F'(X)]^2dX\right\}\\ &=\frac{K}{2\pi}\left\{2\int_0^1 F'(X)\,dX\int_0^X F''(\mu)\ln(X-\mu)d\mu+\int_0^1[F'(X)]^2\left(2\ln\frac{2}{r_B}-1\right)dX\right\} \end{aligned}\right\}\tag{46}$$

It may by difficult to prove that C_{DK} is positive.

§ 6. Conclusion

The general theory of magnetogasdynamic linearized flow is extended and refined. Small unsteadiness and small angle of attack are admitted. The direction of applied magnetic field is completely arbitrary. The fundamental equation derived here is of scalar form even in three-dimensional case. The equation is written in terms of a certain parametric function, and the other quantities are obtained with mere differentiation of the function. All other physical quantities are also governed by the same fundamental equation.

The quadratic expression of pressure disturbance is obtained for steady flow.

For the illustrative purpose some problems with weak magnetic interaction are solved. The general theory saves labour of calculation, and is found to be powerful for the theoretical study of magnetogasdynamic linearized flows.

The author would like to express his gratitude to Dr. T. Sakurai for the guidance and dicussions on the work described in this paper.

On the Ferromagnetism in Manganese-Aluminium-Iron System

By Ichiro TSUBOYA and Makoto SUGIHARA

Electrical Communication Laboratory
Nippon Telegraph and Telephone Public Corporation Musashino-shi, Tokyo, Japan

(Received May 27, 1960)

In early days, 1892, Hogg reported the alloy containing 55 wt. % Mn, 25 wt. % Al, and 13 wt. % Fe showed strong ferromagnetic nature.[1] Further studies on the iron-poor Mn-Al-Fe alloys, however, have not yet been made, except for pure Mn-Al system.[2),3)]

In this note, the authors report that there is a new ferromagnetic phase in the iron-poor Mn-Al-Fe alloys at the composition near Hoggl's specimen. The composition range of the ferromagnetic phase is as follows, 35 to 42.5 at. % Mn, 42.5 to 47.5 at. % Al, and 12.5 to 17.5 at. % Fe.

For the preparation of the specimen, electrolytic Mn (99.9%), electrolytic Fe (99.9%), and pure Al (99.99%) were melted in the suitable proportion in air and cast into rods, 10 mm in diameter. These rods were annealed for 1 hour at 900°C in vacuum to remove segregation, then cooled slowly to room temperature.

It was found that the specimens in composition range, 35 to 47.5 at. % Mn, 40 to 47.5 at. % Al and 10 to 17.5 at. % Fe, respectively, have ferromagnetic natures (Fig. 1).

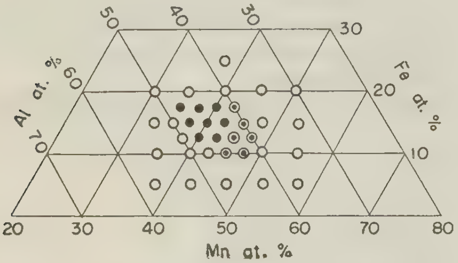

Fig. 1. Results of magnetic examination.
○ non-magnetic,
⊙ week ferromagnetic,
● ferromagnetic.

All specimens were crushed into powder for X ray analysis and the determination of Curie point. According to X-ray analysis, it was found that there is a pure single cubic phase in the composition range of 35 to 42.5 at. % Mn, 42.5 to 47.5 at. % Al, and 12.5 to 17.5 at. % Fe, respectively.

This cubic phase is named "κ phase". (Fig. 2). This composition range coincides with that of the specimens having strong ferromagnetic natures, and weakly ferromagnetic specimens are in the region of the mixture of κ phase and β-Mn phase. The non-magnetic phase have a β-Mn like structure in Mn-rich specimens and an η phase[3)] like in Al-rich ones.

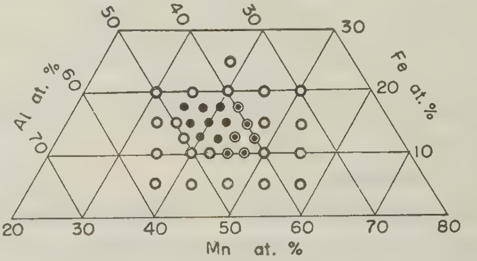

Fig. 2. Results of X-ray diffraction.
● cubic (CsCl type) structure —κ phase,
⊙ mixture of κ phase and β-Mn like phase,
○ β-Mn like phase and/or η phase.

It seems that the structure of κ phase is ordered one of Cs-Cl type, and lattice constant 2.96–2.97Å.

The magnetic properties such as Curie temperature, saturation magnetization, σ-T Curve were also measured. The Curie temperature of the κ phase specimens, measured by the magnetic balance, is from 35°C at the composition of 47.5 at. % Al, 35.0 at. % Mn, and 17.5 at. % Fe to 90°C at 45 at. % Al, 42.5 at. % Mn, and 12.5 at. % Fe. The saturation magnetization of these specimens at liquid nitrogen temperature, at the field strength of 15 K oe, is 380 to 400 Gauss/cc.. As the density of these specimens is 5 to 5.3 gram/cc., the saturation magnetic moment is 75 to 80 Gauss/gram.

It seems that the origin of this ferromagnetism consists in the ferromagnetic exchange interaction between Mn atoms. Further discussion with detailed measurements will be reported later on.

The Influence of Oxidation and Reduction on the Parasitic Ferromagnetism of αFe_2O_3

By Akira TASAKI, Kiiti SIRATORI
and Shûichi IIDA

Department of Physics, Faculty of Science, University of Tokyo

(Received June 3, 1960)

A considerable amount of studies has been made in recent years on the parasitic ferromagnetism of αFe_2O_3.[1),2),3),4)] A remarkable progress has been made by Dzyaloshinsky[5)] who has pointed out the presence of a certain lack of crystal symmetry in this rhombohedral antiferromagnet, which should result in a weak ferromagnetism when the spins lie in the basal plane. This idea has been extended by Moriya[6)] to a semiquantitative expression related with spin-orbit and exchange interactions of two neighbouring Fe^{3+} ions.

In spite of the presence of this clear-cut mechanism, however, the experimental results of this crystal are not so sure enough as to ascribe the whole parasitic ferromagnetism to the same mechanism. Here, a new aspect of the parasitic ferromagnetism of αFe_2O_3 is presented which has been found by heat treating the crystal in various pressures of oxygen.

The preparation of specimens was as follows; electrolytic iron was dissolved in nitric acid, dried, pressed and pre-fired at 1000°C for 3 hours. Five different heat treatments were given to these specimens. They are the annealing for 70 hours at 500°C in 100, 20, 5 Kg/cm² pressure of oxygen, and for 3 hours at 1000°C and 700°C in vacuum respectively. Magnetic measurements were made from −40°C to room temperature using a magnetic balance automatically controlled.

Now the magnetization of αFe_2O_3 is expressed by

$$\sigma = \sigma_0 + \chi H .$$

To determine σ_0 and χ, the magnetization was measured at the field strengthes 6.65, 11.8 and 14.3 KOe.

Fig. 1 shows χ and σ_0 vs T curves of these specimens. Here, no systematic change is found for χ both on oxidation and reduction series. While for σ_0, we notice that both oxidation and reduction introduce a residual parasitic ferromagnetism below the transition temperature. This residual parasitic ferromagnetism seems to be temperature independent and superimpose on the intrinsic one predicted by Dzyaloshinsky. This temperature independent parasitic ferromagnetism will be caused by the deviation of the cation-anion ratio from stoichiometry and is probably equal to the isotropic term σ_0 of Néel.[1)] This residual parastic ferromagnetism disappeared by heat treating again these specimens in air (1000°C, 3 hrs.). By this heat treatment, the weight of a oxidized specimen apparently did not change, but a reduced one gained its weight by about 0.2% (about 0.7% of total oxygen content).

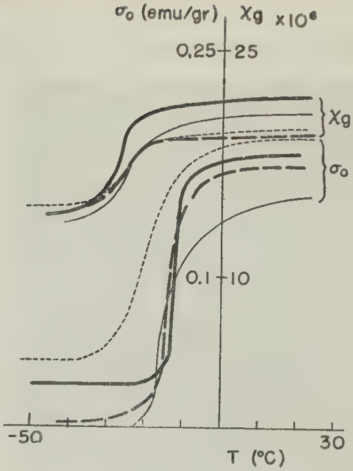

Fig. 1. χ and σ_0 vs T curves of αFe_2O_3. Heat treatments of the samples are as follows:
Oxidized at 500°C, 70 hrs. in 100 (—) and 20 (— —) Kg/cm² oxygen.
Reduced at 1000°C, 3 hrs. in 10^{-3} mmHg (- - -).
Annealed at 1000°C, 3 hrs. in air (—).

From these results, we may conclude that the residual or isotropic part in σ_0 is caused by the deviation from stoichiometry. The relevant ions will be Fe^{2+} in a reduced state and might be Fe^{4+} in an oxidized state. Two mechanisms are possible as the origin of this residual magnetization. One is to assume the presence of another ferromagnetic phase precipitated in the mother matrix of αFe_2O_3 and the other is to ascribe the magnetization to the presence of a certain imperfect structure included substantially in the crystal structure of non-stoichiometric αFe_2O_3. If the former mechanism is true, the relevant phase in a reduced state will probably be a spinel structure like Fe_3O_4 or γFe_2O_3. However, in a oxidized state no ferromagnetic phase is ever known which includes Fe^{4+}.[7)] Further study on this point is going on.

Emission Spectra from Glow Discharge through Vapors of Aromatic Hydrocarbons and *n*-Hexane

By Masato NISHI, Shiro HAMAMURA
and Hiroshi ARAKI
Department of Physics,
Hiroshima University, Hiroshima

(Received June 13, 1960)

Emission spectra from the positive column in D.C. glow discharge through vapors of aromatic hydrocarbons and *n*-hexane were investigated. Although the experimental method was essentially the same as that in the previous papers[1], the discharge tube itself was modified to avoid effect from the electrodes.

Typical intensity profiles (Fig. 1) show four kinds of spectra which will be temporarily designated as "A", "B", "C", and "D" in this note. "A" represents the spectrum due to π-electron transition of benzene ring and is observable also in the ultraviolet absorption. "B" is a continuous spectrum (300–400 mμ). "C" is another continuum (330–500 mμ). "D" is a band with a structure (445–590 mμ), and was emitted only from vapors of toluene and ethylbenzene. In the case of aromatic hydrocarbons "A", "C" and "D" appeared at lower vapor pressures. With an increase of the vapor pressures, the intensities of "A" and "D" decreased but that of "B" increased overlapping with "C" gradually. In the case of *n*-hexane, a continuum covering "B" and "C" regions was observed at lower vapor pressures, and with an increase of the vapor pressures the continuum faded away gradually but a benzene band ("A") became prominent.

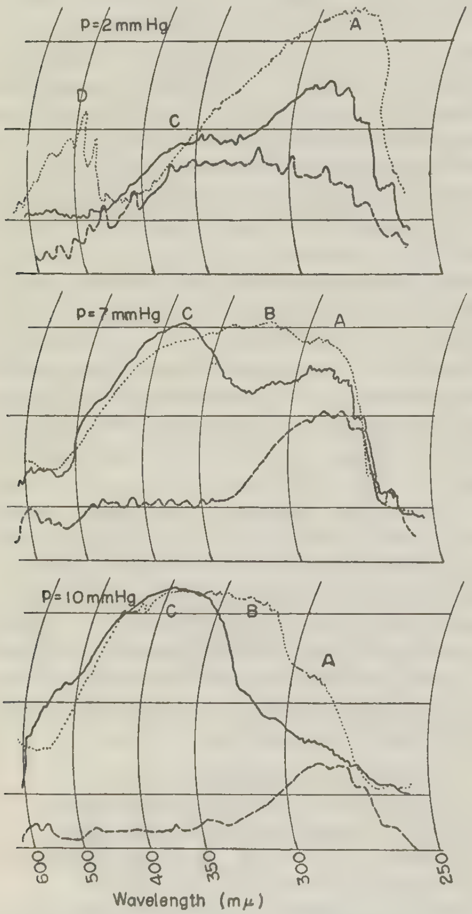

Fig. 1. Typical microphotometric curves corresponding to various pressures with a constant electric current (7 mA). full lines: benzene, dotted lines: toluene, broken lines: *n*-hexane.

H. Schüler et al.[2] found the similar spectra in the discharge through mixtures of aromatic vapors and rare gases. "D" spectrum agrees with the V spectrum named by Schüler et al., and may be attributed to benzyl radicals ($C_6H_5\dot{C}H_2$) as inferred by Schüler et al. Concerning the origin of "B" and "C", Schüler and his coworker inferred benzal radicals ($C_6H_5\dot{C}H$) and $C_6H_5\dot{C}\cdot$ radicals respectively. However, this seems to remain unsolved because of the following observations by the present authors:

(1) Both "B" and "C" were observed in the discharge through benzene vapor.

(2) Concerning the intensity variation of these continua, the pressure dependencies were slightly different with the kinds of molecular species. "B" was more distinct than "C" at higher vapor pressures as a general tendency, and this is reverse to the results by Schüler et al.

A detailed description will be published later.

Observation of an Anomaly in Transistor Characteristics

By Osamu NAKAHARA

Semiconductor Plant, Sanyo Electric Company, Daito City Osaka Prefecture, Japan

(Received April 26, 1960)

It is found[1] that in the alloy type *pnp* transistor whose base germanium used is of 40 ohm-cm *n*-type, the $V_{ce}-I_c$ curve under the constant forward bias voltage V_{be} applied between the base contact and the emitter shows the dynatron-type negative resistance. This is interpreted as originated from the high base resistance due to the portion held between the emitter side surface and the collector junction, which is easily modulated by the collector voltage. H. Nelson[2] reported the phenomenon of slight negative collector conductance which he attributed to the similar effect in the diffused silicon transistor of particular type.

Here we show the anomaly observed in the transistor whose structure is like shown in Fig. 1.

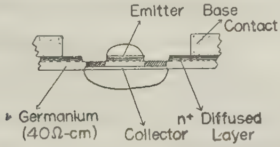

Fig. 1. Cross-sectional view of the transistor. Dimensions except the "neck" part are nearly same with the commercial drift transistor. Geometrical "neck" width was made about 10 microns.

This is just the same with the drift transistor except the high resistivity "neck" in the base formed by the electro-chemical etching. The remaining n^+ diffused surface layer in the base serves only to reduce the unnecessary base resistance for the phenomenon. Impurity gradient under the emitter junction has the effect to be described later besides the accelerating action of minority carriers injected.

In Fig. 2, the photograph of the $V_{ce}-I_c$ characteristics of the transistor is shown with V_{be} as a running parameter. It is seen that the collector current attains to a maximum value within the collector voltage saturation region and further increase in V_{ce} makes it decrease and finally all curves converge into a curve that corresponds to the collector current observed for $V_{be}=0$.

Such negative resistance observed above may be interpreted qualitatively as follows. The base resistance due to the hatched part in Fig. 1 is modulated by the collector voltage so that in the saturation region it is reduced because of the space chage layer shrinking toward the collector junction and the conductivity modulation induced by the injected minority carriers into the base from the collector junction. Thus the emitter action can be set in and the collector current flows easily. As V_{ce} goes to negative direction, however, the base resistance begins to increase because of the space charge layer widening into the base region. This decreases the injected carriers at the emitter under the constant V_{be} by the d.c. voltage drop in the base circuit. If such base resistance modulation feedback effect overcomes the internal feedback effect to increase the collector current, it begins to decrease with increase in V_{ce}, thus the negative collector resistance appears. It is to be noted that the internal feedback effect is much smaller in the case of the graded impurity base than the simple *pnp* structure so that the shape of the negative resistance curve becomes more salient than that observed in the latter structure. Various configurations of the transistor can be considered to realize such a characteristic and an attempt of the optimum design as a negative resistance element may be worthwhile if any its utility is found.

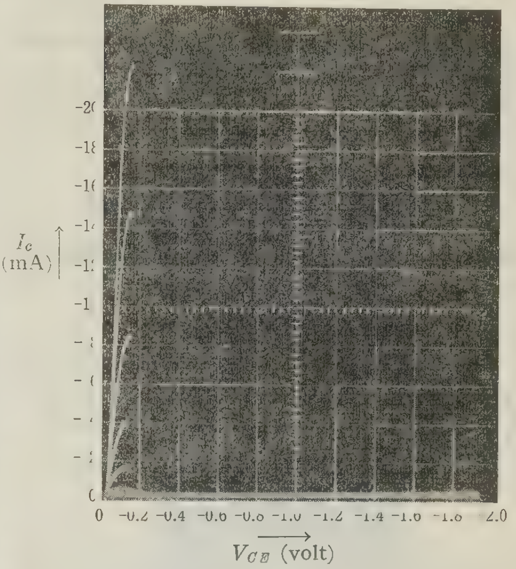

Fig. 2. Photograph of $V_{ce}-I_c$ characteristics of the transistor where V_{be} is taken as a running parameter. Curves are for V_{be} in 0.05 volt step up to 0.45 volt. Collector load resistance is zero.

The author thanks Mr. Endo and Mr. Tomaru, the staffs of the Electrical Communication Laboratory, who have suggested and examined the possible applications of this transistor. He also thanks Dr. Iwase who has guided the work throughout.

Resonance Transfer of Ionization Energy in Semiconductors

By Shigeharu KOSHINO

Radiation Center of Osaka Prefecture,
Shinke-Cho, Sakai, Osaka

and Toshihiko ANDO

Department of Physics, Kyoto University,
Kyoto

(Received June 1, 1960)

The anomalous thermal conductivity has been observed for several types of simiconductor in the intrinsic range of temperature.[1] Interpretations of this phenomenon have been attempted by several authors.[2] We shall discuss here the resononce transfer of ionization energy of impurity level.

Let us first consider two donors, of which one is occupied by an electron and the other is open. When a conduction electron is trapped by the open donor, the electron which has been trapped by the other donor can be simultaneously excited into the conduction band by the interelectronic interaction. The ionization energy of donor level is then transferred from the former to the latter. If there is the temperature difference between the two donor positions and the distribution of electrons is in the local equilibrium, the netcurrent of ionization energy is produced. When the temperature gradient is present in a sample, the transfer of ionization energy between every two donors produces the net thermal current throughout the sample.

It is first assumed that the interelectronic potential is given by a screened Coulomb type. We neglect then, as the lowest order approximation, the dependence of the matrix elements on the wave number of electron, since the matrix elements cannot in general be calculated analytically. In other words, we replace every matrix element by that of the process in which one electron in transferred from and the other electron transferred to the bottom of the conduction band. Furthermore it is assumed that the distribution of donors in the sample is uniform and the temperature gradient is constant.

Let us now imagine a plane perpendicular to the temperature gradient in the sample. The thermal conductivity may be given by the total net current of energy transferred through the plane divided by the area of the plane and the temperature gradient. The calculated thermal conductivity is

$$\kappa=\frac{2^{10}m_e{}^3e^4N^2kTg_0(1-g_0)}{\hbar^7\alpha^6\beta^3\varepsilon^2}I$$

provided $\alpha\gg\beta$, where

$$I=\int_0^\infty(E_0+kTx)\left\{kx-\frac{1}{T}(E_0+2\eta)+2\frac{\partial\eta}{\partial T}\right\}\cdot f_0(x)\{1-f_0(x)\}xdx\ .$$

In the above equations m_e is the effective mass of electron, α the reciprocal of the modified Bohr radius, β the screening constant, ε the dielectric constant, N the concentration of donor, η the Fermi energy, E_0 the energy difference between the bottom of the conduction band and the donor level, and f_0 and g_0 are the distribution functions of electron in the conduction band and in the donor state, respectively. When the temperature is in the intrinsic range, we obtain

$$\kappa=9\times10^{-14}(m/m_e)^{21/4}(m_h/m_e)^{3/8}\varepsilon^{11/2}N^2T^{-3/4}\cdot\{E_0(E_1-E_0)+2E_1kT+6(kT)^2\}e^{-(E_1-4E_0)/4kT}\ \text{erg/sec-cm °K},$$

where m_h is the effective mass of hole and E_1 is the energy depth of the forbidden band. For InSb, as an example, we obtain

$$\kappa=9\times10^{-33}N^2T^{1/4}\exp(-700/T)\ \text{cal/sec-cm °K}.$$

The magnitude of the obtained conductivity is nearly consistent with Bnsch's experimental one[1] provided the concentration of donor in his sample is of the order of 10^{15}. The essential difference of our mechanism from other ones is the dependence on the concentration of impurity. Finally it is noted that our mechanism is based on the localized model of donor state. It is obvious that the resonance transfer of ionization energy is inefficient when the concentration is so large that the impurity band model is useful.

Dislocations in Ferroelectric Glycine Sulfate Single Crystals

By Hiroo TOYODA

Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Tokyo

(Received June 10, 1960)

Observations on the dislocations in ferroelectric guanidine aluminium sulfate hexahydrate crystals were reported by Nakamura[1], and the calculation of the effect of dislocation field on the domain structure was presented by him and his co-workers[2]. Dislocation field may give some interesting effects on the other ferrectric properties. There are, however, a few ferroelectric crystals in which the dislocations have been delineated, that is, above-mentioned GASH and potassium ferrocyanide trihydrate crystals[3].

The author observed interesting etch pits on the surfaces of ferroelectric glycine sulfate crystal. A slow etching in alcohol can delineate the domain structure[4] and the effect may be caused by a small amount of water contained in alcohol, while a rapid etching by water gives etch pits quite different from those corresponding to the domain. They are observed on the various crystal faces and show some characteristic features corresponding to the crystal dislocation, as mentioned in followings.

The etch pits have always clear tips. The pits on (010) faces are cone-shaped and those on (001) and (110) faces have trapezoidal bases, the side faces of them being composed of small steps. When a crystal is cleaved away and etched, the position of the pits on two matching (010) faces fit to each other. As a result of observations on the crystals cut by wet thread, it was confirmed that the fits are nearly perfect on (110) and (001) matching faces, respectively. Chemical polishing reveales that the tips go ahead on lines into the crystal. For the pits on (001) face, an actual observation was performed along the length more than 2 mm and the lines lie in the (010) plane. The density of pits varies from parts to parts and ranges over 10^2 to 10^6 per square centimeter on all of the faces. The density is particularly high on the outer faces of the crystal containing much pores, and the etch pits appear on the interfaces of the pores. Mechanical shock applied to the face, such as dropping of or pushing by steel rod, creates new etch pits on (110) and (001) faces. From these observations, it is most probable to consider the pits as showing the locations of the dislocation lines.

In a (010) plate cleaved from the crystal grown in the ferroelectric temperature range, two triangular areas bounded by the lines connecting the seed crystal with the (110) faces include the domains bound by internal electric field[5]. The pits on (010) face are distributed most densely at the areas, and the fact suggests a probable relation to exist between the dislocation and the domain structure. Fig. 1 shows an interferometric picture of of the etched (010) face, and Figs. 2 and 3 exhibit the pits on (001) and (110) faces, respectively. Fig. 2 includes the pits aligned on lines, which may correspond to grain boundaries. Further studies on the dislocation themselves and their effects on the other properties are now in progress.

A Diffuse Reflexion from a Silicon Carbide Crystal

By Takanori TOMITA

Department of Physics, Saitama University, Urawa

(Received March 29, 1960)

Fig. 1 reproduces the c-axis oscillation photograph showing the diffuse reflexion obtained for a polycrystalline silicon carbide crystal. A small crystallite giving the diffuse reflexion was irradiated with a micro-beam from a fine X-ray source[2]. As shown in Fig. 1, the diffuse reflexion has five intensity maxima corresponding to the reciprocal $(10\bar{1}l)$ period of 6-layer cell and is intense between $(10\bar{1}1)$ and $(10\bar{1}2)$ points and between $(10\bar{1}4)$ and $(10\bar{1}5)$ points.

In order to explain such a feature of diffuse reflexion, we consider a disordered sequence of many ordered ranges having 6-layer structure (ABCACB) and introduce between either two of these ranges the phase relations prepared for the structure analysis of SiC 174 layers[3),4)]. The amplitude of reflexion is

$$\boldsymbol{E}=\boldsymbol{U}\sum_{j=1}^{j_{\max}}\left(\exp 2\pi i\alpha_j\cdot\exp 2\pi i\sum_{n=1}^{j-1}S_nNH_3\right.$$
$$\left.\times\sum_{sN=0}^{S_jN-1}\exp 2\pi isNH_3\right), \qquad (1)$$

where $\boldsymbol{U}$ is the layer form factor for 6-layer cell, the first term in the summation is the phase factor representing translation between two lattices belonging respectively to the first and the j-th ranges ($\alpha_1=0$), H_3 index of 6-layer reciprocal c-axis, N the total number of 6-layer cells along c-axis, and S_jN the number of 6-layer cells in the j-th range; S_nN is not always integer, and the fractional part should be exactly represented as α_n similarly as α_j, but it provides no essential results in the present argument. The intensity can be written as

$$\boldsymbol{I}=|\boldsymbol{E}|^2=|\boldsymbol{U}|^2\left[\sum_j\frac{\sin^2\pi S_jNH_3}{\sin^2\pi H_3}\right.$$
$$+\frac{1}{\sin^2\pi H_3}\sum\sum_{j<k}\left\{\cos 2\pi\left(\alpha_k-\alpha_j+\sum_{n=j+1}^{k-1}S_nNH_3\right)\right.$$
$$\times(\sin^2\pi(S_j+S_k)NH_3-\sin^2\pi S_jNH_3-\sin^2\pi S_kNH_3)$$
$$-2\sin 2\pi(\alpha_k-\alpha_j+\sum S_nNH_3)\cdot\sin\pi S_jNH_3$$
$$\left.\left.\times\sin\pi S_kNH_3\cdot\sin\pi(S_j+S_k)NH_3\right\}\right]. \qquad (2)$$

The first term of Eq. (2) is the sum of contributions from individual range ($j=k$) and gives rise to five maxima corresponding to 6-layer reciprocal period. The second term shows coherency between the reflexions from either two of the ranges ($j\neq k$) and gives on average diffuse reflexion along c-axis. The five maxima are also affected by the phase factors of the second term. The third vanishes on average. The second term is rewritten as

$$\frac{1}{\sin^2\pi H_3}\sum\sum_{j<k}\{\cos 2\pi(\alpha_k-\alpha_j+\delta H_3)\cos 2\pi LH_3$$
$$-\sin 2\pi(\alpha_k-\alpha_j+\delta H_3)\sin 2\pi LH_3\}$$
$$\times\{\sin^2\pi(S_j+S_k)NH_3-\sin^2\pi S_jNH_3$$
$$-\sin^2\pi S_kNH_3\}, \qquad (3)$$

where $L+\delta=\sum_{n=j+1}^{k-1}S_nN$, L and δ being integer and fraction respectively, and the cosine terms in the first parenthesis vanish on average except $L=0$ or at five maxima mentioned above as far as S_nN is considerably large, the sine terms vanishing on average. Finally the intensity becomes

$$\boldsymbol{I}=\frac{|\boldsymbol{U}|^2}{\sin^2\pi H_3}[\sum_j\sin^2\pi S_jNH_3$$
$$-\sum_j\sum_{j+1}\cos 2\pi(\alpha_{j+1}-\alpha_j+\delta H_3)$$
$$\times\{\sin^2\pi S_jNH_3+\sin^2\pi S_{j+1}NH_3$$
$$-\sin^2\pi(S_j+S_{j+1})NH_3\}]. \qquad (4)$$

For $\alpha_{j+1}-\alpha_j+\delta H_3$, 18 phase relations considerable for 6-layer cell (ref. 3) are assumed, and the intensity changes due to these relations are shown in Fig. 2. If all the relations occur at random, the characteristics of the relations are averaged into the intensity given by $|\boldsymbol{U}|^2$ similarly as the photograph presented by Jagodzinski[1]. On the other hand, if some relation occurs dominantly, its characteristic will appear corresponding to the number and size of the ranges having the relation.

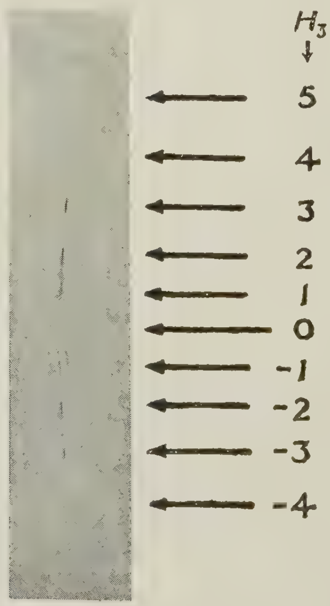

Fig. 1. The diffuse reflexion obtained for 30° c-axis oscillation.

The feature shown in Fig. 1 resembles No. 4 of Fig. 2 corresponding to the phase relation P+2+Q

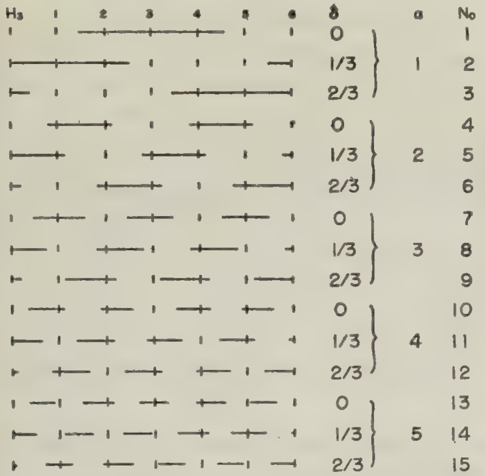

Fig. 2. The intensity change of diffuse reflexion by the phase relation. α and δ are corresponding to those of $P+\alpha+Q(\delta 0)$ of the previous paper (ref. 3). $P+0+Q(00)$, $P+0+Q(+0)$ and $P+0+Q(-0)$ show no changes, and the diffuse reflexions given for them show the intensity of $|U|^2$ own.

(00) (ref. 3) which is also supported by the observation at five maxima as that $(10\bar{1}3)$ peak is strong and sharp compared with $(10\bar{1}1)$ and $(10\bar{1}2)$ peaks (ref. 3 Table II).

The wider interstices between the regular ranges occur, the more intensely the reflexions from the atoms in the interstices appear and prevail over the intensity change introduced here. The coherency between the reflexions from these atoms produces the intensity distribution corresponding to either of Fig. 2, and the total intensity distribution becomes a weighted mean of some of Fig. 2. The point will be discussed in detail in another paper.

On the Determination of Diffusion Coefficient of Boron in Silicon

By Jiro Yamaguchi, Shiro Horiuchi,
Koji Matsumura
Department of Electrical Engineering, Faculty of Engineering Osaka University, Osaka
and Yasumasa Ogino
Department of Electrical Engineering, Osaka Institute of Technology, Osaka

(Received March 25, 1960)

Recently, Rohan et al. have suggested an alternate method for the measurement of the diffusion coefficient of Sb-124 in Si by radioassay[1]. The integrated activity in his method may be replaced with the conductivity of the diffused layer under some conditions, because the conductivity results from the total impurity atoms. Then, the same procedure as Rohan's can be applied to the non-radioactive impurities.

We tried to measure the diffusion coefficient of B in Si by the above method. The samples of 20 Ω-cm n type Si slices were pre-coated with B_2O_3 by dipping in the methyl alcohol solution saturated at 20°C, or pre-deposited with B dissociated pyrolytically from BCl_3 mixed in carrier gas[2]. A large amount of diffusant applied to the sample surface in such ways, fixes the surface concentration at the saturated value which correspond to the solid solubility of B in Si, and the diffusion proceeds according to the error function compliment distribution.

In such case, the following relation holds for the conductance of the diffused layer after the removal of the thin layer of thickness x, parallel to the original surface,

$$\sigma(x)=q\int_{x}^{x_j}\mu(C)\left\{C_0\,\mathrm{erfc}\left(\frac{x}{2\sqrt{Dt}}\right)-C_b\right\}dx \qquad (1)$$

where C_0, and C_b are the impurity concentrations at the surface and in the bulk respectively, and x_j is the original junction depth. If x is considerablly smaller than x_j and C_0 large enough to C_b, the equation (1) can be approximated in the following form,

$$\sigma(x)\simeq 2q\mu(C_0)C_0\sqrt{Dt}\int_{u}^{\infty}\mathrm{erfc}\,u\,du \qquad (2)$$

where

$$u=\frac{x}{2\sqrt{Dt}} \qquad (3)$$

Then the following simple relation holds for $\sigma(x)$ and the original surface conductance $\sigma(0)$

$$\frac{\sigma(x)}{\sigma(0)} \simeq \frac{\int_u^\infty \operatorname{erfc} u du}{\int_0^\infty \operatorname{erfc} u du} = \frac{1}{0.565}\int_u^\infty \operatorname{erfc} u du \qquad (4)$$

From the measurement of $\sigma(0)$ and $\sigma(x)$, the value of u corresponding to x is obtained by equation (4) and D can be calculated from the equation (3) independently of the absolute value of the mobility.

This procedure can be applied to the smaller penetration distance than the method employed by Fuller and Ditzenberger. But it is valid only under the condition that the approximate equation (2) can be held, namely $C_b \ll C_0 \leq 10^{20}$ and σ's are almost determined by the contribution from the very high concentration region, in which the concentration dependence of mobility is considerably small.

The results of the diffusion coefficient of B in Si are shown in Fig. 1, and yield the equation

$$D = 17.1 \exp\left(-\frac{84.800}{RT}\right) \text{ cm}^2/\text{sec}$$

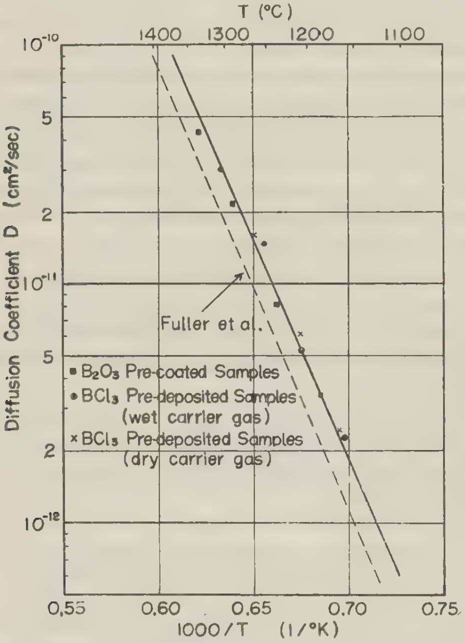

Fig. 1. Temperature Dependence of Diffusion Coefficient of B in Si.

In comparison with the values obtained by Fuller and Ditzenberger[3], the activation energies are in good agreement, while our values of D are about 80% larger over the temperature range studied.

The values of surface concentration C_s obtained from curves of conductivity versus C_s given by Backenstoss[4] are shown in Fig. 2. These values are thought to correspond to the solid solubility of B in Si and shows agreement with the value quoted in the recent paper[5]. On the contrary, C_0's obtained by Fuller and Ditzenberger are so large as to reach the order of 10^{22} atoms/cm³. Although the theoretical value of the solid solubility of B in Si is not yet available, the surface concentrations given by them seem to be unreasonably large and probably result from the underestimation of the diffusion coefficients.

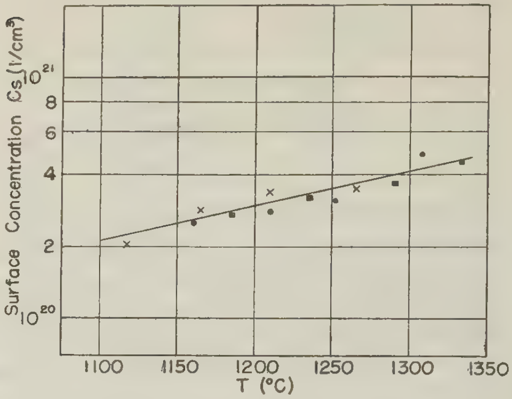

Fig. 2. Temperature Dependence of Surface Concentrations.

On the Weak Interaction of Baryons

By Seitaro NAKAMURA

Department of Physics, University of Tokyo
Tokyo

(Received July 2, 1960)

First, we shall arrange baryons and pions into a triplet and a singlet system with respect to the electric charge[1].

$$p_\mu \equiv \frac{\Xi^- + P}{\sqrt{2}}, \quad \frac{\Xi^- - P}{\sqrt{2}\,i}, \quad \frac{\Xi^0 - n}{\sqrt{2}}, \quad \frac{\Xi^0 + n}{\sqrt{2}}$$

$$q_\mu \equiv \frac{\Sigma^- + \Sigma^+}{\sqrt{2}}, \quad \frac{\Sigma^- - \Sigma^+}{\sqrt{2}\,i}, \quad \Sigma^0, \quad \Lambda$$

$$\pi_\mu \equiv \frac{\pi^- + \pi^+}{\sqrt{2}}, \quad \frac{\pi^- - \pi^+}{\sqrt{2}\,i}, \quad \pi^0, \quad \pi^{0\prime}$$

$$\mu = 1, 2, 3, 0.$$

Since the existence of $\pi^{0\prime}$ is quite doubtful, we omit it in the later discussions.

Next, we describe the Hamiltonian of the weak interaction between baryons and pions in terms of the invariants in this four dimensional isospin space.[2),3)]

$$\begin{aligned} H = a\{&\bar{p}_{[i}\pi_j q_{k]} \\ &+ b\bar{p}_0\pi_j q_j \\ &+ d\{\bar{p}_j\pi_j q_0 + \text{h.c.} \\ &i, j, k = 1, 2, 3 . \end{aligned} \qquad (1)$$

Here a, b and d are the coupling constants. (1) can be written in the usual notation,

$$\begin{aligned} H = \frac{a}{i}\Big\{&(\bar{P}\Sigma^+ - \bar{\Xi}^-\Sigma^-)\pi^0 - (\bar{P}\pi^+ - \bar{\Xi}^-\pi^-)\Sigma^0 \\ &- \frac{1}{\sqrt{2}}\bar{n}(\pi^+\Sigma^- - \pi^-\Sigma^+) - \frac{1}{\sqrt{2}}\bar{\Xi}^0(\pi^-\Sigma^+ - \pi^+\Sigma^-)\Big\} \\ &+ \frac{b}{\sqrt{2}}\Big\{\bar{n}(\pi^+\Sigma^- + \pi^-\Sigma^+) + \bar{\Xi}(\pi^-\Sigma^+ + \pi^+\Sigma^-)\Big\} \\ &+ d\Big\{(\bar{P}\pi^+ + \bar{\Xi}^-\pi^-)\Lambda + \frac{1}{\sqrt{2}}\bar{\Xi}^0\pi^0\Lambda - \frac{1}{\sqrt{2}}\bar{n}\pi^0\Lambda\Big\} . \end{aligned} \qquad (2)$$

Now, let us introduce the assumptions which define the operators of the Minkowski space in the Hamiltonian. Suppose the following charge symmetry transformation (we shall call it S tentatively):

$$\begin{aligned} S:\quad & p_2 \to -p_2, \quad q_2 \to -q_2, \quad \pi_2 \to -\pi_2 \\ & (P \leftrightarrow \Xi^-, \quad \Sigma^+ \leftrightarrow \Sigma^-, \quad \pi^+ \leftrightarrow \pi^-) . \end{aligned} \qquad (3)$$

S will change the sign of the electric charge of charged particles without transforming them into their antiparticle states.

We require that the interaction Hamiltonian must be invariant under the combined transformation of S and X, where $X = \gamma_5$ denotes the chirality transformation proposed by Watanabe.[4)] The chirality was a useful idea which led Marshak and Sudarshan[5)] to determine the $V-A$ type for the universal Fermi interactions.

It will be easily seen that the terms with the coefficient a/i in (2) change sign under the transformation S, while those with the coefficients b and d remain invariant under S. On the other hand, the terms $\bar{\psi}_A\gamma_\mu(1+\gamma_5)\psi_B$ and $\bar{\psi}_A\gamma_\mu(1-\gamma_5)\psi_B$ are chirality invariant and chirality pseudo-invariant,[6)] respectively. Therefore, it is clear that if we take $\Omega_a = \gamma_\mu(1-\gamma_5)$, $\Omega_b = \gamma_\mu(1+\gamma_5)$ and $\Omega_d = \gamma_\mu(1+\gamma_5)$, then we are able to prove the SX invariance in the Hamiltonian (1). Here Ω_a, Ω_b and Ω_d are the Dirac operators to be inserted in the bilinear forms of the two baryon-fields in the terms of (2) with the coefficients a, b and d, respectively. We obtain thus the final expression of (1) with the operators.

$$\begin{aligned} H = ig\{&\bar{P}\gamma_\mu(1-\gamma_5)\Sigma^0\partial_\mu\pi^+ - \bar{P}\gamma_\mu(1-\gamma_5)\Sigma^+\varrho_\mu\pi^0\} \\ &+ ig\sqrt{2}\,\{\bar{n}\gamma_\mu\gamma_5\Sigma^+\partial_\mu\pi^- + \bar{n}\gamma_\mu\Sigma^-\partial_\mu\pi^+\} \\ &+ ig\{-\bar{\Xi}^-\gamma_\mu(1-\gamma_5)\Sigma^0\partial_\mu\pi^- + \bar{\Xi}^-\gamma_\mu(1-\gamma_5)\Sigma^-\partial_\mu\pi^0\} \\ &+ ig\sqrt{2}\,\{\bar{\Xi}^0\gamma_\mu\gamma_5\Sigma^-\varrho_\mu\pi^+ + \bar{\Xi}^0\gamma_\mu\Sigma^+\partial_\mu\pi^-\} \\ &+ ig\Big\{\bar{P}\gamma_\mu(1+\gamma_5)\Lambda\cdot\partial_\mu\pi^+ - \frac{1}{\sqrt{2}}\bar{n}\gamma_\mu(1+\gamma_5)\Lambda\cdot\partial_\mu\pi^0 \\ &\quad + \bar{\Xi}^-\gamma_\mu(1+\gamma_5)\Lambda\cdot\partial_\mu\pi^- \\ &\quad + \frac{1}{\sqrt{2}}\bar{\Xi}^0\gamma_\mu(1+\gamma_5)\Lambda\cdot\partial_\mu\pi^0\Big\} \\ &\quad + \text{h.c.} \end{aligned} \qquad (4)$$

Here we assumed

$$-\frac{a}{i} = b = d \equiv ig . \qquad (5)$$

It is remarkable to note that the present scheme of the weak interaction provides a reasonable explanation on the recent experiments. First, (4) implies that the parity is conserved in the decay processes of $\Sigma^- \to \pi^- + n$ and $\Sigma^+ \to \pi^+ + n$, while it is violated in the processes of $\Sigma^+ \to \pi^0 + P$, $\Lambda \to P + \pi^-$ and $\Lambda \to n + \pi^0$. Cool et al.[7)] have succeeded to measure the angular distribution of the Σ (Λ)-decay in the non-leptonic mode, which seems to support the prediction of the present scheme.[8)] Second, it is quite satisfactory to see that the predicted branching ratios from (5),

$$\begin{aligned} 2:1 \ \text{for}\ & \sigma(\Lambda \to \pi^- + P) : \sigma(\Lambda \to \pi^0 + n) , \\ 1:1:1 \ \text{for}\ & \sigma(\Sigma^+ \to \pi^+ + n) : \sigma(\Sigma^+ \to \pi^0 + P) : \\ & \sigma(\Sigma^- \to \pi^- + n) , \end{aligned}$$

are not at variances with the observed values.[9),10)] The unique prediction of this theory which seems very striking is the sign of the axial vector interaction, A, relative to that of the vector interaction, V.

$$\begin{aligned} V-A:\quad & \Xi^- \to \pi^- + \Lambda , \quad \Xi^0 \to \pi^0 + \Lambda , \\ & \Lambda \to \pi^- + P , \quad \Lambda \to \pi^0 + n ; \\ V+A:\quad & \Sigma^+ \to \pi^0 + P ; \\ A:\quad & \Sigma^+ \to \pi^+ + n ; \qquad V:\quad \Sigma^- \to \pi^- + n . \end{aligned}$$

Experimental check on this problem[11),12)] may come from the studies on the angular distribution of these modes of the hyperon decay.

Reactions of Iron-54 with Alpha-Particles

By Shigeo TANAKA, Michiaki FURUKAWA, Shiro IWATA*,
Masuo YAGI**, Hiroshi AMANO*** and Takashi MIKUMO

Institute for Nuclear Study, University of Tokyo,
Tanashi P.O., Tokyo

(Received May 7, 1960)

Excitation functions for the (α, p), (α, n), (α, pn), $(\alpha, 2n)$, $(\alpha, p2n+\alpha, 3n)$, $(\alpha, \alpha n)$, $(\alpha, \alpha pn)$ and $(\alpha, \alpha 2n)$ reactions on Fe^{54} were measured by the activation method using a "stacked-foil" technique, the alpha-particle energies ranging from 10 MeV to 40 MeV. The predominance of proton emission over neutron emission has been observed. The ratios of $\sigma(\alpha, p)/\sigma(\alpha, n)$ and $\sigma(\alpha, pn)/\sigma(\alpha, 2n)$ in the region of maximum yield were found to be 3.4 and 60, respectively. The ratio of $\sigma(\alpha, \alpha pn)/\sigma(\alpha, \alpha 2n)$ at 40 MeV was about 180. A small "knee" was observed at the incident alpha-particle energy of about 20 MeV in the excitation function for the $(\alpha, 2n)$ reaction. The total reaction cross section was found to agree with the value calculated from continuum theory for a nuclear radius constant r_0 of 1.7×10^{-13} cm assuming a nuclear square well potential.

§1. Introduction

In recent years, the experimental data on the competitive modes of decay of medium-weight nuclei bombarded by alpha-particles have been accumulated by several investigators1)–8). The results show a very large variety for the competition between charged-particle and neutron emission. To what extent and in how much detail the competition between various nuclear reactions could be fitted by the statistical theory have been discussed. The recent report by Dostrovsky, Fraenkel and Friedlander9) shows that the experimental excitation functions of nuclear reactions in the mass range Cr^{50}–Se^{74} could be fitted by the evaporation calculation with a unique set of the pairing and shell energy corrections.

As a part of our systematic study in which the cross sections of alpha-induced reactions on medium-weight nuclei at intermediate energies are investigated, we report here the results of the alpha-induced reactions on Fe^{54}. Fe^{54} is a suitable nucleus for measuring the competing reactions between proton and neutron emission. The excitation functions for the (α, p), (α, n), (α, pn), $(\alpha, 2n)$, $(\alpha, p2n+\alpha, 3n)$, $(\alpha, \alpha n)$, $(\alpha, \alpha pn)$ and $(\alpha, \alpha 2n)$ reactions have been measured****.

§2. Experimental

The bombardments were performed with the external alpha-particle beam from the 160 cm INSJ cyclotron by means of a "stacked-foil" technique. The beam was collected in a Faraday cup and the total charge of the beam was measured by a current integrator. A more detailed description of the bombarding system is given in the previous reports10),11). In different experiments, the initial alpha-particle energies were 40.2 and 32.0 MeV, and certain energy region was covered in the different runs. The experiment with 32.0 MeV alpha-particles was duplicated. For the $Fe^{54}(\alpha, \alpha n)Fe^{53}$ and $Fe^{54}(\alpha, \alpha pn)Mn^{52m}$ reactions, the separate bombardments with short irradiation times were performed.

The targets consisted of natural-iron foils (7.7 ± 0.1 mg/cm²) whose impurities were chemically analyzed.

**** We knew, after our experiment had already finished, that there were the unpublished data for the (α, p), (α, n), (α, pn), $(\alpha, 2n)$, $(\alpha, p2n+\alpha, 3n)$ and $(\alpha, 2pn)$ reactions on Fe^{54} measured recently by Houck and Miller7).

The contribution of manganese impurity to the $Fe^{54}(\alpha, p)Co^{57}$ cross section was examined from the measured reaction cross sections on Mn^{55} (see ref. 10), and was estimated to be within, 5%.

After the bombardment, the target foil was dissolved in acid and nickel, manganese, cobalt and iron were chemically separated by means of an anion exchange resin.

The disintegration rates of the samples were determined by measuring β-particles with a calibrated GM counter and a 4πβ-counter and γ-rays with an (1-¾ in. dia. ×2 in. high, 1-½ in. dia. ×1 in. high and well type) NaI scintillation counter. The counting techniques and the calibration methods are presented in more detail in the Appendix.

▽ $Fe^{54}(\alpha, 2n)Ni^{56}$; The ordinary and the inverse triangles represent the data from each separate runs. The systematically high values of ▽ compared with those of △ may be due to the slight contamination of cobalt into nickel fraction.

↓ Calculated threshold for each reaction indicated above the arrow, on Fe^{54}.

The numerical data not shown in this Figure are
$\sigma(\alpha, 2n)$ at ~18 MeV = ~2×10^{-29} cm²
$\sigma(\alpha, \alpha 2n)$ at 36.4 MeV = $(5\pm1)\times10^{-29}$ cm²
$\sigma(\alpha, \alpha 2n)$ at 34.6 MeV = ~1×10^{-29} cm².

§ 3. Results and Discussion

The absolute cross sections are plotted as a function of alpha-particle energy in Fig. 1, together with the energy spread in target foil and with the estimated error of the magnitude of cross section for some experimental points*. The (α, p) and (α, n) excitation functions on Fe^{54} were measured below the thresholds of the (α, p2n) and (α, 3n) reactions on Fe^{56}, respectively.

In obtaining all these cross sections, corrections were made for the "recoil-loss" from target foil. The amounts of "recoil-loss" for each reaction were measured as a function of alpha-particle energy. The amount of "recoil-loss" is abont 7% for the 7.7 mg/cm² iron foil at the incident alpha-particle energy of 40 MeV, and it decreases with decreasing alpha-particle energy.

The present experiment shows quite strikingly the predominance of protron emission over neutron emission. The energy dependences of the ratios of $\sigma(\alpha, p)/\sigma(\alpha, n)$, $\sigma(\alpha, pn)/\sigma(\alpha, 2n)$ and $\sigma(\alpha, \alpha pn)/\sigma(\alpha, \alpha 2n)$ are represented in Fig. 2.

The ratio of $\sigma(\alpha, p)/\sigma(\alpha, n)$ is about 3.5 in this experiment. It is of interest to compare this ratio with the result of Carver and Turchinetz[13] who measured the competing processes in the photo-disintegration of Ni^{58}. The ratio of $\sigma(\gamma, p)/\sigma(\gamma, n)$ is almost constant at the photon energies between 20 and 32 MeV which correspond to the alpha-particle energies of 15–28 MeV, and is about 2.5. In both cases, the proton emission from Ni^{58} appears to be favoured over neutron emission by about the same factor.

It is interesting to note that there is a small "knee" at the incident alpha-particle energy of about 20 MeV in the excitation function for the (α, 2n) reaction on Fe^{54}. This

---

* A part of the present result was reported previously as the Short Note in this Journal[12]. The data in the previous report have been renewed in this paper by some corrections which are mainly due to the determination of counting efficiencies

"knee" was carefully determined by two separate bombardments. The only source of ambiguity may come from the chemical separation of nickel and cobalt. The contamination of cobalt into nickel fraction was reduced below $\sim 1\times 10^{-5}$ by careful procedures. It is thought that this "knee" is beyond the experimental error.

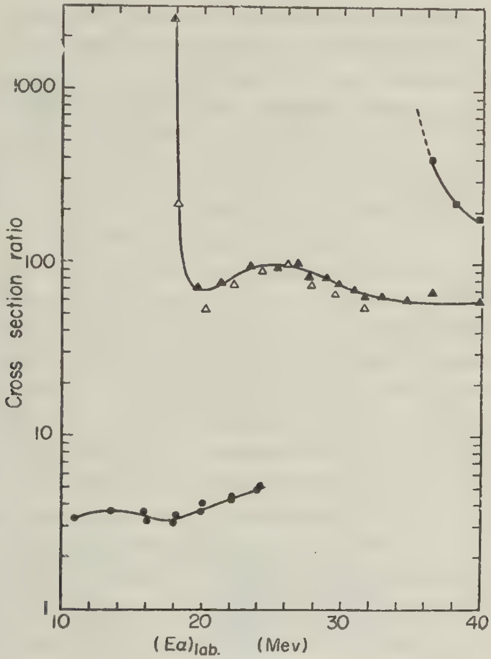

Fig. 2. Ratios for $\sigma(\alpha, p)/\sigma(\alpha, n)$, $\sigma(\alpha, pn)/\sigma(\alpha, 2n)$ and $\sigma(\alpha, \alpha pn)/\sigma(\alpha, \alpha 2n)$.

● $\sigma(\alpha, p)/\sigma(\alpha, n)$ ▲ $\sigma(\alpha, pn)/\sigma(\alpha, 2n)$

■ $\sigma(\alpha, \alpha pn)/\sigma(\alpha, \alpha 2n)$

△ $\sigma(\alpha, pn)/\sigma(\alpha, 2n)$; Derived from the values of ▽ in Fig. 1.

The ratio of $\sigma(\alpha, pn)/\sigma(\alpha, 2n)$ at the incident energy of about 18 MeV shows a large value of about 1000. As the energy of alpha-particles is increased above the threshold for the $(\alpha, 2n)$ reaction this ratio drops rapidly and is observed to have a minimum value of about 70 at $E_\alpha \simeq 20$ MeV, followed by an increase to a maximum of about 100 at 25 MeV, further a gradual decrease with increasing energy. The minimum is a consequence of the "knee" that is observed in the $(\alpha, 2n)$ reaction.

In the compound nucleus picture, the emission probabilities are very sensitive to the binding energies of various particles and to the level densities of residual nuclei. The experimental results in which the (α, pn) reaction competes favourably with the $(\alpha, 2n)$ reaction have been reported in other cases in this mass region; for Ti^{46}, Cr^{50}, Ni^{60}, Zn^{64} and Ge^{70} targets.[1),2),4),5),9)] The residual nuclei of all the $(\alpha, 2n)$ reactions mentioned are even-even, while those of the (α, pn) reactions are odd-odd nuclei and are expected to have a greater density of levels. This differences in the level densities of the residual nuclei may play a role in part to reduce the $(\alpha, 2n)$ reactions, together with the fact that the thresholds of the $(\alpha, 2n)$ reactions are considerably higher than those of the (α, pn) reactions. A support of this view is obtained from the large $(\alpha, 2n)$ cross sections observed for V^{50}, Mn^{55}, Cu^{65}, Ag^{107} and Ag^{109} targets, where the residual nuclei are not even-even.[6),8)-10)] In addition, the effect of closed shell on the level density may be taken into account and this effect further reduces the $(\alpha, 2n)$ reaction on Fe^{54}, since the residual Ni^{56} nucleus is double magic.

The $(\alpha, \alpha pn)$ cross section shown in Fig. 3 is that for ground-state formation. The ratio of the $(\alpha, \alpha pn)$ cross section for isomer formation to that for ground-state formation (σ_m/σ_g) was measured at the incident alpha-particle energy of 40 MeV, and was about 0.05.

The ratio of $\sigma(\alpha, \alpha pn)/\sigma(\alpha, \alpha 2n)$ is about 180 at the highest incident alpha-particle energy attained. As the energy of alpha-particles is increased above the threshold for the $(\alpha, \alpha 2n)$ reaction, this ratio drops rapidly and then probably decreases monotonically to

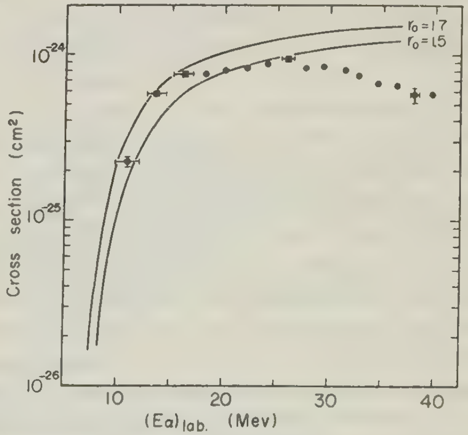

Fig. 3. Sum of the Fe^{54} excitation functions.

— Total reaction cross section calculated from continuum theory.

● Sum of the observed cross sections.

an asymptotic value. Unfortunately, the asymptotic value could not be obtained at the incident alpha-particle energies available in this experiment.

The cross section shown as that of the (α, $p2n+\alpha$, $3n$) reaction is perhaps mainly due to the (α, $p2n$) reaction and of course includes substantial contribution from triton emission. The cross section of the (α, $3n$) reaction may be very small because of the low yield of the (α, $2n$) reaction.

A comparison between the sum of the observed cross sections and the total reaction cross section calculated from continuum theory (according to Shapiro's calculation) is shown in Fig. 3. A value of $r_0=1.7\times10^{-13}$ cm appears to give the reasonable fit to the low energy part of the sum of the observed cross sections. The difference between the calculated total cross section and the sum of the observed cross sections at higher energy part may reflect a substantial contribution of the unobserved reactions. The most probable reactions which are missed in this experiment may be the (α, $2p$), (α, $2pn$), (α, $\alpha\gamma$) and (α, αp) reactions. The threshold of the (α, $2p$) reaction is lower than that of the (α, pn) reaction by about 5.8 MeV, thus the (α, $2p$) reaction may be quite important despite of the Coulomb barrier of proton emission. The (α, αp) reaction may compete favourably with the (α, αn) reaction and contribute substantially to the total reaction cross section, when the enhancement of proton emission and the large ratio of $\sigma(\alpha, \alpha pn)/\sigma(\alpha, \alpha 2n)$ in this study are considered. A rather large value of r_0 has been obtained in other cases in this mass region; 1.7×10^{-13} cm for Mn^{55} and Ni^{58}, 1.6×10^{-13} cm for Zn^{64}.[4),10),14)]

Recently, the total reaction cross section for alpha-particles in the energy range 10–50 MeV has been calculated by Igo[15)] in terms of the optical model using the nuclear potential (exponential at the nuclear surface) derived from the analysis of elastic scattering data. It is interesting to cite that the low energy part of the sum of the observed cross sections in this experiment is found to give a reliable fit to the total reaction cross section predicted from the optical model calculation.

Authors's thanks are due to Prof. I. Nonaka and the other members of staff of Low Energy Division in this Institute for their interest and encouragement. We are grateful to Prof. J. M. Miller and Dr. F. S. Houck (Columbia University and Brookhaven National Laboratory) for making their results available to us prior to publication. The help of Messrs. T. Karasawa, A. Suzuki, H. Ogawa, H. Adachi, Y. Miyazawa and T. Yamada in operating the cyclotron is also gratefully acknowledged.

Appendix

Counting and Calibration Procedures

Ni^{57}—The decay of Ni^{57} was followed by a GM counter. The annihilation radiation and the characteristic γ-rays from Ni^{57} were also measured, and these were served for the calculation of relative yields. After Ni^{57} had decayed to Co^{57}, the disintegration rate and the relative yields of Co^{57} were measured by a well-type NaI scintillation counter. The $4\pi\beta$-counting and the measurement of the coincident annihilation radiation (see Co^{56}) of Ni^{57} were also served for the calculation of disintegration rate, and the consistency between the values from these two methods and the value from the measurement as Co^{57} was very good. The relative yields were consistent (within 5%) with each other in several counting procedures.

Ni^{56}—After Ni^{56} was allowed to decay to Co^{56}, the disintegration rate was measured as Co^{56}.

Co^{57}—The 122 and 137 keV γ-ray photopeaks were measured in a well-type NaI scintillation counter. The measurement was performed at about a year after the bombardment in order to reduce the contribution of Co^{56} and Co^{58} from the (α, pn) reactions on Fe^{54} and Fe^{56}. The counting efficiency was taken as 0.85. (see ref. 10)

Co^{56}—The relative yields were obtained by measuring the γ-rays above 1.5 MeV with an NaI scintillation counter. The determination of disintegration rate is as follows. The two 0.51 MeV γ-rays from positron annihilation were detected in coincidence by two NaI scintillation counters positioned 180° from one another with respect to the source. The disintegration rate was obtained by applying the counting efficiency calibrated with an Na^{22} standard source. The absolute activity of the Na^{22} standard source had been determined by a (annihilation γ-1.28 MeVγ) coincidence counting and a $4\pi\beta$-counting within an error of 5%. The Co^{56} was also measured with a calibrated GM counter and a $4\pi\beta$-counter, and the disintegration rates from these two methods were consistent with that from the measurement of the coincident annihilation radiation within 5%. The disintegration rate was also cross-checked by applying the photopeak efficiency to the counting rate of γ-ray measurement. The disintegration rate from the γ-ray measurement is about 28% smaller than that from the measurement of the coincident annihilation radiation. This deviation may be due to the difficulty of estimating the photopeak in the γ-ray spectrum and to the fact that the calculated photopeak efficiency is not correctly applicable to this experiment. The plotted cross sections for the (α, pn) and $(\alpha, 2n)$ reactions are based on the measurement of the coincident annihilation radiation.

Co^{55}—The relative yields were obtained by analyzing the decay curves of the γ-rays above 1.1 MeV. The decay was also followed by the GM counter whose efficiency had been calibrated with various β-emitters of known disintegration rates, and this was served for the calculation of the disintegration rate of Co^{55}.

Fe^{53}—Immediately after the bombardment, without chemical separation, the decay was followed by measuring the coincident annihilation radiation and the disintegration rate was obtained as in the case of Co^{56}.

Fe^{52}—The 165 keV γ-ray photopeak was measured with a well-type NaI crystal. The photopeak efficiency was estimated as 0.80.

Mn^{52g}—The decay was followed with a calibrated GM counter, and a $4\pi\beta$-counting was also performed. The disintegration rates from these two procedures agreed to within 10%.

Mn^{52m}—Immediately after the bombardment, without chemical separation, the decay of the 1.43 MeV γ-ray photopeak was followed with an NaI scintillation counter. The disintegration rate was obtained by applying the photopeak efficiency to the counting rate.

Gamma-rays from the 7.56 MeV Level in O^{15}

By Tatsuo Tabata* and Kotoyuki Okano

Department of Physics, Faculty of Science, Kyoto University

(Received May 12, 1960)

The gamma-rays from the $N^{14}(p, \gamma)O^{15}$ reaction at the $E_p=278$ kev resonance, corresponding to the 7.56 MeV level in O^{15}, were studied with a large crystal scintillation spectrometer. The direct ground state transition gamma-ray of about 3% in intensity of the total decay was found to exist in addition to the three known cascade lines. Angular distributions of these gamma-rays are all isotropic, supporting the $J\pi=\frac{1}{2}+$ assignment to the resonance state. The transition strength (radiation width in units of Weisskopf single particle width) of the direct ground state transition $E1$ gamma-ray is calculated to be $|M|^2=4.15\times10^{-6}$, which is by a factor of 10^{-4} smaller than the normal $E1$ transition strength found in light nuclei. Other transitions in O^{15} are estimated to be of normal strength compared with Wilkinson's estimation.

§ 1. Introduction

The gamma-rays from the $N^{14}(p, \gamma)O^{15}$ reaction at the 278 kev resonance were first studied by Johnson, Robinson and Moak, who found three cascade lines decaying through the levels in O^{15} at about 6.82, 6.18 and 5.23 MeV.[1] Bashkin, Carlson and Nelson studied the high energy gamma-rays with a three crystal scintillation spectrometer, and assigned $J=\frac{5}{2}\pm$ for the resonance state on the basis of the small 0°−90° difference in the ratio of the 6.1 MeV to the 5.2 MeV gamma-ray and also of the absence (<5% of the 6.10 MeV line) of a direct ground state transition gamma-ray.[2]** Overley, Pixley and Whaling, on the other hand, assigned spin and parity $\frac{1}{2}+$ for the resonance state from their elastic scattering measurement of protons.[3] If the $J=\frac{1}{2}+$assignment is correct, the direct ground state transition must be of $E1$ character, with the consequent result that this $E1$ transition is abnormally inhibited compared with the Weisskopf single particle transition rate, and also even with the Wilkinson's estimation for the normal $E1$ transition rate in light nuclei.[4],[5] This point was further investigated in the present work.

§ 2. Experimental Method

Titanium nitride powder, formed by heating and grinding titanium grains in an atmosphere of natural nitrogen,*** was pressed onto a copper backing, and was bombarded with a proton beam up to 100 μA from a Cockcroft-Walton generator. Gamma-rays were detected with a NaI(Tl) crystal, 5 in. in diameter by 4 in. thick, and a 100-channel or a 10-channel pulse height analyzer. The latter was used for gamma-ray energy measurements because of its superior linearity. Energy calibration was carried out by using the radioisotopes, ThC″(2.615 MeV), Sb^{124}(2.088, 1.692 MeV), Na^{22} (1.277, 0.511 MeV), Sc^{46}(1.119, 0.885 MeV), and Cs^{137}(0.662 MeV). Gamma-ray spectra and angular distributions were measured at 0° and 90° directions to the proton beam, with the front face of the crystal usually 150 mm apart from the target. For the purpose of examining the contribution of the sum peak to the 7.56 MeV ground state transition line, various source to crystal distances were employed, as will be mentioned below. Other details of the apparatus and the method of analysis are nearly the same as were described in previous publications.[6],[7]

§ 3. Results and Discussions

Fig. 1 shows the scintillation spectra measured at 0° and 90° directions to the proton beam. Six gamma-rays belonging to the three cascade lines through the levels at 6.80, 6.16 and 5.18 MeV were apparently observed, with the relative branching ratios of (22.3±1.6)%, (57.5±4.0)% and (17.2±1.2)% of the total decay, respectively. In addition, a small peak at the highest energy can be attributed to the direct ground state transition 7.56 MeV gamma-ray, although at the distance of 150 mm between the front face of the crystal and the source as in the case of Fig. 1, about one third of this peak is attributable to the coincident detection of cascade lines.

* Present address: Radiation Center of Osaka Prefecture.

** Recently S. Bashkin reported that his latest results showed isotropy,[8] superseding the earlier report of anisotropy.

*** The TiN target was kindly prepared by Prof. T. Nishi of Engineering Research Institute, Kyoto University.

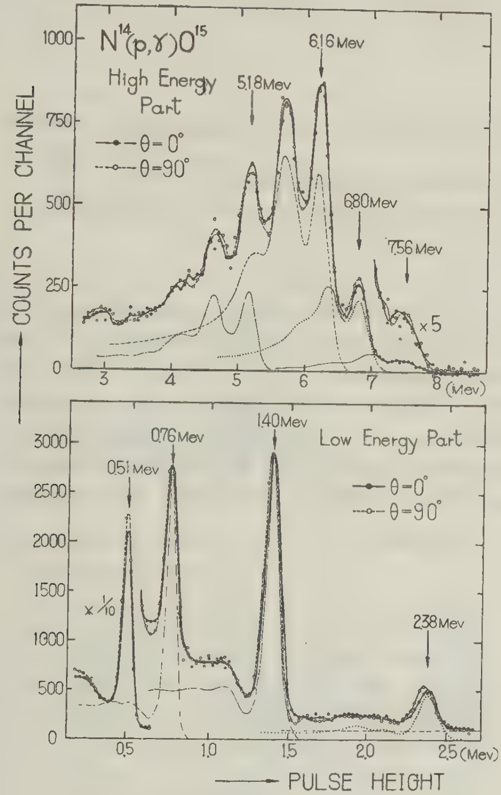

Fig. 1. Scintillation spectra of gamma-rays from the $N^{14}(p,\gamma)O^{15}$ reaction at the 278 kev resonance, taken at zero and 90-degrees to the proton beam. The dotted curves show the decomposed spectra.

To establish the existence of this weak 7.56 MeV gamma-ray, the highest energy part of the spectra was measured at various source to crystal distances between 15 and 280 mm, and the relative counts of the 7.56 MeV peak are plotted as a function of sum peak efficiency in Fig. 2. Least squares fit to the straight line of these points yields (3.03±0.19)% of the total decay as the intensity of the 7.56 MeV gamma-ray. Sum peak contributions in each of these spectra were estimated by using the photopeak efficiencies of the 2.38, 1.40 and 0.76 MeV gamma-rays, taking into account the effect due to the angular correlations of the cascade lines, which were measured recently by Povh and Hebbard.[8] The net relative intensities of the 7.56 MeV gamma-ray thus obtained at each distance are also shown in Fig. 2 (open circles), yieldig (3.03±0.15)% as a mean value, in good agreement with the value cited above. This 7.56 MeV line was checked to be resonant at 278 kev.

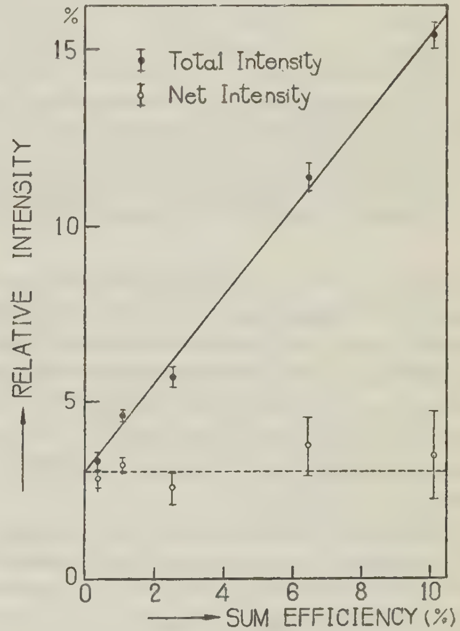

Fig. 2. The relative intensity of the 7.56 MeV peak as a function of sum peak efficiency. The dots represent the total intensity of the 7.56 MeV peak and the circles are the net intensity of the 7.56 MeV gamma-ray after subtracting the sum peak contributions.

Precise energy measurements were carried out for the low energy, primary transitions using the calibration lines already mentioned. Although doublet levels are known to exist in O^{15} at 5.2 MeV (doublet of 5.18 and 5.24 MeV)[9),10)] and 6.8 MeV (doublet of 6.79 and 6.86 MeV),[11)] the inspection of the observed spectral line-shape indicated that the transitions occur mainly to only one member of the doublet. Then, from the measured gamma-ray energies (see Table I), the excitation energies of the feeding levels were estimated as 6.797±0.009, 6.163±0.011 and 5.177±0.016 MeV, using the Q-value of 7.300±0.004 MeV

of the $N^{14}(p, \gamma)O^{15}$ reaction[12] and the resonance energy of 278.1±0.4 kev.[12] These excitation energies agree well with those found by other methods within the experimental error, and clearly show that the lower members of the doublets are populated, in agreement with the results of Povh and Hebbard recently reported.

The angular distribution of each gamma-ray component was measured at 0° and 90° relative to the proton beam, which resulted in a complete isotropy, as can be seen in Fig. 1. This eliminates the possibility of $J=\frac{5}{2}\pm$ for the resonance state and supports the $J=\frac{1}{2}+$assignment from the proton elastic scattering experiments,[3] although other assignments such as $\frac{1}{2}-$ or $\frac{3}{2}\pm$ cannot be excluded only on the grounds of the isotropy of capture radiations. This $J=\frac{1}{2}+$assignment to the 7.56 MeV level fixes the character of the weak 7.56 MeV transition as *E*1.

The measured gamma-ray energies, relative intensities and anisotropies are summarized in Table I, together with the assigned transitions and multipolarities and the calculated transition strength $|M|^2$, about which we shall discuss below.

Wilkinson has examined some 70 radiative transitions in light nuclei ($A\leq 20$),[5] and found that the allowed *E*1 transitions have a transition strength of about $|M|^2=0.032$ Weisskopf units with the spread of about a factor of 7 either way. Here transition strength $|M|^2=\Gamma_\gamma/\Gamma_w$ is a radiation width measured in units of Weisskopf single particle width. In particular, transitions with $|M|^2<10^{-4}$ have all been assigned to be isotopic spin forbidden transitions. By using the radiation width of $\Gamma_\gamma=0.040\pm0.009$ ev for the 278 kev resonance reported by Bashkin *et al.* from the radiation

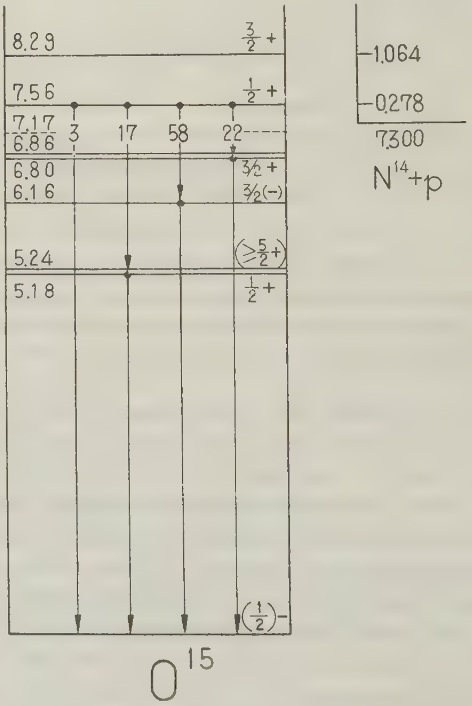

Fig. 3. Level scheme of O^{15} showing the gamma-ray decay of the 7.56 MeV level.

yield measurement,[2] transition strengths of the four primary gamma-rays de-exciting the 7.56 MeV level to the lower levels can be calculated and are listed in Table I. Other known $E1$ transitions in O^{15} are the transitions from the 8.29 MeV $\frac{3}{2}+$ level (corresponding to the 1064 kev resonance) to the ground and 6.16 MeV levels,[13] each having $|M|^2=1.4\times10^{-3}$ and 9.3×10^{-3} respectively. These strengths of $E1$ transitions in O^{15}, which are all of isotopic spin allowed character, are illustrated in the histogram of Fig. 4, together with the other $E1$ transitions compiled by Wilkinson.

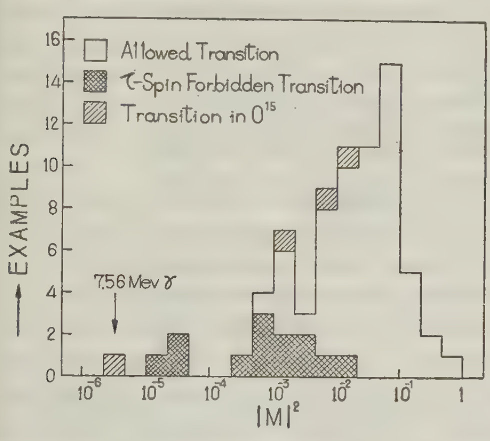

Fig. 4. Distribution of strengths of $E1$ transitions in light nuclei ($A\leq20$).

It is to be added also that the two $M1$ transitions listed in Table I and the 3.05 MeV $M1$ transition from the 8.29 MeV level to the 5.2 MeV level(s) in O^{15}($|M|^2\approx0.55$) all have a normal strength for $M1$ transitions ($|M|^2=0.15$ with the spread of a factor of 20 either way). Only the 7.56 MeV transition is found to have an abnormally small strength compared with all the other known $E1$ transitions in light nuclei, even with the isotopic spin forbidden transitions. This is considered to be due to the very weak fractional parentage overlap of the states concerned, which results in the cancellation of the transition matrix element. Other examples of weak transitions as presented here may also exist, and the distribution of $E1$ or $M1$ transition strengths already known might somewhat have to be modified, since the weak transitions are liable to have escaped detection and are not reported. It would further be necessary to seek for the possible transitions or to set the limits on their strength in order to compare them with model predictions on a firmer basis.

The authors wish to express their gratitude to Prof. K. Kimura, Dr. J. Muto and Dr. S. Yasumi for their encouragements and advices, and to Mr. K. Fukuda for his helpful contributions. This work was supported financially by the Ministry of Education.

(Received May 12, 1960)

The gamma-rays from the $Si^{28}(p,\gamma)P^{29}$ reaction at the $E_p=369$ kev resonance were studied with a large NaI (Tl) crystal scintillation spectrometer. The resonance state, corresponding to the 3.116 ± 0.012 Mev fourth excited state in P^{29}, was found to decay by $(74\pm4)\%$ to the first excited state at 1.384 ± 0.008 Mev and by $(26\pm4)\%$ to the second excited state at 1.961 ± 0.013 Mev which decays predominantly to the ground state.

From the angular distribution measurements of each gamma-ray line, spins and parities of these lower levels in P^{29} were unambiguously assigned as follows: 1.38 Mev(1st), $J=3/2+$; 1.96 Mev(2nd), $J=5/2+$; 3.12 Mev (4th), $J=5/2+$. These assignments are all consistent with the known character of the corresponding levels in the mirror nucleus Si^{29}, and are also in agreement with the theoretical predictions.

From the precise gamma-ray energy measurements, the Q-value of this reaction was estimated as 2.760 ± 0.013 Mev, which is by about 36 kev larger than the published value based on the β-ray end-point energy measurement. The resonance strength $(2J+1)\Gamma_p\Gamma_\gamma/(\Gamma_p+\Gamma_\gamma)$ was found to be $(4.7\pm0.8)\times10^{-3}$ ev.

§ 1. Introduction

The isobaric nuclides Si^{29}–P^{29} are of interest as they possess a single nucleon outside of a closed $d_{5/2}$ sub-shell, and a rather simple theoretical interpretation of their mode of excitation may be possible. Feenberg has applied a weak coupling collective model to the Si^{29}–P^{29} system, assuming the coupling between s and d orbitals through the mediation of surface waves.[1] On the other hand, Bromley, Gove and Litherland have considered the possibility of applying a strong-coupling collective model based on a Nilsson model to explain the level properties of Si^{29}.[2] This model has succeeded in explaining the level sequences of the Mg^{25}–Al^{25} pair, but the extension to the $A=29$ system may not be fully justified on account of decreasing spheroidicity with increasing A in this mass region. Recently Pandya calculated the energy levels and other properties of Si^{29} in some detail, assuming a weak coupling between a single nucleon and the vibrational motion of the core.[3]

The properties of the lower levels in Si^{29} were extensively studied by various reactions, namely, $Si^{28}(d,p)Si^{29}$,[4] $Si^{29}(p,p',\gamma)Si^{29}$ [5] and $Si^{28}(n,\gamma)Si^{29}$,[6] and also by the β-decays of Al^{29} and P^{29}.[5],[7] The low levels of P^{29}, however, have not been so well investigated, but only a study of the $Si^{28}(d,n)P^{29}$ reaction indicated the existence of levels at 1.30 Mev ($l_p=2$), 1.92 Mev ($l_p=2$), 2.5 Mev, 2.9 Mev and 3.5 Mev excitation.[8] Higher excited states in the 4.1–6.4 Mev region in P^{29} ($E_p=1.4$–3.8 Mev) were recently studied through the elastic and inelastic scatterings of protons on Si^{28}, and the spins and parities were assigned.[9] Van Oostrum *et al.* have also established a resonance for the $Si^{28}(p,\gamma)P^{29}$ reaction at 367 ± 2 kev, and the gamma-ray spectra were reported.[10] In the present investigation, more detailed studies of the de-exitation gamma-rays from this reaction were attempted, and some new informations obtained are presented and discussed.

§ 2. Experimental Apparatus

Magnetically analyzed proton beam from a 600 kev Cockcroft-Walton generator was used to bombard a thick metallic silicon target of natural abundance, which was made by grinding pure (99.999%) silicon crystals and pressing onto a 0.5 mm thick copper backing. A rather broad beam spot about 10 mm high and 6 mm wide was used in order to avoid the local melting of the target, and usually a proton beam of about 80μA was safely used.

---

* Present address: Radiation Center of Osaka Prefecture.

Gamma-ray spectra were measured with a large NaI (Tl) crystal, 5 in. in diameter by 4 in. thick, and a Hutchinson-Scarrott type 100-channel or a Johnstone type 10-channel pulse height analyzer. Details of the electronic equipments and the target assembly, together with the method of analysis of gamma-ray spectra, have been described in earlier publications.[11),12)] Special experimental procedures for the present investigation will be described separately in the following sections.

§ 3. Measurements and Results

i) *Gamma-ray Spectra and Decay Scheme*

The excitation curve taken with a thick natural silicon target (Fig. 1) shows resonances for high energy gamma-rays ($E_\gamma > 2.2$ Mev) at about 330 and 415 kev, while for gamma-rays of energies between 0.9 and 2.2 Mev, a sharp step was observed at about 367 kev. These are in complete agreement with the reports for the resonances of the $Si^{29}(p,\gamma)P^{30}$ reaction at 326.4±1.2 and 415.3±1.3 kev, and of the $Si^{28}(p,\gamma)P^{29}$ reaction at 368.9±0.7 kev.[13)] We have measured the gamma-ray spectra above and below the $Si^{28}(p,\gamma)P^{29}$ resonance, namely, at 390±8 kev and at about 340 kev, and the contributions from the $Si^{29}+p$ and the possible contaminant $F^{19}+p$ reactions were subtracted together with various backgrounds. The gamma-ray spectra at the 326 kev resonance of the $Si^{29}(p,\gamma)P^{30}$ reaction have only a weak (5% of the total decay) single 1.45 Mev line in the energy region between 1 and 3 Mev,[14)] which, associated with the small abundance of

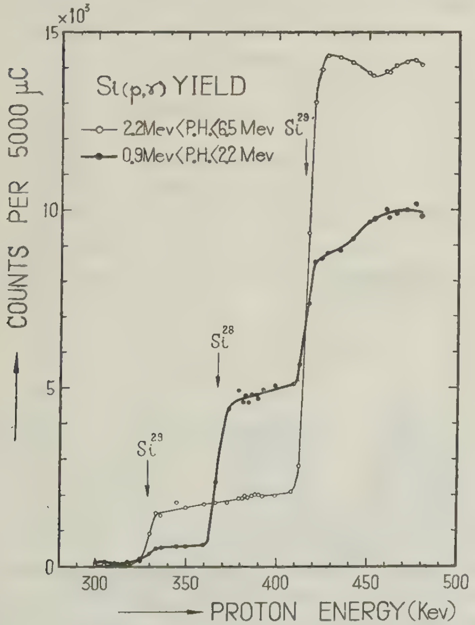

Fig. 1. Gamma-ray yield from proton bombardment of a thick natural silicon target. Slight slopes observed are due to the broad $C^{12}+p$ resonance.

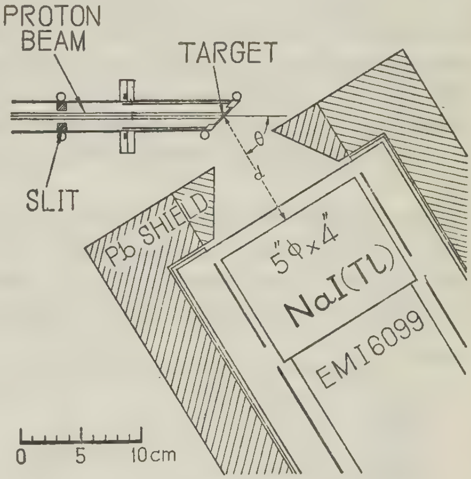

Fig. 2. Target and spectrometer assembly, employed in the measurements at $d=10$ cm. In the case of $d=15$ cm, a cone-shaped lead shield of another type was used.

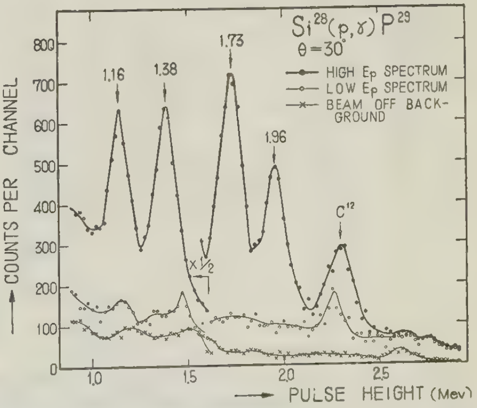

Fig. 3. Gamma-ray spectra taken on the resonance, below the resonance and with no proton beam, at $\theta=30°$ and $d=10$ cm. Background proportion was of nearly the same magnitude in the measurements at $d=15$ cm, on account of increased proton intensity.

Si^{29} (4.68%), made the presence of this lower resonance reaction easily tolerable. At $E_p=390$ kev, 2.30 Mev contaminant gamma-ray from the $C^{12}(p, \gamma)N^{13}$ reaction always appeared. At $E_p=340$ kev, this gamma-ray appeared as 2.25 Mev and much reduced in intensity, so only a part of the low energy side of the peak was subtracted.

Since the radiations from the $Si^{28}(p, \gamma)P^{29}$ reaction were low in energy and weak in intensity, counting rate due to the natural radioactive background was rather appreciable, and a lead shield of cone shape was installed in front of the crystal, as shown in Fig. 2. Examples of the spectra taken on and below the resonance, as well as of the natural background, obtained at θ (direction of the detector to the proton beam) = 30° and at d (distance between the target and the front face of the crystal) = 10 cm, are illustrated in Fig. 3.

The net spectra obtained at $\theta=90°$, 45° and 0°, at $d=15$ cm, with a 100-channel pulse height analyzer, are shown in Fig. 4. Four gamma-rays with energies of 1.96, 1.73, 1.38 and 1.16 Mev were apparently observed, together with the C^{12} contaminant peak. Total spectra were decomposed into these five gamma-rays with the help of the standard line shapes obtained by the interpolation of the line shapes of monochromatic gamma-rays from the $C^{12}(p, \gamma)N^{13}$ reaction (2.37 Mev) and from the radioisotopes Y^{88} (1.85 Mev), Na^{22} (1.28 Mev) and Zn^{65} (1.12 Mev). These standard spectra were taken at $d=10$ and 15 cm respectively, with the standard arrangement, and are shown in Fig. 5 for the case of $d=15$ cm. Each peak in the total spectrum was able to be well fitted to the monochromatic line shape. The relative intensities were calculated using the decomposed spectra and the total detection efficiencies of NaI crystal, tabulated by Wolicki *et al.*, and are listed in Table I. The angular distributions as well as the absorption in the target backing were taken into account.

These relative intensities and the precise determination of gamma-ray energies (see the next section) support the cascade scheme through the 1.38 and 1.96 Mev levels, as had

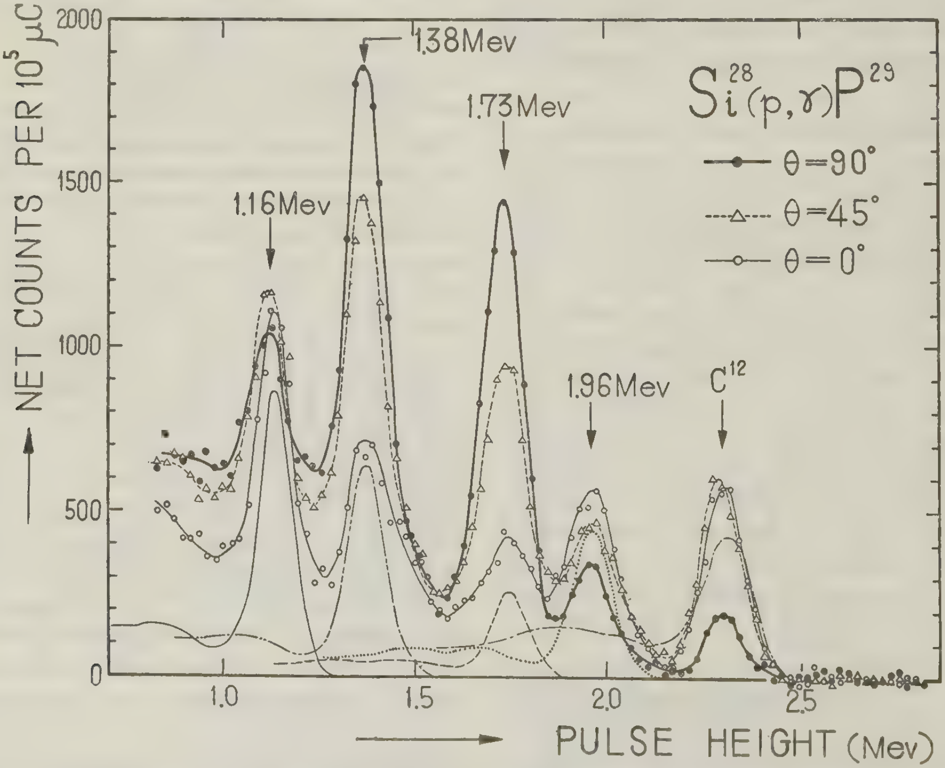

Fig. 4. Scintillation spectra taken at $\theta=90°$, 45° and 0° relative to the proton beam, at $d=15$ cm. Contributions from the lower $Si^{29}+p$ resonance were subtracted. The dotted curves show the individual pulse height spectra into which the zero degree spectrum was decomposed.

been proposed by Van Oostrum *et al.*[10] This was also checked by a coincidence measurement. The branching ratios of these two cascades were calculated to be (74±4)% to (26±4)% from the average of the intensities of cascade lines.

The 3.12 Mev direct ground state transition gamma-ray from the resonance state was estimated to be less than 2.7% of the total decay, after correcting the sum peak contributions due to the coincident detection of cascade lines.

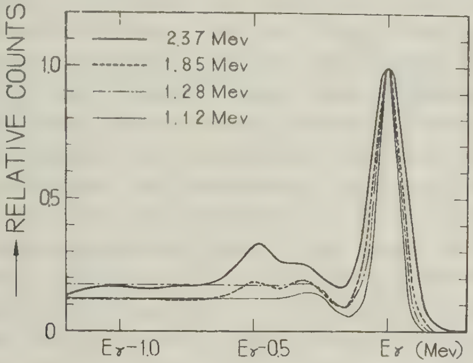

Fig. 5. Line shapes of four monochromatic gamma-rays of energies between 1 and 2.5 Mev, for 5 in. dia.×4 in thick NaI crystal, measured at $d=15$ cm and with no collimation.

Table I. Gamma-rays observed at the 369 kev resonance in the $Si^{28}(p, \gamma)P^{29}$ reaction.

A possible 0.577 Mev gamma-ray as the transition between the 1.96 Mev second and the 1.38 Mev first excited states was not positively observed. An attempt to detect this cascade transition by the coincidence method was unsuccessful because of the very low yield of the gamma-ray and the proximity of the 0.51 Mev annihilation line. Careful examination of the singles spectra indicated the 0.58 Mev cascade line to be at most 15% of the 1.96 Mev direct transition line, if present. This cascade line is expected to be very weak considering the decay mode of the corresponding 2.03 MeV state in Si^{29}, in which case cascade branching ratio of about 1% is reported.[5]

The existence of a level at about 2.5 Mev, known from the $Si^{28}(d, n)P^{29}$ reaction, appears to give rise to a possibility of cascade decays through this level, but from the absence of the 2.5 Mev line in the singles spectra (<2% of the total decay), the cascades through the 2.5 Mev level are believed to be fairly weak if present, considering that the corresponding level in Si^{29} at 2.43 Mev decays directly to the ground state by an appreciable fraction.[7]

The decay scheme obtained is shown in Fig. 6.

ii) *Gamma-ray energies and Q-value*

The gamma-ray energies were precisely

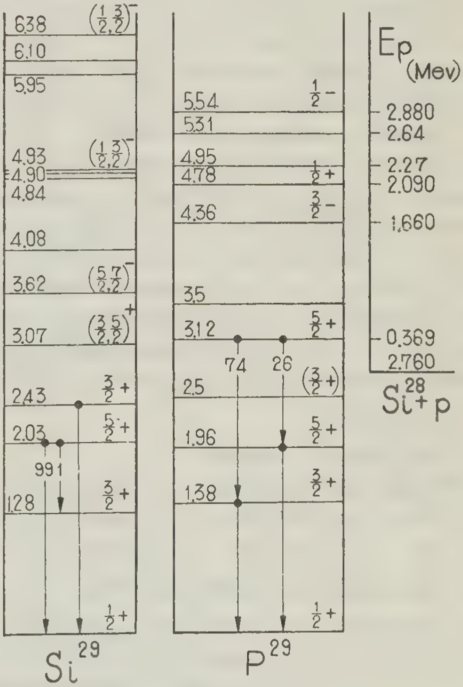

Fig. 6. Level scheme of the mirror pair Si^{29}–P^{29}. The excitation energies of the lower levels in P^{29} were computed from our gamma-ray energies. Higher level energies were calculated from the resonance energies using the measured Q-value of 2.760 Mev. The spin assignements of the lower levels in P^{29} are discussed in the text.

determined using a 10-channel pulse height analyzer. Overall linearity of the measuring system was better than 1% and care was taken to reduce the counting rate so as no shift of the peak to occur. Energy calibration was carried out before and after each run of experiments with the gamma-rays from the following radioisotopes; ThC″ (2.615 Mev), Sb^{124} (2.088, 1.692 Mev), Y^{88} (1.851 Mev), Co^{60} (1.332, 1.172 Mev), Na^{22} (1.277 Mev), Zn^{65} (1.119 Mev). Several measurements were performed at $\theta=0°$ for the 1.96 and 1.16 Mev lines as well as at $\theta=90°$ for the 1.73 and 1.38 Mev lines. The results obtained are cited in Table I. From these gamma-ray energies the excitation energies of the first, second and fourth excited states were determined to be 1.384±0.008, 1.961±0.013 and 3.116±0.012 Mev, respectively. These values are approximately in agreement with the results of the $Si^{28}(d, n)P^{29}$ reaction, yielding levels at 1.30, 1.92 and 2.9 Mev.[8] An alternative order of the cascade gamma-rays would yield levels at 1.16 and 1.73 Mev, which are incompatible with the (d, n) measurements. The Q-value of the $Si^{28}(p, \gamma)P^{29}$ reaction is calculated to be 2.760±0.013 Mev, using the resonance energies of 368.9±0.7 kev, reported by Kuperus, Smulders and Endt.[13]* This Q-value is by about 36 kev larger than the published value, $Q=2.724$ Mev,[15] which was based on the end-point energy measurement of the P^{29} positron decay ($E_{\beta+}(\max)=3.945\pm 0.005$ Mev)[7] and on the Q-value of the $Si^{28}(d, p)Si^{29}$ reaction ($Q=6.246\pm0.010$ Mev).[16] This discrepancy may be due to some instrumental error in the measurement of the positron end-point energy.

iii) *Angular distributions*

The angular distributions of four gamma-ray lines were measured at $\theta=0°$, 15°, 30°, 45°, 60°, 75° and 90° with respect to the proton beam. The earlier experiments were performed at the closer distance of $d=10$ cm between the counter and the target to reduce the natural background counts, but the distance was increased to 15 cm in the later measurements to reduce the attenuation effect of the finite solid angle of the detector on the coefficients of $P_4(\cos\theta)$ term. This was essentially necessary to establish the spin of the 1.96 Mev level. The distance between the counter and the target was held constant within one millimeter at each angular setting. The radiation yield was monitored by an integrated proton current, since the intensity of the contaminant 2.3 Mev gamma-ray varied considerably with time. Several data taken at each angle were checked to be consistent with each other and were decomposed into five component gamma-rays as described in section i). After correcting the absorption in the target and target backing, angular distributions were fitted into the formula $W'(\theta)=1+G_2A_2P_2(\cos\theta)+G_4A_4P_4(\cos\theta)$ by the method of least squares. The attenuation factors due to the finite solid angle of the counter were taken from the curves calculated by Gove and Rutledge.[17] The data obtained at $d=10$ cm and at $d=15$ cm were separately analyzed, and the resultant A_2 and A_4 coefficients are tabulated in Table II, to-

Table II. Angular distribution coefficients and their standard deviations obtained by the least squares fit of the data taken at $d=10$ cm as well as at $d=15$ cm, to an expansion of the form, $W'(\theta)=1+G_2A_2P_2(\cos\theta)+G_4A_4P_4(\cos\theta)$. The adopted values for the attenuation factors G_2 and G_4 are also listed.

---

* *Note added in proof*:—From this Q-value, the mass of P^{29} is calculated to be 28.990980±17 a.m.u., using the mass excess of −13.223±0.009 Mev for Si^{28}. This is in excellent agreement with the recent results of Hinds and Middleton obtained by the magnetic analyses of the $Si^{28}(He^3, d)P^{29}$ reaction products, yielding the mass of P^{29} as 28.990978±16 a.m.u. They also locate the first and second excited states in P^{29} at 1.368±0.010 Mev and 1.960±0.010 Mev, respectively. [S. Hinds and R. Middleton: Proc. Phys. Soc. **75** (1960) 444].

gether with the adopted attenuation factors, G_2 and G_4. The errors quoted in Table II are to be understood as standard errors and are mainly of statistical origin. In Figs. 7 and 10, the angular distributions measured at $d=15$ cm are shown as a function of $\cos^2\theta$, together with the least squares fitted curves.

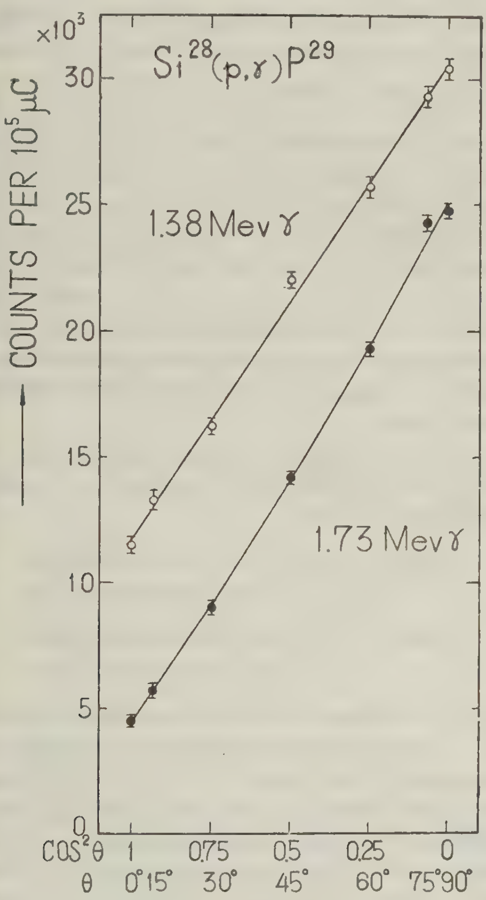

Fig. 7. Angular distributions of the 1.73−1.38 Mev cascade lines measured at $d=15$ cm. The solid lines represent the least squares fitted curves, $A_0(1-0.785\,P_2+0.036\,P_4)$ for the 1.73 Mev line and $A_0(1-0.518P_2)$ for the 1.38 Mev line.

As the angular distributions of the 1.73 Mev–1.38 Mev cascade lines, we have adopted the mean values of the two data, i.e.

$$1.73\text{ Mev}: \quad W(\theta)=1-(0.84_3\pm0.02)P_2(\cos\theta) + (0.04_4\pm0.02)P_4(\cos\theta) \,,$$

$$1.38\text{ Mev}: \quad W(\theta)=1-(0.56_2\pm0.02)P_2(\cos\theta) - (0.02_4\pm0.02)P_4(\cos\theta) \,.$$

From these angular distributions we can deduce spins and parities of the levels concerned. Since the ground state of Si^{28} is $J=0+$, the resonance state formed is expected to be $J_1=1/2+$ for *s*-wave capture, $J_1=1/2-$ or $3/2-$ for *p*-wave capture, and $J_1=3/2+$ or $5/2+$ for *d*-wave capture. Higher wave capture is highly improbable as will be discussed in the next section. Then the resonance state at 3.12 Mev must be either $J_1=3/2\pm$ or $5/2+$, since the obvious anisotropies observed eliminate the case of $J_1=1/2\pm$. On the other hand, the first excited state at 1.38 Mev has been assigned as either $J_2=3/2+$ or $5/2+$ on the basis of the $l_p=2$ stripping pattern from the $Si^{28}(d, n)P^{29}$ reaction. These informations propose four possible cases of $3/2(DQ)3/2$, $3/2(DQ)5/2$, $5/2(DQ)3/2$ and $5/2(DQ)5/2$ as the spin sequence involving the 1.73 Mev transition. Calculated A_2 coefficients for

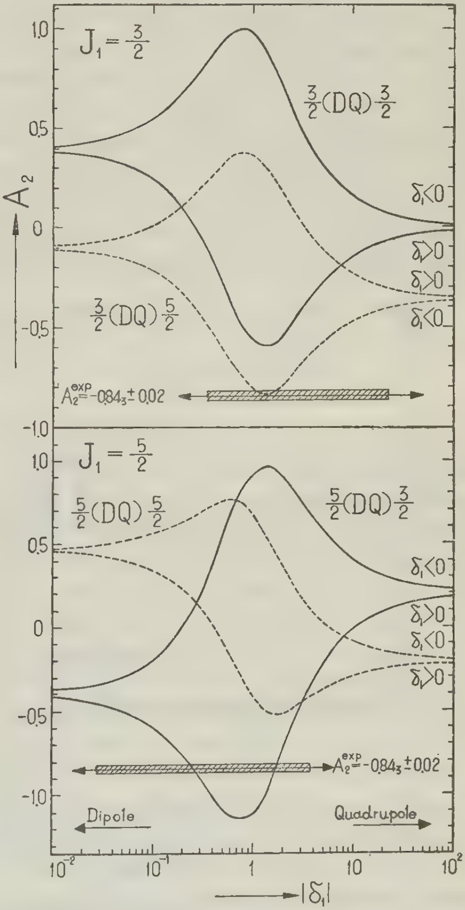

Fig. 8. Theoretical A_2-coefficients, calculated as a function of dipole-quadrupole mixing ratio δ_1, for the first gamma-ray de-exciting a resonance state with spin $J_1=3/2$ (upper figure) or $5/2$ (lower figure) to the state with $J_2=3/2$ (solid curve) or $5/2$ (dotted curve).

these cases are illustrated in Fig. 8, as a function of mixing ratio δ_1. Here Huby phase correction[18] which affects the sign of mixing ratio has been taken into account. As is clearly seen, experimental A_2 coefficient of the 1.73 Mev gamma-ray cannot be fitted with the sequence 3/2(*DQ*)3/2 or 5/2(*DQ*)5/2. A slight possibility exists for the 3/2(*DQ*)5/2 sequence with the mixing ratio $-1.52<\delta_1<-1.02$. In the case of 5/2(*DQ*)3/2, experimental A_2-coefficient can be fitted to the theoretical one with either $\delta_1=0.251\pm0.014$ or $\delta_1=1.69\pm0.05$. These mixing ratios yield the coefficient of $P_4(\cos\theta)$ term as $A_4=0.039\pm 0.004$ or 0.483 ± 0.008 respectively, which, compared with the experimental value of $A_4{}^{\text{exp}}=0.04_4\pm0.02$, eliminates the larger value of δ_1.

In order to distinguish between the two spin sequences 3/2(*DQ*)5/2(*QO*)1/2 and 5/2(*DQ*)·3/2(*DQ*)1/2, which were not uniquely selected by the above considerations, the measured A_2-coefficient of the 1.38 Mev second gamma-ray is also compared with the calculated value in Fig. 9, with the mixing ratio δ_2 as a parameter. Here use was made of the mixing ratio of the first gamma-ray determined above, and the known character of $J=1/2+$ for the ground state of P^{29}. Obviously only in the case of the sequence 5/2(*DQ*)3/2·(*DQ*)1/2 the measured distribution can be fitted to the calculated one with either $\delta_2=-0.167\pm0.021$ or $\delta_2=-1.215\pm0.051$, although unique choice between these two solutions cannot be made from our present informations. Thus the resonance state at 3.12 Mev was found to have $J=5/2+$ due to *d*-wave capture and to decay by a transition of predominatly *M*1 character with (6.3±0.8)% *E*2 admixture to the first excited state at 1.38 Mev, which was together determined to be $J=3/2+$ and to decay to the $J=1/2+$ ground state by a transition involving either (3.0±0.6)% or (146±10)% *E*2 mixture to *M*1 component. Here we have used the angular distribution $W(\theta)=1-(0.570\pm0.015)P_2(\cos\theta)$ for the 1.38 Mev second transition, excluding the $P_4(\cos\theta)$ term on account of the $J=3/2$ nature of the initial level.

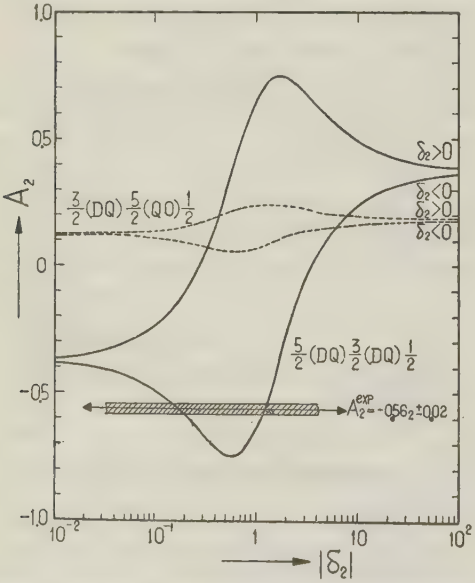

Fig. 9. Theoretical A_2-coefficients, calculated as a function of multiple mixing ratio δ_2, for the second gamma-ray of the spin sequence 5/2(*DQ*)3/2(*DQ*)1/2 (solid curve) or 3/2(*DQ*)·5/2(*QO*)1/2 (dotted curve), involving the cascade from the resonance to the ground state through the first excited state.

Next we consider angular distributions of the 1.16 Mev–1.96 Mev cascade lines which were found to be,

$$1.16\text{ Mev}:\quad W(\theta)=1+(0.31_9\pm0.04)P_2(\cos\theta)+(0.01_9\pm0.05)P_4(\cos\theta)\,,$$

$$1.96\text{ Mev}:\quad W(\theta)=1+(0.26_6\pm0.03)P_2(\cos\theta)+(0.11_2\pm0.04)P_4(\cos\theta)\,,$$

after averaging the two data cited in Table II. The intermediate state at 1.96 Mev is expected to be either $J=3/2+$ or $5/2+$ from the $l_p=2$ pattern in the $\text{Si}^{28}(d,n)\text{P}^{29}$ stripping reaction.[8] Of these two assignments, $J=3/2+$ may at first seem to be preferable since the level decays directly to the ground state. The corresponding level in Si^{29} at 2.03 Mev, however, has been assigned as $J=5/2+$ from the angular distribution measurements of gamma-rays following the inelastic scattering of protons on Si^{29}.[5] Theoretical predictions also support this assignment. On the other hand, our experimental A_2-coefficients indicate that if the $J=5/2+$ assignment is correct, the 1.96 Mev second gamma-ray must be an *E*2-*M*3 mixture, with the mixing ratio $\delta_2=-0.23\pm 0.09$ or -1.58 ± 0.28, although alternative 3/2+ assignment requires only several percents of *E*2 mixture to *M*1 for both the first and second gamma-rays. To clarify these situations definitely, the existence of $P_4(\cos\theta)$ term in the distribution of the 1.96 Mev line was carefully checked with improved geometry. The results showed evidently the existence of $P_4(\cos\theta)$ term, as illustrated in Fig. 10, which eliminates the case of $J=3/2+$ and establishes the $J=5/2+$ assignment for the 1.96 Mev level. Then the 1.16 Mev first transition is calculated to include $\left(1.4_5\,{}^{-0.7}_{+0.9}\right)\%$ $E2$ component to $M1$, while the 1.96 Mev direct ground state transition must involve $\left(5{\cdot}2^{-2.8}_{+5.0}\right)\%$ $M3$ component to $E2$, as noted above. With these assignments, the A_4-coefficients for the 1.16 and 1.96 Mev gamma-rays are calculated to be -0.005 ± 0.003 and 0.144 ± 0.017 respectively, in agreement with the experimental values, $0.01_9\pm0.05$ and 0.11_2 ±0.04.

iv) *Resonance Strength*

From the absolute thick target yield of gamma-radiations, the resonance strength $\omega\gamma=(2J_1+1)\Gamma_p\Gamma_\gamma/(\Gamma_p+\Gamma_\gamma)$ was calculated to be $(4.7_2\pm0.8)\times10^{-3}$ ev, or $\gamma=(0.78_6\pm0.13)\times10^{-3}$ ev, using the calculated efficiencies of NaI crystal and the mean intensities of cascade lines. The proton width Γ_p of this resonance is then 0.79×10^{-3} ev or larger, and the reduced proton width in units of sum rule limit, *i.e.* $\gamma_p^2/(\hbar^2/\mu R^2)$ is calculated to be 2.1×10^{-2} or larger for *d*-wave capture, using a nuclear radius of $1.5A^{1/3}\times10^{-13}$ cm. If we assume *f*-wave capture, the corresponding figure is computed to be 110×10^{-2}, which safely eliminates the assignment of *f*- or higher wave capture to this resonance. The value 2.1×10^{-2} for *d*-wave capture is consistent with the general trend of the dimensionless reduced proton widths in nuclei with $22<A<35$,19) but was found to be by about a factor of ten larger than the value calculated for the 3.07 Mev mirror level in Si^{29}, using the (d,p) stripping reaction cross sections.20)

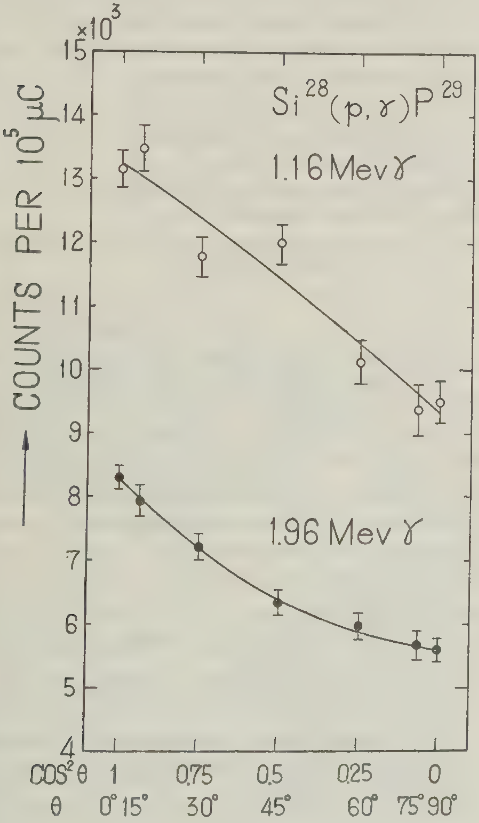

Fig. 10. Angular distributions of the 1.16-1.96 Mev cascade lines measured at $d=15$ cm. The solid lines represent the least squares fitted curves, $A_0(1+0.248P_2-0.011P_4)$ for the 1.16 Mev line and $A_0(1+0.252P_2+0.081P_4)$ for the 1.96 Mev line.

On the other hand, the radiative width of the 3.12 Mev state expressed in units of single particle width is calculated as $|M|^2\geqslant6.2\times10^{-3}$, the lower limit being by a factor of four smaller than the mean value, $|M|^2_{\text{ave.}}\approx25\times10^{-3}$, found for $M1$ transitions in nuclei in the region $22<A<35$. But it is not sure which of Γ_p or Γ_γ limits the resonance strength in the present case.

§ 4. Discussion

The results obtained in the present investigation well establish the mirror properties of the low levels in Si^{29} and P^{29}. $J=3/2+$ assignment to the 1.38 Mev level in P^{29} is in accord with that to the 1.28 Mev level in Si^{29}, which is considered to be mainly of a $d_{3/2}$ single-particle nature. $J=5/2+$ character of the 1.96 Mev level in P^{29} also agrees with that of the 2.03 Mev level in Si^{29}, as discussed already in the previous section, and the strong $E2$ decay of this level to the ground state was observed in both nuclides. The 3.07 Mev level in Si^{29} has been assigned to be either $J=3/2+$ or $5/2+$ from the $l_p=2$ pattern of the $Si^{28}(d,p)Si^{29}$ stripping reaction products, which is consistent with our $J=5/2+$ assignment to the corresponding 3.12 Mev level in P^{29}.

The strong *p*-wave resonances in P^{29} established at $E_p=1.66$ and 2.88 Mev9) ($E_x=4.36$ and 5.54 Mev) seem to have a single-particle nature and to correspond to the 4.93 and 6.38

Mev levels in Si^{29} which have been assigned to be single-particle $p_{3/2}$ and $p_{1/2}$ states. Then, it should be noted that an f-wave resonance, corresponding to the 3.62 Mev level in Si^{29}, which is known to be either $J=5/2-$ or $7/2-$ from the $Si^{28}(d, p)Si^{29}$ reaction and is presumably a single-particle $f_{7/2}$ state, still remains to be found at $E_p=700\sim900$ kev region.[21] The 3.5 Mev level found by the (d, n) measurements might be of this character.

Bromely *et al.* have applied a strong coupling collective model to the description of the low levels of Si^{29}, and assigned 0, 2.43 and 2.03 Mev levels as a $K=1/2$ rotational band based on the 1/2+ ground state ($2s_{1/2}$ Nilsson orbit) and the levels at 1.28 and 3.07 Mev as a $K=3/2$ band based on the 3/2+ 1.28 Mev level ($1d_{3/2}$, $K=3/2$ orbit), assuming a negative spheroidicity with $\delta=-0.15$.[2] Recently Pandya has calculated the energy levels of Si^{29} assuming a weakly coupled system of the collective vibrational motion of the spherical core with the $2s_{1/2}$ and $1d_{3/2}$ single-particle orbitals.[3] Both models predict $J=5/2+$ for the 3.07 Mev level, as was experimentally confirmed for the corresponding 3.12 Mev level of P^{29} in the present investigation. Other spin values found in P^{29} are also consistent with these pictures, and application of the collective description to this mirror pair seems to be appropriate, although detailed structure of the model must further be checked and improved. In particular, it seems still doubtful in the present stage whether the Si^{29} and P^{29} are really deformed or not.

Strong $E2$ enhancement compared to $M1$ observed in the decay of the 1.96 Mev level seems to indicate collective effects, and the weakness of the 3.12 Mev $E2$ direct ground state transition from the resonance state may be due to the different K-values of the states concerned. The relatively strong $M1$ component to $E2$ ($\Gamma_{M1}/\Gamma_{E2}=35.5$ or 0.68) observed in the decay of the 1.38 Mev $d_{3/2}$ level indicates the existence of mixing of s-d orbitals in these levels, as was suggested to explain the magnetic moment of Si^{29} and the ft-value of P^{29} positron decay. The transition rate observed in this experiment would further serve to check the model if explicit numerical calculations are performed.

We would like to thank Prof. K. Kimura and Dr. S. Yasumi for their supports, encouragements and advices throughout the course of this work. We also wish to thank Dr. H. Ikegami of the Institute for Nuclear Study, University of Tokyo, and Dr. M. Kawamura and Dr. A. Aoki of Kyoto Prefectural University for their kind supports. This work was financially aided by the Ministry of Education.

Note added in proof:—We were informed recently that Van Oostrum and Olness *et al.* have also investigated the gamma-rays from the $Si^{28}(p, \gamma)P^{29}$ reaction in some detail. Their results are consistent with those presented here. [K. J. Van Oostrum: Thesis (Delft) (1959) unpublished. J. W. Olness and J. L. Parker: Bull. Amer. Phys. Soc. **5** (1960) 56.]

On the Electronic Component of Extensive Air Showers near the Axis

By Tadashi Kameda, Yoshio Toyoda and Toshio Maeda
Department of Physics, Kobe University, Japan

(Received February 9, 1960)

Using two multiplate cloud chambers and five density detectors consisting of 250 G.M.-counter hodoscopes, characters of the electronic component of extensive air showers were investigated for various distances from the axis in the range $r \leq 10$ m at 2770 m altitude. The size N of the selected showers extended from 1×10^5 to 2×10^6.

The following results were obtained :

(1) The integral size spectrum can be represented by a power law of the form $N^{-\gamma}$, where the value of γ varies from 1.5 to 2.0 as the size increases.

(2) The lateral density distribution of the high-energy electronic component with the energy $E \geqslant 1$ Bev fits well to that of the pure electronic shower with the age parameter $s=1.4$.

(3) The ratio of the density of high-energy electrons and photons to that of all electrons is independent of the atmospheric depth.

(4) The integral energy spectrum can be expressed by the E^{-n} within the energy region 250 Mev $\leqslant E \leqslant 1$ Bev, and the value of n shifts from 0.7 to 1.2 with increasing r.

(5) The lateral distribution of the energy flux carried by the electronic component is expressed by the form $r^{-(1.57\pm0.24)}$.

(6) The showers having steeper lateral distribution of electrons than the average one near the axis contain more high-energy rays.

(7) The averge zenith angle distribution is represented by the form $\cos^{6.7\pm1.4}\theta$, however that of showers containing more high-energy rays by the form $\cos^{10.0\pm2.0}\theta$.

§ 1. Introduction

The experiments on the extensive air showers (EAS) at the mountain altitude have been carried out by many authors from various points of view. Owing to them, we have fairly precise knowledge on the lateral distribution of the electrons and the density distribution of EAS. Moreover, the mean characters of EAS were revealed by these authors for electronic component, penetrating component, and nuclear active component. The studies on the high-energy electrons and photons near the axis of EAS are reported by a few authors[1),2),3)]. However, character of the individual shower from a viewpoint of high-energy electronic component is scarcely studied hitherto.

The comprehensive knowledge on the high-energy electronic component in EAS is of necessity not only to research into the development of the EAS, but also to study the mechanism of the nuclear interaction of ultra high-energy nucleons.

Our experiments were intended to make researches on the high-energy electronic component near the axis in great detail as could be possible, study the character of the individual shower through it, and increase the reference materials on the structure of EAS at the mountain altitude. For this purpose, we especially gave attentions to the followings:

i) The location of shower axis was determined by the method of the maximum electron density, because the determination of axis by the core selector (for example, the type used by Cocconi etc.) was found to be inadequate on account of giving a considerable bias to some EAS.

ii) Two cloud chambers were used to obtain informations as much as possible on the individual shower. Moreover, they were separately located and set up at right angle with each other, giving the accurate zenith angle of EAS.

§ 2. Apparatus

The arrangement of the apparatus is shown in Fig. 1. D_1, D_2, D_3, D_4, and D_5 in the figure are the electron density detectors, each of which contains 20 large counters of 122 cm² sensitive area each, and 30 small counters of 38 cm². The long axes of every counters were directed to south-north direction. All counters are connected to the 250 channel neon-hodoscope separately. The error of the electron density determined by these detectors are within 30% in the range from 50/m² to 600/m², and it increases outside the above range. The density more than 1000/m² is not determined. A and B in the Fig. 1. are the similar rectangular cloud chambers. Each of them has effective area of 0.08 m², and contains 9 lead plates of 1 cm thickness which serve to estimate the energy of electrons and photons. The top of the chamber is made of 2.7 g/cm² thickness of Dulalmin (0.11 r. 1.), and the dead space under the Dulalmin plate is filled up with 2.5 g/cm² thickness of paraffin (0.05 r. 1). Both chambers were placed apart by 3.5 m at their centres, and at right angle each other, as seen in the figure. The cloud chambers and neon-hodoscope are triggered by the master pulses, which are the coincidence pulses of discharges of one or more counters of the specified three large counters in each of the density detectors D_2, D_3, D_4, and D_5, and simultaneous discharge of the specified two large counters in D_1, *i.e.* 6-fold coincidence (Master Pulse I). Most of the measurements were performed by triggering the apparatus by this master pulse, but in some of the measurements, the above mentioned three counters in D_2, D_3, D_4, and D_5 were increased to five, and simultaneously the number of the specified large counters in double coincidence in D_1 was increased to four, (Master Pulse II). The more stringent bias for large density of D_1 is based on the intention that we are concerned in selecting EAS whose axis fall within the square area subtended by D_2, D_3, D_4, and D_5, and in its vicinity. D_1 and both cloud chambers were placed in wooden hut whose roof has 1.5 g/cm² wood and 0.2 g/cm² copper, and D_2, D_3, D_4, and D_5 were placed in wooden boxes which were covered by 0.4 g/cm² wood.

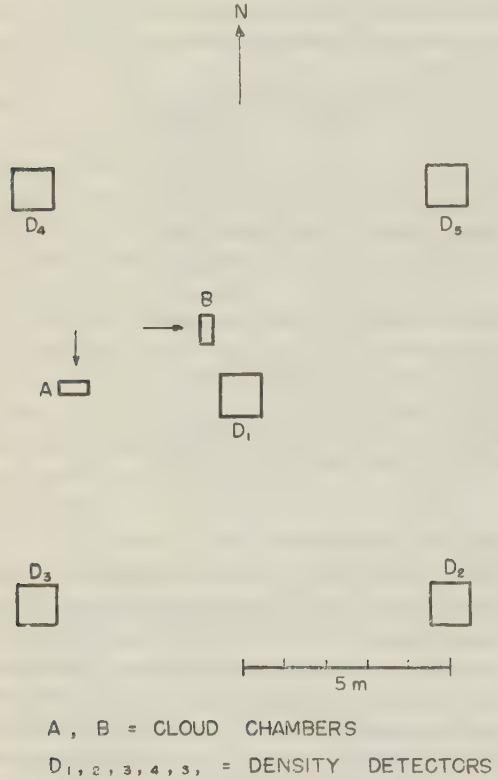

Fig. 1. Arrangement of apparatus.

The experiment was carried out at Mt. Norikura, 2770 m elevation, 741 g/cm² average atmospheric pressure in the measuring period, in 1957.

§ 3. Size Spectrum

The location of the axis and the size of EAS were determined simultaneously by the electron densities at D_1, D_2, D_3, D_4, and D_5*, using the AS computer of the I.N.S. type and assuming the vertical incidence of the electrons**. The following procedures were taken for analysing density data:

i) The densities at every place are tried to fit to the lateral distribution curve of the density, derived from the N-K function[4] of $s=1.25$,[5] taking account of the errors of densities obtained by the density detectors.

ii) If the densities at every place do not fit to the above mentioned curve, the most smoothly fit distribution curve is assumed, and the total number of such EAS is determined by the density at the farthest place, assuming that the density at a great distance should obey the lateral distribution of $s=1.25$.

---

* The number of particles in the top sections of A and B cloud chambers is also referred to the determination of the axis location.

** For the EAS of zenith angle of 45°, the difference of the location of the axis determined by this assumption is 0.8 m in the extreme case, and usually is within 0.5 m.

The error of determination of the location of shower axis is within 1 m in the interior of the square of D_2, D_3, D_4, and D_5, in most of the showers, and outside the area the accuracy decreases gradually in different way, depending on the size of EAS and on the position of axis. The probability of generating the master pulses was calculated numerically for 196 positions (centres of 1 m² area) and for several size, assuming the vertical incidence of EAS and the lateral distribution of $s=1.25$. It is a very tedious work to obtain the accurate triggering probability when the effect of zenith angle distribution of EAS is considered, because the probability depends on the azimuth as much as the zenith angle owing to the parallel arrangement of counters. According to the calculated results on the EAS which is detected by MP (I) and whose axis falls within a square area subtended by D_2, D_3, D_4, and D_5 and at 37° of zenith angle, the triggering probability increases by 6% and 7% for EAS which are incident from east-west direction with $N=5\times10^5$ and 2.5×10^5, respectively, compared with the vertical incident EAS of the same sizes, and decreases by the same amount for EAS from the north-south direction. Taking into account the above mentioned results, and the zenith angle distribution of the form $\cos^7\theta$, our assumption of vertical incidence seems to give a negligible errors in the determination of the triggering probability.

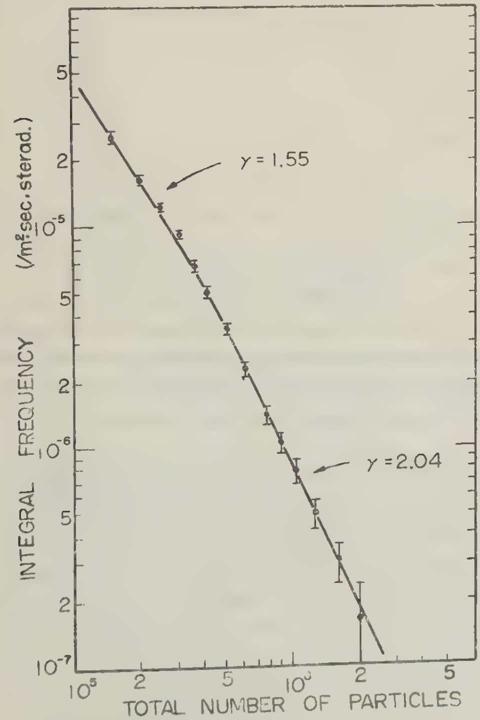

Fig. 2. Integral size spectrum of EAS

The size spectra of EAS were separately obtained in the following four cases; a) EAS detected by MP (I) or MP (II), the axes of which fell inside a 10 m square with D_1 at the centre, and b) EAS detected by the same master pulses in a those in a), the axes of which fell within the area of a 14 m square substracted by a 10 m square, each with D_1 at the centre. As no significant differences are found between them, each results is summarized, and the size spectrum thus obtained is shown in Fig. 2. The ordinate in the figure is the absolute frequencies calculated assuming the zenith angle distribution of $\cos^7\theta$ (§ 5).

Representing the size spectrum by the power law of

$$F(\geqslant N)=a\left(\frac{N}{10^5}\right)^{-\gamma}$$

where N is the total number of the charged particles, a and γ take the following values, respectively,

$$\left.\begin{array}{l}a=4.9\times10^{-5}/\text{m}^2.\ \text{sec. sterad.}\\ \gamma=1.55\pm0.10\end{array}\right\}\ \text{for}\ N\leqslant4\times10^5$$

$$\left.\begin{array}{l}a=8.2\times10^{-5}/\text{m}^2.\ \text{sec. sterad.}\\ \gamma=2.04\pm0.20,\end{array}\right\}\ \text{for}\ N\geqslant4\times10^5$$

where the errors are standard deviations. (Hereafter the errors are shown by standard deviations).

Here it should be noted that the above mentioned size spectrum was obtained assuming that the lateral distribution of all EAS obeyed that of $s=1.25$. In actual the individual shower is divergent in the age, and it is not appropriate to represent the lateral distribution of all showers with an unique one, as seen in the distribution near the axis (§ 4e). However, as it is estimated that the proportion of showers having young age and old one to all showers is about 30%, and the ratio of the showers of young age to those of old age is nearly one, the drastic change may not occur in the size spectrum obtained by us, and so the above mentioned variation of values of γ may occur in actual in the range observed.[2] The similar variation of γ was observed on EAS near the sea level in the same range of size.[6],[7] This fact seems to be connected with the variation of character of nuclear interaction in super high energy region, as pointed out by Russian authors,[8] or with the shortening of the absorption mean free path for nucleons of higher energy.

§ 4. Electronic Component near Shower Axis

Characters of high-energy electronic component were investigated for various distances from the shower axis in the range of $r \leqslant 10$ m. The energy E of electrons and photons was determined from the total number of the track segments of the cascade showers initiated in the lead plates in the cloud chambers. We estimated the shower energy to be 50 Mev per segment for lead plates of 1 cm thickness according to the experimental results of Bender[9] and Hazen[10] and took account of the effective thickness for oblique incidence. This value might be over-estimated if compared with that of Danilova *et. al.*[3] based on the calculation of Ivanenko. We selected the showers whose axes fell within a 12 m square around D_1, in order to keep errors of the distances from the axis to the chambers within about 1 m. The sizes of the selected showers extend from 1 to 15×10^5 and the mean size was $\bar{N} = 4 \times 10^5$.

(a) *Lateral Density Distribution of High-energy Electronic Component*

The lateral density distributions of the high-energy electronic components with $E \geqslant 1$ Bev, $E \geqslant 2$ Bev and $E \geqslant 5$ Bev were investigated by inspecting 1100 photographs of the cloud chambers, making use of the determined sizes and distances from the axis. The high-energy cascade showers originating in the first or the second lead plate were accepted to find the density of high-energy particles. This limitation was taken in order to decrease the chance of confusing the cascade showers from the nucleonic showers originating in the lead plates, and avoid to overestimate the density of high-energy particles in oblique showers. Accordingly, this has such a tendency that the density of high-energy rays is apt to be underestimated in oblique showers, but the effect is small.[1]

To decide the distribution, at first, the data were divided into three groups according to the shower size, $1 \times 10^5 \leqslant N \leqslant 2.7 \times 10^5$ ($\bar{N} = 1.8 \times 10^5$), $2.8 \times 10^5 \leqslant N \leqslant 4.4 \times 10^5$ ($\bar{N} = 3.5 \times 10^5$) and $4.5 \times 10^5 \leqslant N \leqslant 1.5 \times 10^6$ ($\bar{N} = 7.5 \times 10^5$). The distributions of the high-energy electronic component with $E \geqslant 1$ Bev are given in Fig. 3 for each size, where the densities are normalized for EAS with $\bar{N} = 4 \times 10^5$ (those that follow are the same). We did not find for these distributions to have any difference within the limits of experimental errors, and moreover the densities of high-energy rays were approximately in proportion to each size for the same r.

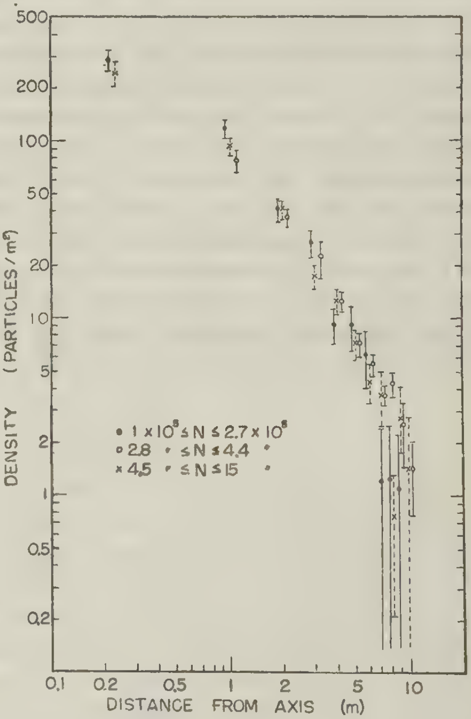

Fig. 3. Lateral density distribution of the electronic-component with the energy $E \geqslant 1$ Bev in EAS for three shower sizes. The density is normalized to showers with $\bar{N} = 4 \times 10^5$.

Accordingly, we treated all showers of different size altogether for the purpose of decreasing the statistical errors. The results obtained are presented in Fig. 4. For comparison of the experimental results with the theoretical distributions of the pure electronic shower, the integral lateral distributions of electrons with the age parameter $s = 1.0$ and $s = 1.4$ for each energy are shown in the figure, They were calculated from the structure function based on Approximation A, assuming that primary energy is infinite in the result of Kamata and Nishimura.[4] In the figure, the experimental distributions are very close to the curves of $s=1.4$ in the range $1\,\mathrm{m} \leqslant r \leqslant 10\,\mathrm{m}$. This means that those of $s=1.4$ are the closest in available ones ($s=0.6$, 1.0, 1.4, and 2.0). The experimental values include, however, both electrons and photons, but theoretical distributions only electrons.

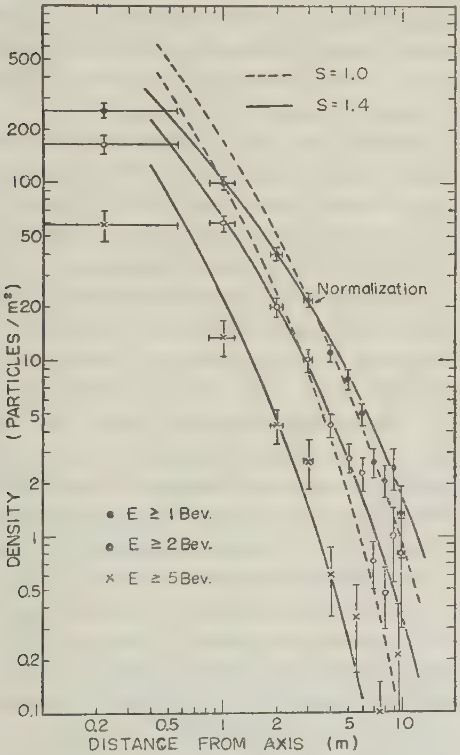

Fig. 4. Lateral density distribution of high-energy electronic-component in EAS with $\bar{N}=4\times10^5$ for three energy region. Theoretical curves are normalized for $E\geqslant1$ Bev at 3 m.

Therefore, if the lateral spread of photons is not very different from that of electrons, this fact shows that the lateral spread of the high-energy electronic component with the energy of $E\geqslant1$ Bev can be explained only by Coulomb scattering in the range $r>1\,\mathrm{m}$ just as that of the low-energy electronic component. Namely, it seems that the main source of the energy supply of EAS is confined in the narrow region $r\leqslant1\,\mathrm{m}$.

(b) *Ratio of the Density of High-energy Electrons and Photons to that of Electrons of all Energies*

These ratios can be calculated by the results of (a) and the assumed lateral density distribution of all electrons, but we tried to get the ratios experimentally using about one-third of the data in (a). In estimating the density of all electrons from the number of electrons in the top section of the chamber, the transition effect in the top wall of the chamber and the roof of the hut must be taken into account. With the aim of doing this the lateral density distribution of electrons in the top section was investigated. The result shows that the distribution is the form $r^{-(1\cdot00\pm0\cdot05)}$ in the range $1\,\mathrm{m}\leqslant r\leqslant10\,\mathrm{m}$ and $r^{-(0\cdot55\pm0\cdot35)}$ in $r\leqslant1\,\mathrm{m}$. The form r^{-1} distribution is close to that of $s=1.25$ in $1\,\mathrm{m}\leqslant r\leqslant10\,\mathrm{m}$. As the energy spectrum does not suffer a radical change in the investigated range of r as shown by (c), the dependence of the transition effect on r in our apparatus does not vary

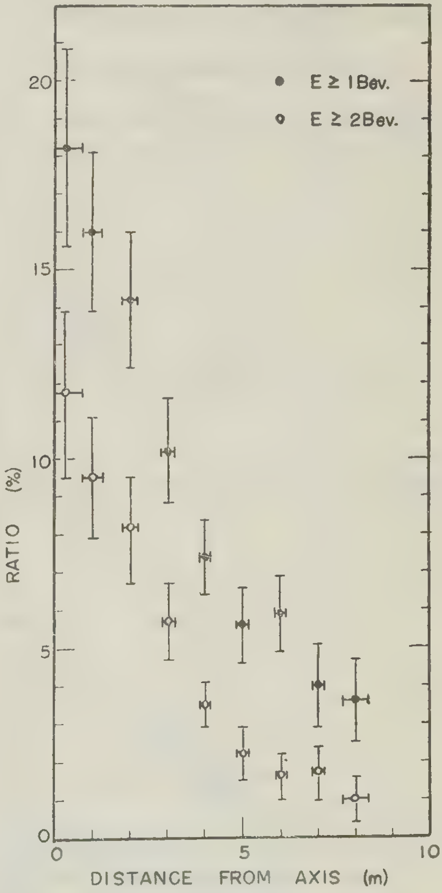

Fig. 5. Ratio of the density of the electronic-component with $E\geqslant1$ Bev and $E\geqslant2$ Bev to that of all electrons versus distance from the axis.

so much. But the absolute values of the density in the top sections is 26% more than that of $s=1.25$ at the distance $r=1$ m and 18% at $r=8$ m. Consequently the number of electrons in the sections was corrected by the above quantities. (These quantities of correction may be possessed of the error of about −10% because the boundaries of the illuminated regions were not necessarily very clear). The ratios found for high-energy rays with $E \geqslant 1$ Bev and $E \geqslant 2$ Bev are given in Fig. 5. These absolute values are higher than that of Danilova *et. al.*[3] because of the difference of the energy estimate.

Further, in an attempt to see the variation of the fraction of the high-energy component, $\Delta(e+\gamma, E \geqslant 1 \text{ Bev})/\Delta(e, E \geqslant 0)$, with the atmospheric depth, we picked up the data which satisfied the following criterion among the preceding data, and investigated the variation with the projected zenith angle: the distance from the shower axis to the chamber is 3 m, 5 m and 7 m or less for showers of the size $1\times10^5 \leqslant N \leqslant 3.4\times10^5$, $3.5\times10^5 \leqslant N \leqslant 6.4\times10^5$ and $6.5\times10^5 \leqslant N \leqslant 1.5\times10^6$ respectively. Only 9% of the data picked up by this criterion was ruled out on account of the indetermination of their projected zenith angles. Therefore, the investigated variation is hardly biased, but the values of the ratio become a little higher because the data ruled out did not contain a high-energy ray (see § 5). The mean space angles corresponding to the respective intervals of the projected angle were calculated using the zenith angle distribution seen in § 5, and those were further reduced to the mean atmospheric depth.

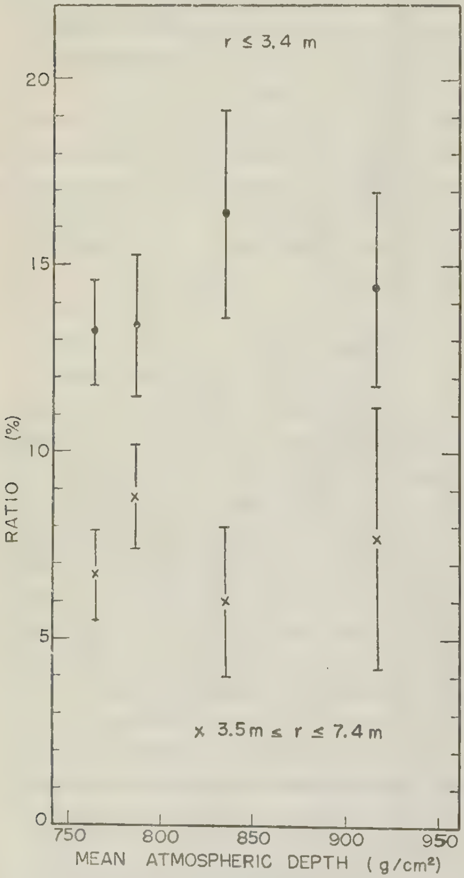

Fig. 6. Variation of $\Delta(E \geqslant 1 \text{ Bev}, e+\gamma)/\Delta(E \geqslant 0, e)$ with mean atmospheric depth.

The results in the range $r \leqslant 3.4$ m and $3.5 \text{ m} \leqslant r \leqslant 7.5$ m are shown in Fig. 6, where the ratios hardly vary with the atmospheric depth. Hereupon, this comparison of the ratio is not done for EAS with the same primary energy, but for EAS with the same size under the different atmospheric depth. However, as stated at the beginning of (a), the density of high-energy rays was in proportion to the size for the same distance from the axis, namely, this ratio is independent on the size within the investigated region. Accordingly, this ratio does not vary with the atmospheric depth for EAS with the same primary energy, too. This result agrees with that of Danilova *et. al.*[3] which was obtained by comparing the measurement at sea level with that at 3860 m.

It seems that this fact shows a state of equilibrium between the electronic component and the high-energy nucleonic component.

(c) *Energy Spectrum*

The integral energy spectra of the electronic component with $E \geqslant 250$ Mev were investigated in the three intervals, $r \leqslant 3.4$ m, $3.5 \text{ m} \leqslant r \leqslant 6.4$ m and $6.5 \text{m} \leqslant r \leqslant 10$m. In this analysis, we adopted only the showers, the project zenith angle of which is less than eight degrees in the vertical plane perpendicular to the front glass of the chamber. This treatment was done to eliminate cascade showers whose particles come out of the illuminated region on the half way in the chamber, and thus to avoid the accuracy of estimated energy of showers to be reduced. As little difference was recognized between those of two groups divided according to the size, we investigated all showers of different size altogether. The results are given in Fig. 7, and in the range $250 \text{ Mev} \leqslant E \leqslant 1$ Bev each spectrum can be represented by a power law of the form E^{-n} and the values of n are given below,

$n=0.75\pm0.08$ for $r\leqslant 3.4$ m
1.03 ± 0.09 for $3.5\text{ m}\leqslant r\leqslant 6.4$ m
1.22 ± 0.13 for $6.5\text{ m}\leqslant r\leqslant 10$ m.

In the energy range $E\geqslant 1$ BeV, the values of n become larger.

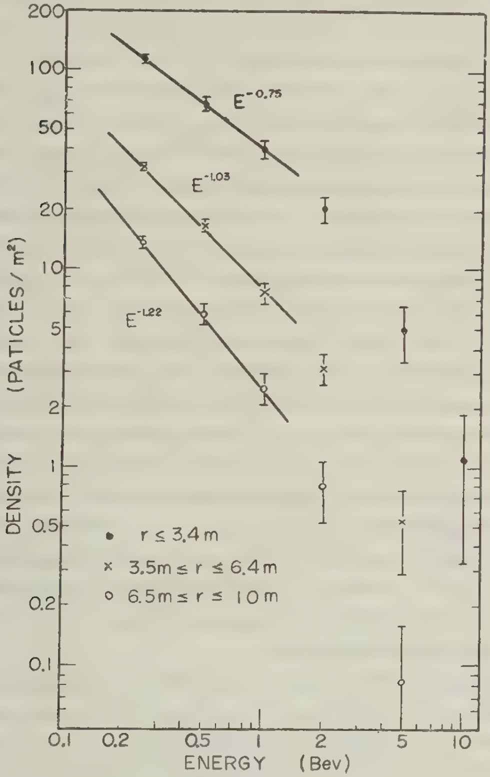

Fig. 7. Integral energy spectrum of electronic-component in EAS with $\bar{N}=4\times10^5$ for three distance intervals.

(d) *Lateral Distribution of the Energy Flux*

Using the results given in (c), it is possible to construct the lateral distribution of the energy flux carried by the electronic component. In doing so, the curves of the energy spectrum were extrapolated to the very high-energy region, and the flux in the low energy region were estimated, using the number of electrons of all energies and the number of photons obtained from the spectrum of Richard and Nordheim.[11] The errors based on these assumptions were estimated in a reasonable way. The result found for the showers with $\bar{N}=4\times10^5$ is shown in Fig. 8. Generally, the form of the distribution for the size N in the

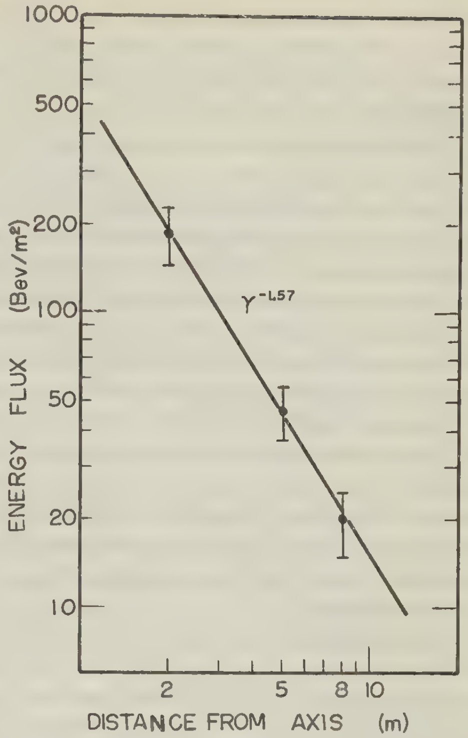

Fig. 8. Lateral distribution of the energy flux of electronic-component in EAS with $\bar{N}=4\times10^5$.

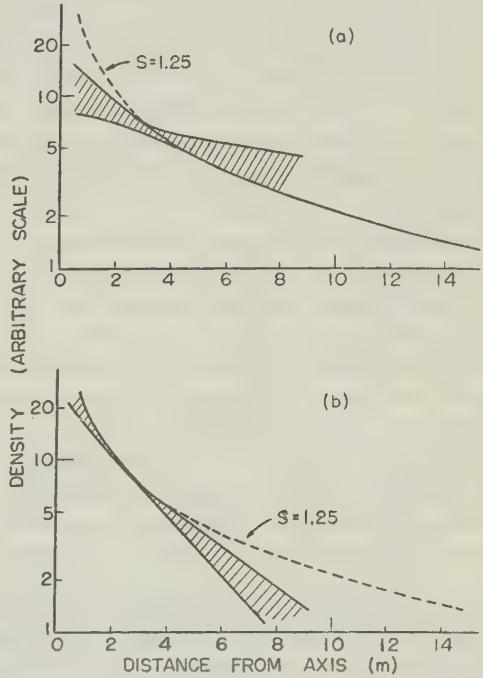

Fig. 9. Lateral distribution of charged particles near the shower axis. Density lies in the hatched region. 9(a) F-distribution; 9(b) S-distribution.

investigated region can be written as follows

$$E_p=(1.38\pm0.48)\cdot N\cdot r^{-(1.57\pm0.24)}\text{Mev}\cdot\text{m}^{-2}.$$

The value of this power index agrees with the result of Danilova *et al.*[3]

(e) *Lateral Density Distribution of All Electrons near the Axis*

In most of the showers, the lateral distribution of charged particles is well fit to the one expected from the N-K function of $s=1.25$. However, there are some showers whose distribution of particles does not fit clearly to the expected one, and their distributions are divided into two groups as follows:

a) The distribution in which the density near the axis (1~3 m from the axis) is remarkably less than the expected one, as shown in Fig. 9(a). This type of distribution is designated as *F*-distribution, and that which is expected from the N-K function of $s=1.25$ as *N*-distribution.

(b) The distribution in which the density at $r>3$ m is less than the expected one, and is well represented by exp $(-\alpha r)$, where $\alpha=0.25\sim0.4$/m, as shown in Fig. 9(b). This type of distribution is named as *S*-distribution.

The proportion of showers with each distribution is studied for EAS whose axis fall within 3 m from the density detectors, and the results obtained are listed in Table I. This proportion is nearly independent on the shower size of less than 8×10^5, and for $N\geqslant8\times10^5$ the fraction of *F*-distribution decrease, and that of *S*-distribution increases gradually, and seems to tend to $S/N\sim1/3$ at $N=2\times10^6$.

Table I.

N	F	S
74±8%	16±3%	10±2%

Table II.

	N	F	S
AcS	65±19%	3±3%	32±12%
NAcs	61±18%	39±14%	0

As mentioned in § 5(a), the lateral distribution of the high-energy electrons and photons ($E\geqslant1$ Bev) does not depend on the shower size, and so the mean number of them in each cloud chamber is known from the position of the axis and the size of showers. We pick up the two kinds of EAS in which the number of high-energy electrons and photons falling on both cloud chambers is thrice as many as the mean number, and less than one third of it. The former may be regarded as the active showers (AcS), and the latter the non-active showers (NAcS). The types of the lateral distribution of these showers are examined, and the results are listed in Table II.

As seen in Table II, the proportion of the showers with *S*-distribution and *F*-distribution is reversed in AcS and NAcS.

From these results, the followings may be concluded qualitatively:

i) Considerable parts of EAS, which contain more high-energy electronic component than the average, reveal *S*-distribution, and this shows that the showers of *S*-distribution are relatively young age. The reverse holds for the showers of *F*-distribution.

ii) The result that for EAS of large size ($N\geqslant8\times10^5$) the showers of *F*-distribution decrease and those of *S*-distribution increase, means that there are few showers of large size which are of old age, and this result seems to give some suggestions on the development of EAS in the air. However, the narrow arrangement of our apparatus used and poor data of the showers of large size obtained, make it dangerous to go deep into more consideration.

iii) In some period of the measurement, we used the core selector similar to the one used by Cocconi *et al*,[12] to trigger the whole apparatus. Almost all of EAS selected by this method are of *N*- and *S*-distribution. This shows the correctness of the above mentioned results, and also implies that the lateral distribution of EAS selected by the core selector has a tendency to reveal that of the showers of young age.

§ 5. Zenith Angle Distribution

The projected zenith angle distribution of EAS was measured, using the two cloud chambers which were set at right angles with each other. Generally, low-energy electrons being scattered to various directions, it is difficult to determine the angle of the showers containing no high-energy cascade shower and having small densities in the chambers. Accordingly, if only the showers whose angles are easily determined were picked up for the analysis, the obtained distribution would have some biases, characters of which are not known well.

At first, we investigated the zenith angle distribution averaged for all showers having various characters. If most of showers whose zenith angles are undecided are showers with specific characters, and their zenith angle distribution is different from the average one, the obtained distribution does not answer the purpose. Therefore, in order to reduce the above mentioned biases as much as possible and to increase the accuracy of the angle, the showers which satisfied together the following two criteria were accepted for analysis:

(i) The distance from the shower axis to the chamber is 3 m, 5 m and 7 m or less for the showers of the size $1\times10^5 \leqslant N \leqslant 3.4\times10^5$, $3.5\times10^5 \leqslant N \leqslant 6.4\times10^5$ and $6.5\times10^5 \leqslant N \leqslant 1.5\times10^6$ respectively. (In these regions, on the average, about one or more rays with $E \geqslant 1$ Bev are expected to fall into the chamber from the result of § 4(a).)

(ii) The picture of the chamber contains either at least one high-energy ray with $E \geqslant 1$ Bev and a few parallel tracks, or five or more parallel tracks, where tracks were regarded to be parallel if their projected angles did not differ by more than 8°.

On the above criteria, the projected zenith angles of EAS were determined mainly by high-energy rays, and for 85% of the showers accepting the criterion (i), their projected zenith angles could be determined. The number of selected data was 393 and the mean size was $\bar{N}=4.5\times10^5$.

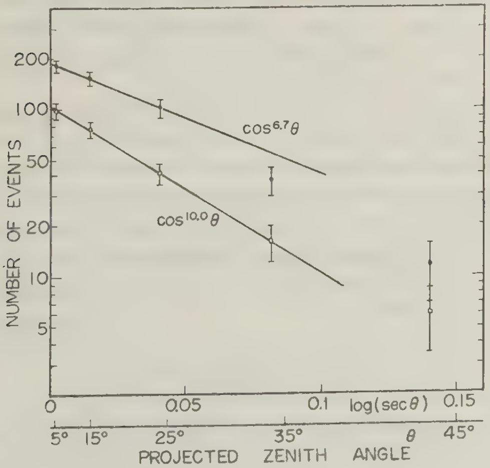

Fig. 10. Projected zenith angle distribution of EAS The upper curve shows distribution averaged for all showers, and the lower curve shows that of young showers.

As every triggering counter was arranged in the north-south direction, inclined showers have the different triggering efficiency according to the azimuth angle. As the result of this effect, the projected zenith angle distribution of A chamber becomes flatter than the space-angle distribution and on the contrary that of B becomes steeper. This tendency was verified experimentally. In order to exclude it, the total data of A and those of B were averaged with equal weight, and moreover the variation of effective area in registering EAS was taken into account.

The result is shown by the upper curve in Fig. 10, and the distribution is of the form of $\cos^{6.7\pm1.4}\theta$ in the range 0–30°. This form should be agreed with that of the space-angle, and accordingly we get the absorption mean free path Λ of the intensity of EAS

$$\Lambda=113\pm22 \text{ g cm}^{-2}.$$

This value is in agreement with the result of Miura *et al.*[13] measured at Mt. Norikura, but they did not measure the size. Moreover, the value agrees with the result of Clark[14] measured for EAS with the primary energy approximately equal to ours at sea level. The absorption m.f.p. of the number of particles λ defined by $\lambda=\gamma\Lambda$ can be determined to be

$$\lambda=203\pm42 \text{ g cm}^{-2}.$$

with $\gamma=1.8\pm0.15$ in § 3.

In addition, we investigated the zenith angle distribution of the EAS in which the number of high-energy electrons and photons with $E \geqslant 1$ Bev falling in the chamber is more than twice as many as the mean number seen from § 4(a). Of course, the above criterion (i) was not imposed on these EAS. The rate of high-energy rays is independent on the zenith angle, as seen from § 4(b). Hence, the data selected in such a manner contain mostly showers with specific character, but their zenith angle distribution is not biased in favor of specific angles. The number of the selected data was 238 and the mean size was $\bar{N}=5\times10^5$. The zenith angle distribution obtained from them is given by the lower curve in Fig. 10, where the distribution well represented by the form $\cos^{10.0\pm2.0}\theta$ in the range 0°–30°. From this, we get the following absorption m.f.p. Λ^* of intensity

$$\Lambda^* = 76 \pm 15 \text{ g cm}^{-2}.$$

This value is pretty smaller than the average m.f.p. Λ.

This result can be interpreted as follows; the majority of the selected showers are young, namely, they develope mainly near the apparatus, and accordingly the obtained value Λ^* seems to show the effective collision m.f.p. of the primary particles of EAS.

§ 6. Conclusion

From the experimental results of EAS measured at 2770 m elevation (741 $\text{g}\cdot\text{cm}^{-2}$ atmospheric pressure), the following conclusions were obtained:

(1) The integral size spectrum can be represented by the following form

$$F(\geqslant N) = 4.9\times10^{-5}(N/10^5)^{-(1.55\pm0.10)}\text{m}^{-2}\cdot\text{sec}^{-1}\cdot\text{sterad}^{-1}.$$

$$\text{for} \quad 1\times10^5 \leqslant N \leqslant 4\times10^5$$

$$F(\geqslant N) = 8.2\times10^{-5}(N/10^5)^{-(2.04\pm0.20)}\text{m}^{-2}\cdot\text{sec}^{-1}\cdot\text{sterad}^{-1}.$$

$$\text{for} \quad 4\times10^5 \leqslant N \leqslant 2\times10^6.$$

(2) The lateral spread of the high-energy electronic component can be explained only by Coulomb scattering in the range $r > 1$ m. Namely, the main source of the energy supply of EAS is confined in the narrow range $r \leqslant 1$ m.

(3) In a greater part of the EAS with the size $1\times10^5 \leqslant N \leqslant 1\times10^6$, the electronic component is in a state of equilibrium with the high-energy nucleonic component in the region of the atmospheric pressure 700∼1000 $\text{g}\cdot\text{cm}^{-2}$.

(4) In the range 1 m $\leqslant r \leqslant$ 10 m, the integral energy spectrum can be represented by the form E^{-n} within the energy region 250 Mev $\leqslant E \leqslant$ 1 Bev, and the value of n shifts from 0.7 to 1.2 as the distance from the axis r increases. In the energy region $E \geqslant 1$ Bev, the value n becomes larger.

(5) The lateral distribution of the energy flux carried by the electronic component can be expressed by the form $r^{-(1.57\pm0.24)}$ in the range $1 \leqslant r \leqslant 10$ m.

(6) The lateral distribution of electrons near the axis is not expressed by an unique distribution. Generally, the showers having steeper distribution seem to contain more high-energy electronic component and to be young in age, and those of flatter distribution have the reverse character. The proportion of the showers with S-distribution increases with increasing size in the range $N \geqslant 8\times10^5$.

(7) The absorption m.f.p. of the intensity of the EAS with the mean size $\bar{N} = 5\times10^5$ is 113 ± 22 $\text{g}\cdot\text{cm}^{-2}$, and the absorption m.f.p. of the number of the particles is 203 ± 42 $\text{g}\cdot\text{cm}^{-2}$. The effective collision m.f.p. of the primary particles is nearly 76 ± 15 $\text{g}\cdot\text{cm}^{-2}$.

We wish to express our gratitude to Prof. O. Minakawa for his valuable discussions and encouragement. We are also grateful to Prof. G. Fujioka and I. Kita for their useful discussions and kind advices and to Mr. K. Watanabe for his cooperation, and to Prof. S. Kikuchi, the director of Mt. Norikura Cosmic Ray Laboratory of Tokyo University, who offered us facilities to achieve the experiment. This study was supported partly by the Scientific Research Expenditure of the Ministry of Education.

Lattice Frequency of Ionic Crystals

By S. S. MITRA and S. K. JOSHI

Department of Physics, The University, Allahabad-2, U. P., India

(Received February 17, 1960)

"Using an inverse power type repulsive potential two different expressions for the lattice frequency of ionic crystals are obtained, one in terms of the cohesive energy and the other in terms of the compressibility of the crystal."

In a recent communication1) the authors have derived an expression for the lattice frequency, ν, of ionic crystals in terms of the cohesive energy, E_0, using a simplified Born-Mayer potential of the type

$$u=-\frac{\alpha e^2z^2}{r}+Mbe^{-\sigma(r/r_0)}$$

The relation is

$$\nu=\frac{1}{2\pi}\left(\frac{E_0}{r_0^2NM\mu}\right)^{1/2}\left[\frac{2\sigma(\sigma-2)}{(\sigma-1)}\right]^{1/2}$$

where r_0 is the closest equilibrium distance between two unlike ions, M is coordination number, μ is the reduced mass of the ions, N is Avogadro's number and σ a potential parameter. The lattice frequency calculated from the above relation compares well with the experimental values of $\nu_{\max}$, the infrared eigen frequency as determined by Barnes2) for some of these crystals.

The purpose of the present communication is to derive a similiar expression for the lattice frequency using a repulsive energy of the inverse power type. The following potential energy has been used:

$$u=-\frac{\alpha e^2z^2}{r}+\frac{Mb}{r^n} \tag{1a}$$

symbols having their usual meanings. In the above expression for the potential energy the overlap potentials between other than nearest neighbours, van der Waal interactions and zero point energy have been neglected.

Neglecting anharmonicity, the frequency, ν, is given by

$$\nu=\frac{1}{2\pi}\sqrt{\frac{f}{\mu}}$$

where the force constant, f, is the coefficient of Δr, the change in inter nuclear distance, in the expression for $\frac{du}{d\Delta r}$, and μ the reduced mass.

For a crystal of the NaCl type, equation (1a) may be rewritten in terms of Δr as

$$u=-e^2z^2\left[\frac{1}{r_0-\Delta r}+\frac{1}{r_0+\Delta r}+\frac{4}{(r_0^2+\Delta r^2)^{1/2}}\right]+b\left[\frac{1}{(r_0-\Delta r)^n}+\frac{1}{(r_0+\Delta r)^n}+\frac{4}{(r_0^2+\Delta r^2)^{n/2}}\right] \tag{1b}$$

for convenience $(\Delta r)^2$ has been denoted as Δr^2. Differentiating u with respect to Δr and collecting terms in Δr, one obtains for f

$$f=2n(n-1)br_0^{-(n+2)}$$

In equation (1b) we have confined ourselves only to the six nearest neighbours. The poor convergence of the first sum (coulomb part) demands the consideration of the next nearest and farther neighbours. But because of origin being a centre of symmetry, irrespective of the number of neighbours considered, the first sum will not have any term in Δr. In other words electrostatic interactions between the various ions contribute nothing to f. The highly convergent nature of the second sum (repulsive part) in equation (1b) justifies the consideration of only the nearest neighbours.

The cohesive energy, E_0, is given by

$$E_0=-N(u)_{r_0}=N\left(\frac{\alpha e^2z^2}{r_0}-\frac{Mb}{r_0^n}\right)$$

The constant b is determined from the condition $\left(\frac{du}{dr}\right)_{r_0}=0$ giving

$$b=\frac{\alpha e^2z^2}{Mn}r_0^{n-1}$$

Thus

$$\nu=\frac{1}{2\pi}\sqrt{\frac{2nE_0}{MN\mu r_0^2}} \tag{2}$$

The lattice frequency may also be expressed in terms of compressibility, x. The compressibility is given by

$$\frac{1}{x}=V\frac{d^2U}{dV^2}$$

Table I.

a See reference 4). b See reference 5). c reference 6).

where V and U are volume and energy per unit cell. In terms of crystal parameters one obtains

$$x=\frac{18r_0{}^4}{\alpha e^2z^2(n-1)}$$

for the NaCl type lattice.

Hence

$$\nu=\frac{1}{2\pi}\sqrt{\frac{36r_0}{xM_\mu}} \qquad (3)$$

which is very similiar to the expression obtained by Huggins[3] using an exponential type repulsive energy.

In Table I, ν calculated from relations (2) and (3) are compared with the experimental values of $\nu_{\max}$ due to Barnes.

The authors wish to thank Prof. K. Banerjee for his interest in the investigation. Thanks are also due to the University Grants Commission, Govt. of India for the award of a senior fellowship to one of them (S.S.M.).

The Resonance Type Absorption of Very Thin Silver and Gold Films

By Shigeo YAMAGUCHI

Department of Physics, Faculty of Science,
Tokyo Metoropolitan University

(Received April 19, 1960)

The spectral transmission from 200 mμ to 1,200 mμ of silver and gold thin films was measured. It was found that for heated silver films a strong resonance type absorption appeared with the peak at 435 mμ ~ 480 mμ and then the absorption due to electrons in the conduction band disappeared. For heated gold films, the similar results were also obtained but the absorption strength was rather weak and the peak position shifted to 510 mμ ~ 550 mμ.

By taking into account the two dimensional aggregations, some discussions were made from the view point of the collective motion of conduction electrons within small metallic particles of which the film was composed.

§ 1. Introduction

It is known that very thin films have optical properties different from those of the bulk metal. The optical constants as determined in connection with metallic films change remarkably with film thickness. While the refractive index n increases as the thicknes becomes smaller, the extinction coefficient k decreases promptly in many cases, thus the thinner metallic film having the more properties of an insulator. On the other hand, thin films of many metals absorb light selectively, and the absorbing manner varies with thickness. For example, silver films viewed by transmitted light show light yellow at a thickness of about 10Å and deep blue for thickness thicker than some value.

A number of experimental and theoretical works on this subject has already been made.[1] The phenomena are owing to the fact that thin metallic films are not homogeneous slab of the metal, but are composed of small agregates of metallic atoms. Application of Maxwell-Garnett theory in which the film is regarded as a three dimensional suspenoid of spherical metallic particles possessing the same optical constants as those of the bulk metal can explain many experimental features, but seems to be still unsatisfactory from a quantitative point of view.[3)-5)] The theory modified by Schopper[6] in which the film was considered to be a two-dimensional set of rotational ellipsoids having the same optical constants as the bluk metal, and the dipole interaction among ellipsoids was ignored showed the result which agreed with his experiment relating to the evaporated gold film.

In the work to be reported here, the author investigated spectral transmission of thin metallic films, and found a resonance type absorption, which for the thinnest silver films had the maximum at about 435 mμ and completely isolated from the absorption due to the electronic interband transition and also from the absorption due to the electrons in the conduction band. The letter will be refered to the conductive absorption hereafter. The absorption band was though to be the similar kind one to that observed by Hampe[7] in gold film at about 550 mμ. In accordance with Hampe, the author ascribed it to the resonance oscillation of the electron gas in the metallic particles composing the film. Some calculations were made in order to test the propriety of the above explanation and to get some information about the film structure.

§ 2. Experimental

Films were prepared by the deposition of the evaporated metal from a heated molybenum ribbon in an evacuated vessel in which the pressure was maintained below 2×10^{-5} mmHg. Evaporated metals were silver and gold. The substrate was either fused sillica plate or collodion film. During evaporation the substrate was kept at a constant temperature between room temperature and 160°C controlled by an electrical heater behind the substrate. The deposit was laid between the two aquadac coatings on substrate, which were served as the electrodes for the measurement of the electrical conductivity of film. The electrical current across the film with terminal voltage 45V～135V was recorded by an electromagnetic oscillograph through a high gain d.c. amplifier during and after deposition of metal. Samples of various thicknesses were prepared and their spectral transmission was measured in the wavelength region from 200 mμ to 1,200 mμ using a Beckman type spectrophotometer. The transmission was determined in reference to that of a clear substrate. The error of transmission measurement was within about 0.5%. It was found that the anomalous absorption which is to be stated became sharper, if the film was heated for some time after its preparation. This heat treatment for silver was done successively to the deposition in the same evacuated vessel, while for gold films it was done in a separate vacuum oven, as it required a higher temperature, 400～500°C.

The determination of the film thickness is the most important factor to decide the optical properties of film. The author determined three thicknesses in following ways: the first was estimated from the evaporation speed and the evaporation time, the second from the transmission at $\lambda=265$ mμ and the third from the activation analysis.

The speed of evaporation was controlled by the heating current, and was estimated previously for several values of heating current in two ways: one from the weight change of the metal source and the other from the thickness of the formed film determined by means of multiple beam interference. If the deposition was done on substrate at room temperature, and the evaporation occurred into solid angle 2π, the rates of deposition estimated in the above two ways fairly agreed. Hence we obtained a thickness d_w' of each sample from the relation:

$$d_w' = \frac{(\text{deposition weight per unit area per unit time}) \times (\text{deposition time})}{(\text{bulk density of the metal})}$$

assuming that the deposition occurred in constant rate throughout that time. Another thickness, sybolized by d_{265} below, was obtained from the optical transmission at $\lambda=265$ mμ. The reason and procedure will be explained in the next section. In order to check the above thicknesses and to estimate the actual mass thickness correctly, the activation analysis for several samples was made using reactions $\mathrm{Ag}^{109}(\mathrm{n}\gamma)\mathrm{Ag}^{110}$ and $\mathrm{Ag}^{107}(\mathrm{n}\gamma)\cdot\mathrm{Ag}^{108}$ in following procedure*: a sample activated in an atomic reactor for 30 sec. was dissolved into 2 c.c. of 8 Normal $\mathrm{HNO_3}$ and its activity was measured by a γ-ray scintillation counter. For reference the weighed silver and the relatively thick film deposited on substrate at room temperature were used. The results are shown in Table II and Fig. 5.

§ 3. Experimental Results

(A) *Silver on Fused Silica*

An example of a series of spectral transmission for silver films of gradually varying thickness is shown in Fig. 1(a). The figure given to each curve is the sample number. The samples were made with the same condition but different evaporation times, the

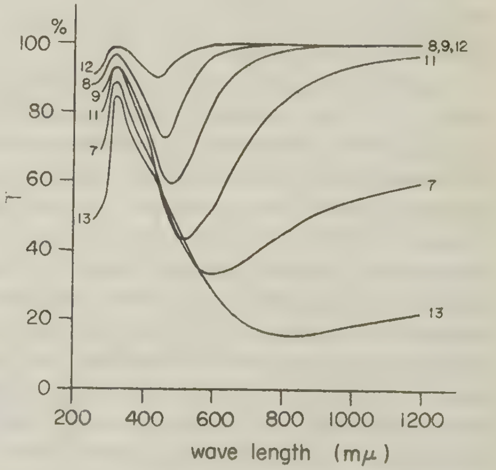

Fig. 1(a) Transmission curves of silver films deposited on fused silica at room temperature with the deposition rate 7Å/sec.

---

* The author thanks Mr. F. Ichikawa, Japan Atomic Energy Research Institute, for his kindness to give many conveniences for this measurement.

latter values being given on the horizontal time axis of Fig. 1(b). Fig. 1(b) shows the electrical conductivity record of a film for which the evaporation was continued longer than usual but under the same evaporation conditions as for the above samples.

The conduction does not occurr for some period after opening the shutter of atomic beam, and when it occurred, increases nearly exponentially. If the shutter was closed in this stage, the conduction begins to decrease at once, and falls to zero as a function of the substance of substrate, its temperature, and the rate of deposition. These behaviours indicated that silver atoms arriving at the surface of substrate moved easily to agglomerate into minute grains, thus remaining non-conductive in the early of evaporation. When the grains grew by continued evaporation, and bridges were formed among them, the current begins to flow. As the agglomeration continues still after the stop of evaporation, the unstable bridges will be broken, and the film becomes again non-conductive.

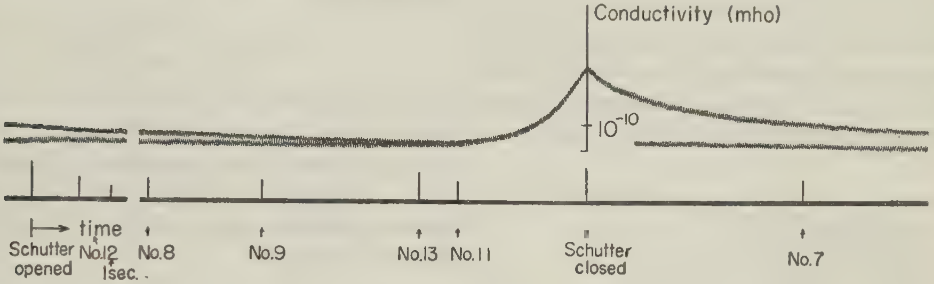

Fig. 1(b) The electrical conductivity record for a silver film formed under the same conditions.

All the samples but No. 7 and No. 13 given in Fig. 1(a) are those for which the evaporations were stopped within the period of non-conductive.

The spectrophotometric curves of thinnest films Nos. 12, 8 show, in addition to the absorption band at ultraviolet end, which is already known to be due to the electronic interband transition, the existence of an absorption band with a peak at 434~450 mμ. We will call provisionally the latter an anomalous absorption band. There does not appear the usual conductive absorption for these films. Such thin films exhibit light yellow when viewed by transmitted light. As thickness is increased, and the anomalous absorption band becomes stronger, its peak is slightly displaced to longer wavelength and begins to broaden on the same side. In this stage, films viewed by transmitted light exhibit ruddy orange. For still thicker films the broadening on the longer wavelength side of anomalous absorption continues, and finally there remains only the transmission gap at 320 mμ. Such films display blue colour in the transmitted light. That the considerable decreasing in transmission due to conductive absorption occurs for the film such as No. 7 for which the electrical conduction has decayed may be understood by considering that for electrical conduction it needs long metal chains eventually joing the electrodes, while for the conductive absorption not so long chains is needed.

For all cases of the various evaporation conditions, the above mentioned results are similar except minute details, but there is no constant relation between each stage and the mass thickness. Generally films formed on substrate at higher temperature have their electrical and optical properties belonging to the second and the third stage for the thicker mass thickness on lower temperature substrate.

It was found that the anomalous absorption band of films of such thickness as No. 9 and 11 or even No. 7 and No. 13 was changed into that corresponding to the thinnest one with respect to the peak position and breadth, and the conductive absorption was disappeared, if the films were heated at a temperature above 100°C for 30 min.~1 h. successively to their formation. Examples of transmission curve of heated films are shown in Fig. 2. The thickness are given here by d_{265}.

The effect on the band-breadth was conspicuous, while the peak position still depended on the thickness as shown in Fig. 3.

The ratio of transmission through the film and substrate, which was measured directly in the present experiment, is to be expressed with the good approximation by[8)]

$$T=\frac{1}{\left[1+\frac{1}{\mathrm{n}_2+1}\frac{2\pi d}{\lambda}(2\mathrm{nk})\right]^2} \tag{1}$$

when $2\pi(\mathrm{n}-i\mathrm{k})d/\lambda \ll 1$. Here the film is considered to be optically homogeneous slab having the optical thickness d and the optical constants n, k. λ is the wavelength of light and n_2 the refractive index of the substrate.

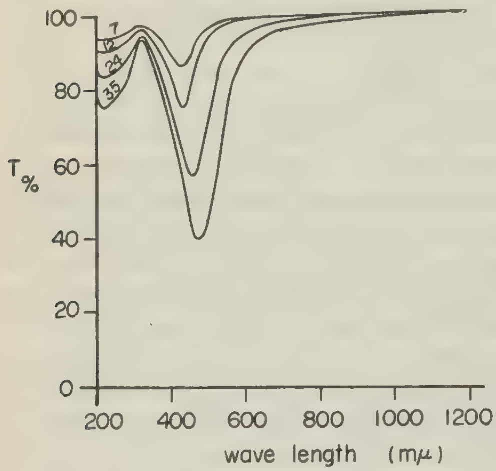

Fig. 2. Transmission curves of heated silver films of fused silica at about 160°C for one hour.

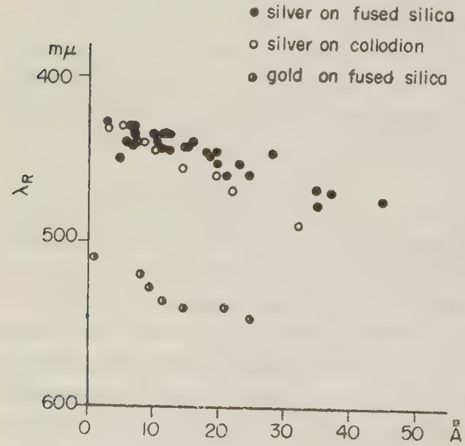

Fig. 3. The peak position of resonance type absorption vs. thickness for heated silver and gold films.

The quantity

$$X=\frac{2}{\mathrm{n}_2+1}\frac{2\pi d}{\lambda}(2\mathrm{nk}) \tag{2}$$

represents the amount of energy dissipated in the film per unit time and per unit area, and was obtained from the experiment for heated films. This quantity in the region of the anomalous absorption band can be expressed very well by the following resonance type formula as a function of the light angular frequency:

$$X=X_{\max}\frac{\gamma_0^2x^2}{(1-x^2)^2+\gamma_0^2x^2} \tag{3}$$

where $X_{\max}$ is the peak value of X, γ_0 is known from the half breadth $\Delta\omega/\omega_R$, and x is ω/ω_R, ω_R being the frequency of peak position. Example of experimental curve and the fitted resonance curve of the formula (3) is shown in Fig. 4.

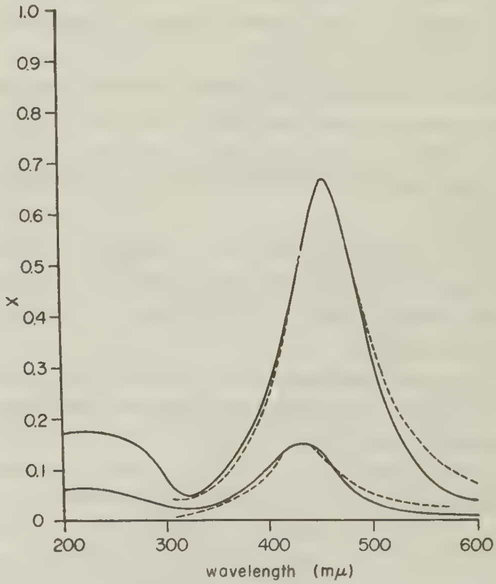

Fig. 4. The anomalous absorption curve of heated silver films and the fitted resonance curve.

In Table I are given the values of d_w', λ_R, $X_{\max}$ and γ_0 obtained for heated films. As is seen in the table, the dependence of $X_{\max}$ on d_w' is very irregular. This is the circumstance that metallic atoms re-evaporate during the heat treatment very irregulary and so the d_w' does not correspond to the actual mass thickness. On the other hand, the $X_{\max}$ of anomalous absorption band is nearly proportional to the X value at $\lambda=265$ mμ. In the films not heated, the X value at 265 mμ is

almost proportional to d_w' and if we put $2nk = 3.7$ in the formula (2) the thickness d_{265} calculated from the observed X agrees well with d_w'. Moreover the heat treatment has almost no effect on the shape of absorption band in ultraviolet region. Hence also for heated films, we calculated the thickness d_{265} in the same way from their X value at 265 mμ, which seems to correspond to the actual mass thickness and is given in Table I as d_{265}. The dependence $X_{\max}$ of anomalous absorption on d_{265} is shown in Fig. 5. As is seen in Fig. 5, $X_{\max}$ is nearly proportional to d_{265}, but more exactly $(d_{265})^{1.37}$. γ_0 does not change remarkably for all thickness and has the mean value 0.223.

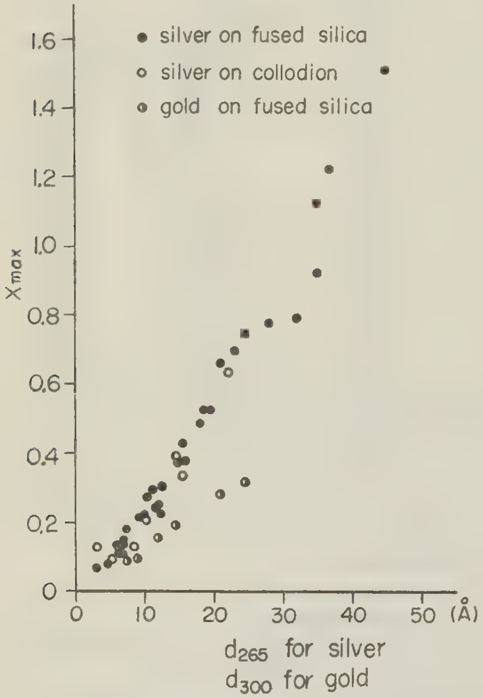

Fig. 5. The dependence of the $X_{\max}$ value of anomalous absorption on thickness for heated silver and gold film.

The results of the activation analysis is shown in Table II. In this case, the activity again correlates more to d_{265} than to d_w'. Thus the thickness d_{265} corresponds better to the actual mass thickness, and the relation between the mass thickness d_A estimated from the activity and d_{265} is shown in Fig. 6. For larger thickness than $d_{265}=40$Å, the thickness d_{265} agree with the thickness d_A but for small thickness than $d_{265}=40$Å, it gives larger than d_A. Using this relation, the linearity in the dependence of $X_{\max}$ on thickness is fairly improved d_A values estimated by using the curve shown in Fig. 6 for each sample are tabulated in Table I.

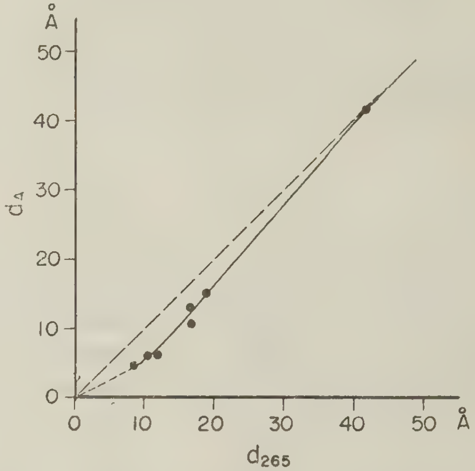

Fig. 6. The relation between thicknesses d_A estimated by activation analysis and d_{265} estimated from transmission at $\lambda = 265$ mμ.

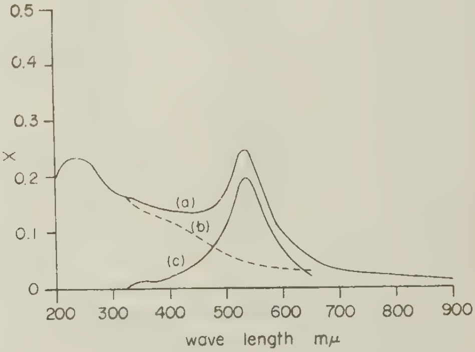

Fig. 7. The absorption curve of a heated gold film on fused silica at about 500°C for one hour.

(B) *Silver on Collodion*

The electrical conductivity records showed that silver atoms on collodion surface moved rather slowly to agglomarate than those on fused silica.

The transmission curve was similar to that for a film on fused silica, but the conductive absorption appeared for thinner film and the anomalous absorption band was displaced more rapidly and its breadth was somewhat larger than those for films on fused silica. The peak position of anomalous absorption band and the $X_{\max}$ value are shown in Fig. 3 and Fig. 5 respectively. The average γ_0

value is 0.25.

(C) *Gold on Fused Silica*

The absorption of a thin evaporated gold film is shown in Fig. 7 by the curve (a). The film was formed on fused silica and heated at about 500°C for 1 h.. The anomalous absorption as in the case of silver is perceived with a peak at about 550 mμ, but it is overlapped now by the tail of the absorption due to the interband transition. The separation of them was made by using the result of Joos and Kropfer[9] relating to the temperature dependence of absorption edge of thick gold film. Assuming that the anomalous absorption falls to zero already at 300 mμ, this portion of the curve (a) is extended to longer wavelengths according to nk curve obtained by Joos and Kropfer. The extended portion is shown in Fig. 7 by the broken curve (b). The anomalous absorption proper (curve (C)) is obtained by subtracting (b) from (a). The curve (C) is well represented by the formula (2) with $\gamma_0=0.17$. The thickness d_{300} was determined from the X values at 300 mμ in similar way as done in silver. The $X_{\max}$ value of anomalous absorption is proportional to d_{300} as shown in Fig. 4.

The electrical conductivity record showed that the agglomeration of gold atoms occurred more slowly and its dependence on temperature is slighter than in the case of silver. In parallel with this, it was more difficult to remove perfectly the conductive absorption and to narrow the anomalous absorption band by heating.

§ 4. Discussion of Results

The shape of absorption curve suggests that the anomalous absorption was induced by the resonance oscillation of the conduction electrons in the metallic particles of the film. The electron within a particle may oscillate collectively, if the dipole approximation can be used, and the oscillation frequency ω satisfies the condition $2\pi/\omega \ll \tau_{\text{coll}}$, where τ_{coll} is the mean collision time of electrons. We assume that the electron gas is bounded around the equilibrium position by a restoring force $-\kappa\xi$, ξ being the displacement of the electron gas as a whole. Let the electron density in a metal be n_0 and the volume of the particle V. The restoring force must be due to the depolarizing force of the particle $L\cdot P/V$, where $p=-Vn_0e\xi$ is the dipole moment resulting from the displacement and L the depolarizing factor. Hence we have

$$\kappa = L V n_0^2 e^2$$

and, dividing this by the total mass Vn_0m

$$\omega_0^2 = L\frac{n_0e^2}{m}\,^{*} \tag{4}$$

as the natural frequency.

To obtain the actual resonance frequency ω_R, we must take into account of the dipole interaction among the particles composing the film. Assuming that N dipoles per unit area lie with average spacing 'a', and their moments are all equal and in the same direction parallel to the plane, the interaction field R is given by (Appendix I)

$$R = 2\pi\frac{N}{a}p\,. \tag{5}$$

The equation of motion of the electron gas in the film is

$$\ddot{p}+\gamma\dot{p}+\omega_0^2 p = \frac{Vn_0e^2}{m}[E_0e^{i\omega t}+R] \tag{6}$$

where $E_0e^{i\omega t}$ is the electric vector of incident light. We obtain the resonance frequency ω_R and the amplitude of oscillation p_0 as follows:

$$\omega_R^2 = \frac{4\pi n_0 e^2}{m}\left(\frac{L}{4\pi}-\frac{d_w}{2a}\right) \tag{7}$$

$$p_0 = \frac{Vn_0e^2}{m}\,\frac{1}{\omega_R^2-\omega^2+i\gamma\omega}E_0 \tag{8}$$

where the notation $d_w=NV$ means the true mass thickness of the film. If we imagine a substance which is formed by piling up such films with interval τ, the optical constants n, k of it are given by

$$(\mathrm{n}-i\mathrm{k})^2 = 1+\frac{d_w}{\tau}\,\frac{4\pi n_0e^2}{m\omega_R^2}\,\frac{\gamma_0 x}{(1-x^2)^2+\gamma_0^2x^2}\,. \tag{9}$$

Considering again the single film, we obtain the quantity as

$$X = \frac{2}{\mathrm{n}_2+1}\,\frac{2\pi d_w}{\lambda}\,\frac{4\pi n_0e^2}{m\omega_R^2\gamma_0}\,\frac{\gamma_0^2 x}{(1-x^2)^2+\gamma_0^2x^2} \tag{10}$$

---

* From Eq. (4), one may see that the conduction electrons, for example, in a spherical metallic particle resonate at the frequency $\omega_R=\omega_p/\sqrt{3}$. It was suggested by Dr. H. Kanazawa, University of Tokyo, that the similar phenomenon could also be expected in the characteristic energy loss of fast electrons due to the electron plasma in such particle. (private communication from Dr. H. Kanazawa.)

where $x=\omega/\omega_R$ and $\gamma_0=\gamma/\omega_R$. Eq. (9) becomes the formula used to represent the experimental result, if we put

$$X_{\max}=\frac{2}{n_2+1}\,\frac{2\pi d_w}{\lambda_R}\,\frac{4\pi n_0 e^2}{m\omega_R{}^2\gamma_0}\,. \qquad (11)$$

Assuming that the conduction electrons are perfectly free, we can calculate the value d_w from experimental values $X_{\max}$, λ_R, and γ_0 for each sample.

The calculated d_w values are 0.6~0.7 times d_A. This result may be reasonable, but, for the more quantitative discussions, the assumptions made in the above consideration are needed to examine.

By Eq. (7) we can determine d_w/a from the experimental value ω_R, if the depolarizing factor L is assumed. We assume that the particles are of the form of flat rotational ellipsoid with the axis of symmetry perpendicular to the film and axial ratio m. $L/4\pi$ as the function of m has the value 1/3 for $m=1$ and decreases with increasing m. For obtained experimental results several models for films structure are possible, that is, the possible range of m value is given by $d_w/2a=L/4\pi-m\omega_R{}^2/4\pi n_0e^2>0$. The interparticle spacing 'a' relaties to the true mass thickness d_w as below:

$$a=\frac{d_w}{2\left(\dfrac{L}{4\pi}-\dfrac{m}{4\pi n_0 e^2}\omega_R{}^2\right)}\,. \qquad (12)$$

For $m=1$, 2, and 3, the above equation gives the value $a\approx 3d_w$, $6d_w$ and ∞, respectively.

As for gold films, the circumstance is more complicated by the superposition of anomalous absorption on interband transition absorption band. This may be counted for one of the reasons for the smaller peak value of anomalous absorption than that of silver film.

The breadth of anomalous absorption band is of the same order as that of Hampe, but there is no appreciable dependence on thickness in contrast with his results. Before one states the damping mechanism, one will have to make clear the origin of the disagreement between experimental results.

Many features of optical anomaly appearing in their metallic films can be qualitatively understood from present view point. For example, the displacement of peak position of anomalous absorption and the wide band breadth are owing to longer joining among particles and the fluctuation of joining order. In order to explain quantatively, the exact knowledge of actual film structure is needed (Appendix II). Since the effect of heating on the film structure is large as seen in silver case, the electronmicroscopic observation does not always give us the information of film structure exactly corresponding to the optical properties.

The author wishes to thank Professor M. Kiuchi for his kind guidance and encouragement throughout the present work.

Appendix I. Calculation of Dipole Interaction Field

Suppose that N dipoles per unit area uniformly distribute on the film plane with spacing 'a', and their moments are equal and parallel. The electrostatic energy between two parallel dipoles of equal moment is given by

$$\frac{p^2}{r^2}(1-3\cos^2\psi) \qquad \text{(AI 1)}$$

where r is the distance between them and ψ is the angle between $\boldsymbol{r}$ and $\boldsymbol{p}$. Total energy is obtained from (AI 1) by summation over all dipoles, i.e.

$$\begin{aligned} I&=\Sigma_i\frac{p^2}{r_i{}^2}(1-3\cos^2\psi_i)\\ &=p^2\int_{a/2}^{\infty}\int_0^{2\pi}\frac{1}{r^2}(1-3\cos^2\psi)Nrdrd\psi \qquad \text{(AI 2)}\end{aligned}$$

where for $r>a/2$, isolated dipoles was replaced by the continuous distribution. The dipole interacting force R can be calculated by following equation:

$$(-Vn_0e)R=-\frac{\partial}{\partial\xi}I(\xi)\,. \qquad \text{(AI 3)}$$

Thus we have

$$R=2\pi\frac{N}{a}p\,. \qquad \text{(AI 4)}$$

Surface density N relates to interparticle spacing 'a' with $N=f\cdot 1/a^2$, where f is the correction factor of the order of unity. Then the field in another form is given by

$$R=f\frac{2\pi}{a^3}p\,. \qquad \text{(AI 5)}$$

It should be noted that in three dimensional case the Lorentz field was $4\pi/3\cdot 1/a^3\cdot p$ and now $2\pi\cdot 1/a^3\cdot p$, which is 3/2 times as much as that in three dimensional case.

Appendix II.

Here we consider the film composed of various type of particle form and size. We classify particles by the depolarizing factor L and volume V. The natural frequency of conduction electrons in the particle having L and V is given by

$$\omega_R^2(L)=L\frac{n_0e^2}{m}. \quad \text{for all } V \qquad (\text{AII } 1)$$

If such particles uniformly distribute on a plane with surface density N_{LV} and the average spacing a_{LV}, the dipole interacting field R is approximately given by

$$R=\Sigma_{LV}e\pi\frac{N_{LV}}{a_{LV}}P_{LV}. \qquad (\text{AII } 2)$$

The equation of motion of the electron gas in such film is

$$\ddot{p}_{LV}+\gamma_{LV}\dot{p}_{LV}+\omega_0^2(L)p_{LV} = \frac{Vn_0e^2}{m}(E_0e^{i\omega t}+R) \qquad (\text{AII } 3)$$

We take the average in following meaning:

$$\Sigma_V\frac{1}{a_{LV}^3}=\frac{1}{a_L^3},\quad \Sigma_V\frac{V}{a_{LV}^3}=\frac{V_V}{a_L^3},$$
$$\Sigma_V\frac{p_{LV}}{a_{LV}^3}=\frac{p_L}{a_{LV}^3} \qquad (\text{AII } 4)$$

and ignore the dependence γ_{LV} on L, and V. Then the equation of motion is reduced to

$$\ddot{p}_L+\gamma\dot{p}_L+\omega_0^2(L)p_L = \frac{V_Ln_0e^2}{m}\left(E_0e^{i\omega t}+\Sigma_{L'}\frac{2\pi}{a_{L'}^3}p_{L'}\right). \qquad (\text{AII } 5)$$

It is difficult to obtain the concrete solution for an actual film, but one may say that the resonance frequency distributes around the mean value so that the wide breadth of anomalous absorption band occurs.

Present view point is equal to that of Maxwell-Garnett theory. For simplicity we consider the optical properties of the three dimensional suspensoid of small spherical particles possessing the optical constants $\mathcal{E}=(\mathrm{n}-i\mathrm{k})^2$. The optical constants of the suspensoid $\mathcal{E}_e=(\mathrm{n}_e-i\mathrm{k}_e)^2$ is given by

$$\frac{\mathcal{E}_e-1}{\mathcal{E}_e+2}=q\frac{\mathcal{E}-1}{\mathcal{E}+2} \qquad (\text{AII } 6)$$

where q is the full factor of suspensoid. If the optical properties of particles is well represented by Drude-Zener formula such as sodium the optical constants $\mathcal{E}=(\mathrm{n}-i\mathrm{k})^2$ is

$$\mathcal{E}=1-\frac{\omega_p^2}{\omega^2-i\gamma\omega} \qquad (\text{AII } 7)$$

where $\omega_p^2=4\pi n_0e^2/m$, and $1/\gamma$ is the mean collision time of conducting electrons in the bulk metal. Substituting Eq. (AII 7) into Eq. (AII 6), we have

$$\mathcal{E}_e=(\mathrm{n}_e-i\mathrm{k}_e)^2=1+\frac{\omega_p^2q}{\frac{1}{3}\omega_p^2(1-q)-\omega^2+i\gamma\omega} \qquad (\text{AII } 8)$$

which is the same formula given by Hampe. Thus all the authors including the present author stand the same physical origin.. Sennett and Scott's criterion of the apperance of a maximum in the absorption vs. thickness is satisfied in the wavelength region in which the conductive absorption lay the main role for the optical properties of metal.

(Received March 2, 1960)

The electrical properties such as the electronic and ionic conductivities, Hall coefficients, etc. of the alloys Ag_2 (Te, Se; Te, S; Se, S) are studied with use of the galvanic cell Ag|AgI|specimen|Pt, the excess Ag content being controlled by sending a current across the cell. The electrical properties of these alloy systems change continuously in the α phase as the mixing ratio x is varied, while they change discontinuously or rapidly at certain x's in the β phase. The experimental results are compared with theory under simplifying assumptions such as the energy-independent relaxation time and the energy-momentum relation given by $\varepsilon=\hbar^2k^2(1-Bk^2)/2m^*$.

§ 1. Introduction

In previous works[1,2] it was shown that the comparatively large mobility of Ag ions in Ag_2VI's, namely Ag_2S, Ag_2Se and Ag_2Te, makes the study of these substances easy. This is due to the fact that the galvanic cell Ag|AgI| specimen|Pt is available and hence the excess Ag amount and free electron density in the specimen can be easily controlled by sending a proper current across the cell, from Ag-saturated state to S, Se, or Te-saturated state, and moreover the e.m.f. of the cell E gives a useful information about the position of the Fermi level in the specimen. This cell is also available in the present systems since Ag ions are as mobile in them as in Ag_2VI's. Hence we can expect that the present alloy systems can be studied with similar easiness by the help of this cell.

Before describing the electrical properties of the alloys, let us review the properties of their components, namely Ag_2Te, Ag_2Se and Ag_2S. Fig. 1 shows the electrical conductivity σ_e vs temperature for these three substances and corresponding E curves. The ionic conductivity σ_i is $1\sim4\ \Omega^{-1}\,\mathrm{cm}^{-1}$ in the α phase and much smaller in the β phase[2]. The transport number σ_i/σ_e is therefore very small (1% or less) except β-Ag_2S. See first the E graphs in Fig. 1. Since the value of E can be varied from zero (Ag-saturated state) to about 0.2 volt (VI-saturated in vacuum), it can be seen from these curves whether a given state is near to Ag- or VI-saturated state. More exactly, E is given by

$$eE=(\zeta_i^0+\zeta_e^0)-(\zeta_i+\zeta_e)\ , \qquad (1)$$

where ζ_i and ζ_e are the chemical potentials of Ag ion and electron in a sample respectively and ζ_i^0 and ζ_e^0 are those in the sample in Ag-saturated state. The α phase of these substances is known as 'average crystal' which possesses many available sites with similar occupation energies for each Ag ion[10].

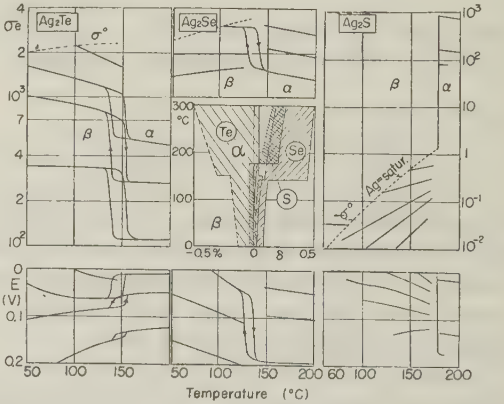

Fig. 1. $\sigma_e(\Omega^{-1}\,\mathrm{cm}^{-1})$ and corresponding E vs temperature for three Ag_2VI's. In the center is shown the permissible range of δ by hatching somewhat schematically.

In such a case, ζ_i is equal to ζ_i^0 and then eE is equal to $\zeta_e^0-\zeta_e$. In other words, E represents the position of the Fermi level relative to that in the Ag-saturated state. The crystal structure of the β phase is different and hence ζ_i will be in general different from ζ_i^0. As mentioned in the previous paper[2], such a composition-dependence of ζ_i seems remarkable in

β-Ag_2Se, negligible in β-Ag_2S and appreciable at lower temperatures in β-Ag_2Te. Thus it may be said that the E curves in Fig. 1 represent the position of the Fermi level relative to the Ag-saturated state except for β-Ag_2Te below 100°C and β-Ag_2Se. Now the figure shows that E changes suddenly at the phase transition. In particular such a change of E is so large for Ag_2S that even Ag-saturated sample is changed to S-supersaturated one at $\beta \rightarrow \alpha$ transition, accompanying precipitation or evaporation of S. In other words there is a remarkable difference of Ag-solubility between α and β phases.

We next consider the electrical conductivity curves in Fig. 1. The σ_e values are comparatively large except β-Ag_2S, while β-Ag_2S shows typical semiconducting behaviors. As for the mobility of conduction electron, see Fig. 4. From Figs. 1 and 4 we see that the change of σ_e at $\beta \rightarrow \alpha$ phase transition has different causes for different Ag_2VI's; for Ag_2Te it is due to the decrease of the electron density caused by the increase of the energy gap, for Ag_2Se it is due to the decrease of the electron mobility, the electron density being conserved, and for Ag_2S it is mainly due to the increase of the electron density caused by the escape of S.

Finally we consider the deviation from the stoichiometric composition. As mentioned above, the Ag content can be varied in a certain range. In other words the deviation lies in a certain permissible range. Hence Ag_2VI should be, exactly speaking, written as $Ag_{2+\delta}VI$ though we have omitted δ so far and shall also omit henceforth because of its smallness. Now at supply or removal of Ag across the cell the excess Ag density D is of course changed by the density of Ag supplied or removed, D being obviously related to δ by $D = N_A \delta d/A$ (N_A=Avogadro's number, d=density, and A=molecular weight). The value of D can be thus determined relatively. The absolute value of D is estimated as follows. The concentration of free electron n_1 obtained from Hall coefficient is changed at supply of Ag nearly by the change of D, for α-Ag_2Se and α-Ag_2S, indicating the simple relation $n_1 = D$. The analysis of experimental data for α-Ag_2Te shows also that the concentration of holes n_2 becomes dominant in this case but the similar simple relation

$$n_1 - n_2 = D \qquad (2)$$

seems valid, the former relation $n_1 = D$ being a special case of $n_1 \gg n_2$. Thus we have the absolute value of D. It may be noted that the validity of such a simple relation means that there is no neutral defect such as Ag ion vacancy with trapped hole.

We can now construct the permissible δ range diagram as shown in the center of Fig. 1. We see from this figure that α-Ag_2Te can contain a large amount of Ag ion vacancies while α-Ag_2Se can contain a large amount of excess Ag ions. Corresponding to these facts, the hole conductivity dominates the electron conductivity at large negative δ for α-Ag_2Te while the former is negligible and the electron gas is highly degenerate for α-Ag_2Se. In contrast, the β-Ag_2S can contain only a very small amount of excess Ag, resulting in its typical semiconducting behavior.

We have so far reviewed the general features of three Ag_2VI's. They are similar to each other in some points, e.g. they have the large ionic conductivity and plasticity in the α phase, which will be due to the similar crystal structure. On the other hand they have of course their characteristic features, and in particular β-Ag_2S is remarkably different from other β phases. When two of Ag_2VI's are mixed, the similar natures will be conserved but the different points will be gradually changed from one to the other as x is varied. In §2 such gradual changes will be surveyed. The more detailed data will be described in §3 and compared with the theory.

§2. General Survey

(a) *Experimental arrangements*

The sample is prepared by melting two of Ag_2VI's of proper proportion in a sealed silica tube. The sample obtained is soft at the α phase and so it is pressed or rolled to a plate of proper thickness at the α phase temperature. Then the specimen is cut from it to proper size. The β phase of S-rich sample (β_S phase mentioned later) is as soft as the α phase and so the S-rich samples can be rolled to thin foil at room temperature. Other β phases are rather brittle.

The volume of a specimen is estimated from its weight under the assumption that the density (A_2Te: 8.5, Ag_2Se: 8.0, Ag_2S: 7.3

g/cm³) is linearly changed with mixing ratio x. The method of measurement is the usual direct current method. To the specimen are attached Pt electrodes, Pt-headed potential probes, Ag|AgI probes, and copper constantan thermocouples on the electrodes (Fig. 10). They are set in a glass tube which is evacuated by a rotary pump. The potential differences between the probes are measured by means of a potentiometer through a rotary switch. When the temperature is lower than the phase transition point of AgI (~140°C), AgI+5%AgCl is more suitable than pure AgI for our purpose.

When a direct current is sent through Pt electrodes, the ionic current flows together with the electronic current. The former decays out soon with the time constant τ_i given by $(L/\pi)^2|d(eD)/dE|\sigma_i^{-1}$, L being the length of the specimen[2)]. The potential drop between two Pt-headed potential probes changes at such a decaying process. This change is obviously of order of σ_i/σ_e and so negligibly small in our cases except β-Ag_2S and its neighboring compositions. On the other hand the potential drop between two AgI|Ag probes appears at the instant of switching-on and off of the current and decays as such a polarization builds up and decays out. The ionic conductivity σ_i can be obtained from the time constant τ_i of this decay. In order to get a proper value of τ_i, the length of specimen should be properly chosen, e.g. 3 cm for α phases and 1~0.3 cm for β phases.

(b) *Examples of σ_e and E vs temperature and α-β transition point*

The space does not permit to describe the σ_e and E curves for many mixing ratios, so that only two examples for each system are shown in Fig. 2, where we write three systems $Ag_2Te_xSe_{1-x}$, $Ag_2Se_xS_{1-x}$ and $Ag_2Te_xS_{1-x}$ as Te-Se, Se-S, and Te-S for simplicity. From such measurements we can construct the phase diagram as shown in Fig. 3, where the curves dividing the phases are double owing to the hysteresis effect, the upper one representing the transition point at increasing temperature and the lower one at decreasing temperature.

Let us now give some explanations about Fig. 2. Comparing it with Fig. 1, we see that (d) and (f) are Ag_2S-like, (a) and (e) are Ag_2Te-like but (b) and (c) are somewhat singular, that is, the phase transition takes place twice. This double transition will be more apparent if one see Fig. 3, which shows that for $x=0.6$~0.7 in Te-Se there appears an intermediate phase between α and β phase and for Se-S the β phase is divided into two different phases. The appearance of the intermediate phase is also justified by the appearance of a step of the ionic conductivity shown by the dotted line in (b). As for the α-β transition temperature, it is not very much lowered for Te-Se and Se-S systems but it is so lowered for Te-S system that the α phase is stable at 20°C for $x=0.2$~0.8.

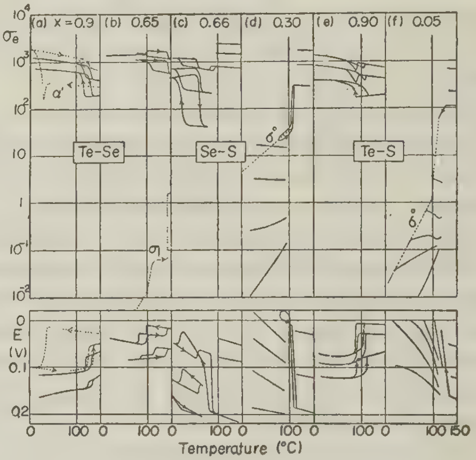

Fig. 2. $\sigma_e(\Omega^{-1}\,\mathrm{cm}^{-1})$ and corresponding E vs temperature for two examples of each system.

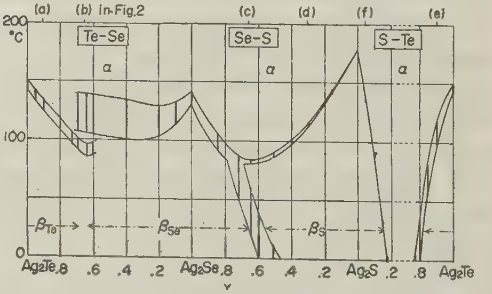

Fig. 3. Phase diagram of three systems. The examples shown in Fig. 2 correspond to the x-values shown on the upper axis.

At measurements of those transition temperatures, some complex situation appears for Te-Se system. That is, for $x=0.9$~0.6 the α-β transition is suppressed when Ag is too much removed at the α phase. As mentioned later, the α phase seems to change to another phase α' if Ag is removed over a certain amount. Once such a change occurs, α' phase does not change to β at the normal $\alpha \rightarrow \beta$ transition temperature. For example, $\alpha' \rightarrow \beta$ change is suppressed down to 40∼30°C for $x=0.9$ as shown by the dotted line in (a). For $x=0.8$ or less, α' is stable even at room temperature. When the temperature is raised up to above 300°C, α' is changed back to the previous α phase. The similar phase change is also observed for Te-S system but the suppression of the transition is not so remarkable as Te-Se system.

(c) *Mobility of conduction electron*

Fig. 4 shows $R\sigma_e$ vs temperature. Actually $R\sigma_e$ depends on eE/kT or δ (Fig. 8 (b)), especially in the case of high degeneracy as Ag_2Se and in the case of high hole density as Ag_2Te.

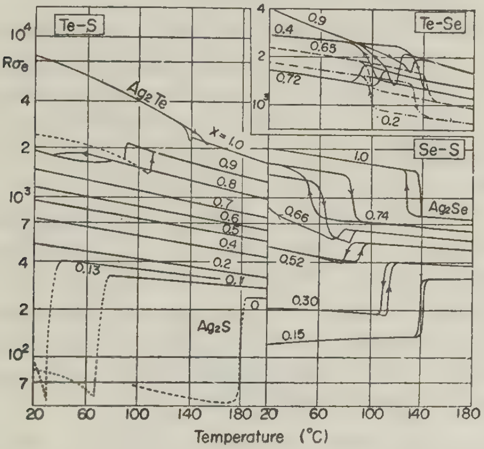

Fig. 4. $R\sigma_e$($cm^2 s^{-1} v^{-1}$) vs temperature for three systems. The $R\sigma_e$ value for $x \leq 0.13$ of Te-S is small and inaccurate and so is shown by the dotted line. For $x=0.9$ of Te-S it is somewhat affected by a heat treatment right below the transition point (quenching of the lattice disturbance at a pre-stage of the transition ?).

The values shown in Fig. 4 are almost their maximum values and may be taken as representing the electron mobilities. In order to see the x-dependence of the mobility thus obtained, Fig. 4 is rewritten to Fig. 5. We see from this figure that there are two types of x-dependence in the β phase; that is, the sensitive one in the Te-side and S-side as expressed by $\exp bx$ and rather insensitive one in the Se-side. Thus the whole β phase is divided into three regions β_{Te}, β_{Se} and β_S, as shown in Fig. 5 and also in Fig. 3. This division is in fact justified by the X ray study mentioned later. In contrast to the β phase, $R\sigma_e$ in the α phase (dotted curve in Fig. 5) is varied rather smoothly with x, suggesting the structure of the α phase is similar to each other in the whole range. In addition, Fig. 5 shows also $E_\alpha - E_\beta$ roughly which is the maximum value of the change of E at the α–β transition and so gives a measure of the difference of the Ag-solubility between two phases.

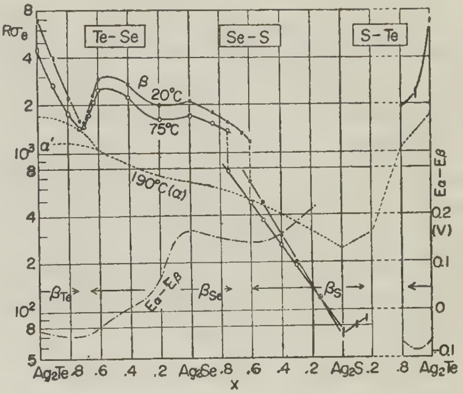

Fig. 5. $R\sigma_e$($cm^2 s^{-1} v^{-1}$) vs x. The change of E at $\alpha \rightarrow \beta$, $E_\alpha - E_\beta$, is also shown roughly in the linear scale on the right-hand ordinate axis.

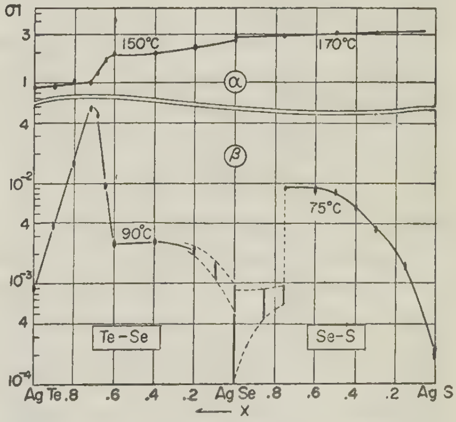

Fig. 6. σ_i($\Omega^{-1} cm^{-1}$) vs x for two systems. The graph is shortened by unit in logarithmic scale between the curves for α and for β.

(d) *Ionic conductivity*

Fig. 6 shows the x-dependence of the ionic conductivity σ_i for two systems where σ_i is estimated by the ionic polarization method mentioned already in (a) of this paragraph. As seen from the figure, σ_i is not only D-independent but also nearly x-independent in the α phase, while it is D-dependent in the

β_{Se} phase as shown by the broken lines and it is D-independent but sensitively x-dependent in the β_{Te} and β_S phases. Thus the ionic conductivity also shows that the β_{Se} phase should be distinguished from the β_{Te} and β_S phases. As for the temperature-dependence, σ_i increases slightly in the α phase but it increases rapidly (The activation energy is of the order of 0.7 ev.) in the β phase with increasing temperature.

(e) *X-ray study at room temperature*

In order to confirm the conclusion that the β phase is divided into three regions, X-ray diffraction profiles are recorded for the plates of the present systems with use of X-ray diffractometer (‘*Geigerflex*’). The result is shown in Fig. 7, twice of Bragg angle being plotted against the mixing ratio. This shows clearly that X-ray profiles are different between three β phases β_{Te}, β_{Se} and β_S, and discontinuous at their borders, justifying the conclusion mentioned above.

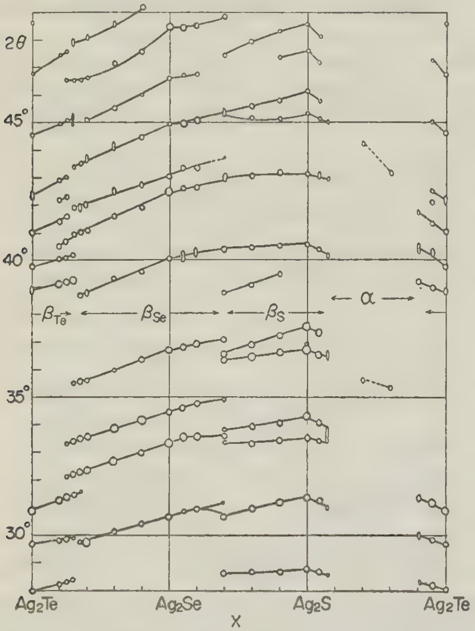

Fig. 7. 2θ (θ: Bragg angle) vs x at room temperature. The intensity of each reflection is roughly shown by the magnitude of each circle. Cu target with Ni filter.

The crystal structures of β-Ag_2VI's are of low symmetry; β-Ag_2S is reported as monoclinic ($a=9.47$Å, $b=6.92$Å, $c=8.28$Å, $\beta=124°$)[8] and β-Ag_2Te is as rhombic (16.27Å, 26.68Å, 7.55Å)[9], while β-Ag_2Se seems unknown (missing in Landolt-Börnstein (1955)). On the other hand, α-Ag_2VI's are reported as cubic[10] and so have a few reflections. In our case the α phase is stable at room temperature for $x=0.2\sim0.8$ in S–Te system, showing only two peaks in the angle range shown in Fig. 7. Further the background is dominant like amorphous substances for the α phase. The analysis of the crystal structures for our systems is thus difficult and will be left to the future. Finally we add a note on α' phase. As mentioned in (b) of this paragraph, α phase is changed to α' in a certain x range of Te–Se system and α' is stable at room temperature. The X-ray profiles of this α' are recorded, showing that they are quite different from the β phase, though not shown in Fig. 7.

§ 3. Electrical Properties as Functions of eE/kT and Discussions

In the preceding paragraph, we surveyed the general features of the present systems. In this paragraph we treat them a little more in detail. As mentioned in Introduction, E represents the relative position of the Fermi level if the chemical potential of Ag ion is D- or E-independent. Then the electrical properties such as σ_e and $R\sigma_e$ (in logarithmic scale) plotted against eE/kT can be directly compared with the corresponding theoretical curves plotted against the reduced Fermi energy. We first consider the α phase and then β phase briefly.

(a) σ_e, $R\sigma_e$ and $d(eD)/dE$ *vs* eE/kT *in the* α *phase*

Fig. 8 shows the plots vs eE/kT; (a) is of σ_e, (b) is of $R\sigma_e$, and (c) is of $d(eD)/dE$ approximated by $\Delta S/\Delta E$, where ΔS is the amount of electricity sent across AgI divided by the volume of the specimen, and ΔE is the change of E at that time. Also, the right-hand half is for Se–S system, and the left-hand half is for Te–Se and Te–S systems. Let us consider first $d(eD)/dE$, since it is not related to the scattering process. If we assume that Eq. (2) $n_1-n_2=D$ is valid and further the energy-momentum relation is of the standard form $\mathcal{E}=\hbar^2k^2/2m_1$, then we have

$$-\frac{d(eD)}{dE}=\frac{e^2}{kT}\frac{2}{\sqrt{\pi}}\left\{N_1\frac{1}{2}F_{-1/2}(\eta_1)+N_2\frac{1}{2}F_{-1/2}(\eta_2)\right\}, \qquad (3)$$

where N_1 stands for $2(2\pi m_1kTh^{-2})^{3/2}$, N_2 for the similar quantity for hole with the effective mass m_2, and $F_r(\eta)$ is the Fermi integral of order r with reduced Fermi energy η, η_2 being related to η_1 and energy gap E_G by $\eta_1+\eta_2=-E_G/kT$. As seen in Fig. 8 (c), the hole contribution given by the second term in Eq. (3) may be negligible for Se–S system in the whole range of x, while it predominates for Te-rich samples of Te–Se and –S systems. We consider therefore first Se–S system where we may assume $n_1=D$ always. Comparing Fig. 8 (c) with theoretical curve log $(F_{-1/2}/2)$ vs η (Fig. 12), e.g. overlapping two graphs (one being written on a semitransparent paper), we find that any adjustment of the origin does not make them coinside with each other. The discrepancy between them becomes larger as Se is richer or degeneracy is higher. It can be, however, removed by giving up the assumption of the standard form of conduction band as follows.

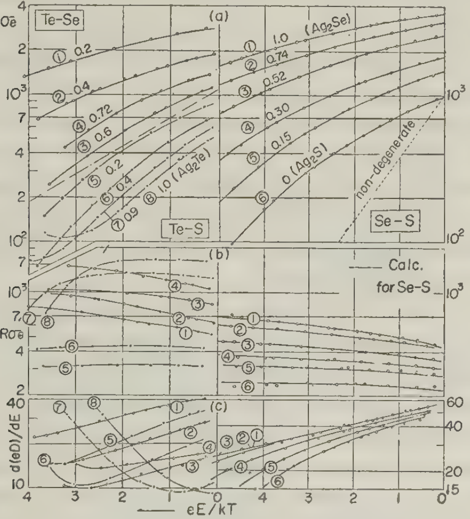

Fig. 8. (a) $\sigma_e(\Omega^{-1}\,\mathrm{cm}^{-1})$, (b) $R\sigma_e(\mathrm{cm}^2\,\mathrm{s}^{-1}\,\mathrm{v}^{-1})$, and (c) $d(eD)/dE(\mathrm{C\,cm}^{-3}\,\mathrm{v}^{-1})$ vs eE/kT in the α phase. The temperature is 170°C for Se–S except 180°C for $x=0$ (Ag_2S), 190°C for Te–Se (No. 1∼4) and 195°C for Te–S (No. 5∼8). The effect of the small temperature difference between them is not so serious as to give a notifiable change to these curves.

Let the energy of electron be given, as usually done6), by

$$\mathcal{E}=\frac{\hbar^2k^2}{2m_1}(1-Bk^2)\,, \qquad (4)$$

or reducing $\mathcal{E}$ and k to non-dimensional,

$$y=\kappa^2\left(1-\frac{a}{2}\kappa^2\right);$$

$$\kappa=\frac{\hbar}{\sqrt{2m_1kT}}|k|\,,\quad a=\frac{4m_1kT}{\hbar^2}B\,, \qquad (5)$$

where y stands for $\mathcal{E}/kT$. Then $F_{-1/2}/2$ in Eq. (3) should be replaced by G_n' defined in Appendix (Fig. 12). We choose the value of a as 0.035 so as to get best fit with experiment, assuming the same value is valid even for small x, for which a-value can not be so definitely chosen as for large x.

We next consider σ_e and $R\sigma_e$ which are related to the scattering process. Here we must assume some energy dependence of the relaxation time τ or mean free path l of free electrons. As discussed by several authors5,7), the energy dependence of τ or l relies on the scattering mechanism; e.g. the accoustical or disorder scattering leads to l=constant, the optical scattering to τ=constant for slow electrons and to $\tau\propto k$ for fast electrons, and the impurity scatterings also to their characteristic energy dependences. Furthermore two or more scatterings are present in general, making the quantitative treatment for this problem very difficult unless we have full understanding to the substance under consideration. Unfortunately, our knowledge about the scattering mechanism for the present systems characterized by the 'average, mixed, and ionic crystal with degenerate electron gas' is as yet so poor that we only choose a simple energy dependence so as to get a good agreement with the experiment as possible. The result of trial shows that the energy-independence of τ can account for the experimental data fairly well, as seen shortly. The more convincing treatment will be left to the time when we have the more detailed knowledge such as the Debye temperature, the most effective mode of lattice vibration, and the effect of average structure and alloying.

Under such a simplification, the theoretical expressions for σ_e and $R\sigma_e$ are given by

$$\sigma_e=e\mu N_1\frac{4}{3\sqrt{\pi}}G_\sigma\,,\quad R\sigma_e=\mu G_{R\sigma}\,, \qquad (6)$$

where G_σ and $G_{R\sigma}$ are as defined in Appendix, and μ stands for $e\tau/m_1$. We can draw, therefore, these theoretical curves (Fig. 12) on the experimental plots so as to get best fit. The curves for Se–S in Fig. 8 are such theoretical one, showing a good agreement with experiment. The result of such a comparison reveals that the values of μ obtained from $R\sigma_e$

are larger by a factor of about 20% than those obtained from σ_e with use of m_1-value determined from $d(eD)/dE$, or obtained from $d\sigma_e/d(eD)$, showing the experimental systematic error of such a extent which may come from the roughness of measuring magnetic field, specimen size, etc.

We consider next the Te–S and Te–Se systems. In these cases it is difficult to determine the reliable a-value for a large range of x, since the hole contribution in Fig. 8 (c) becomes predominant and further the available range of eE/kT is narrowed by the α–α' change. Hence we assume the same a-value 0.035 for every case. We may expect that this value can account for, at least, the Se-side and nearly the S-side of the systems under consideration. At any rate, under this a-value, the experiment plots can be compared with the theoretical curves although not shown in the figure. For Te-rich case, further, the energy gap can be estimated from Fig. 8 (c) if we assume the value of N_2 or m_2.

(b) *x-dependence of the electrical properties*

By the analyses mentioned above we obtain the position of the Fermi level, the effective mass of free electron m_1, and the mobility of electron μ, and further the energy gap for Te-rich case. Fig. 9 shows the result of analyses, where $\zeta_e{}^0$ is the Fermi energy in Ag-saturated state and $\mu m_1/m$ gives the τ-value (sec) by being multiplied by 5.7×10^{-16}. The lower limit of ζ_e is also shown roughly by the chain line. Thus we have the permissible range of ζ_e which corresponds to the permissible range of δ mentioned in Introduction. Seeing the $\zeta_e{}^0$ curve, we notice that it varies smoothly but has two minima near $x=0.6$ in Te-Se and –S systems. The dotted lines representing $\zeta_e{}^0$ of the α' phase continue to the $\zeta_e{}^0$ of the α phase without such minima, suggesting that, if the α and α' are different phases or of different structures, the α is Ag_2Te-like structure while the α' might be Ag_2Se (or Ag_2S)-like one rather than Ag_2Te-like. The figure shows also the positions of the top of the valence band for Te-rich samples, which is estimated, as mentioned in (a), from the hole contribution (non-degenerate) in Fig. 8 (c) under the assumption of $m_2/m=1.6$ (the mean value obtained for Ag_2Te). For comparison, those obtained optically are shown by the circles marked by ' From I. R. ' for Te–S, where they are obtained from the absorption edge at transmission of infrared ray at 20°C[4], 20°C being of course in the α phase range in this case as known from the phase diagram Fig. 3.

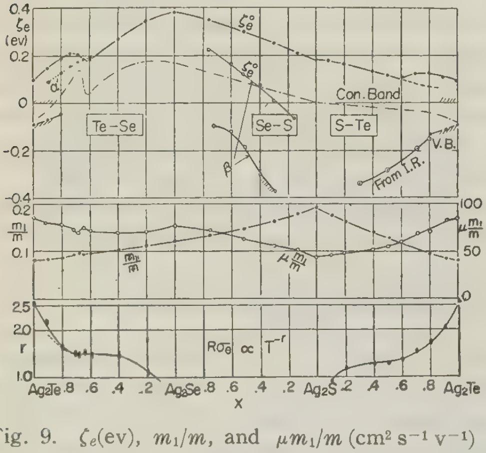

Fig. 9. ζ_e(ev), m_1/m, and $\mu m_1/m$ ($cm^2\,s^{-1}\,v^{-1}$) in the α phase (170∼200°C). The two curves in Se–S marked by β are $\zeta_e{}^0$ and valence band position at 75°C (β_s) refered later. The lowest graph shows the temperature-dependence of $R\sigma_e$ by the r-values for the α phase.

On the other hand, the middle graph of Fig. 9 shows that the electron mobility is minimum in Ag_2S because of the largest effective mass and smallest relaxation time, while it is maximum in Ag_2Te because of the opposite extrema. Further, the lowest graph shows the r-value, where $R\sigma_e$ (electron mobility) is assumed to be proportional to T^{-r} in the α phase below 300°C. The r-value for Te-rich samples is fairly large while it is small for Se–S system and not shown.

(c) *An example of α–α' transition*

In this section we consider the α–α' transition with an example of $Ag_2Te_{0.9}Se_{0.1}$ shown in Fig. 10. It shows $R\sigma_e$, σ_e, $d(eD)/dE$, the reduced thermoelectric power $\theta=e\Theta/k$ and the reduced Nernst coefficient $q=eQ/(kR\sigma_e)$. On the σ_e curve, σ_e decreases e.g. from the point A to B as Ag is removed. If Ag is supplied back without approaching B, the previous A is recovered. If B or its neighboring point is attained, σ_e begins to decrease without further removal of Ag and reaches C after sufficient waiting. Then σ_e changes on the lower curve CD and never returns to upper curve at this temperature. We call this lower state α' in contrast to the upper state α.

The two curves corresponding to α and α'

are connected by the broken lines which show the same composition or D. Comparing two values connected, we notice that the decrease of σ_e is about twice as large as the decrease of $R\sigma_e$ at B–C, that means, the concentration of free electron n_1 becomes about half, while n_1 is almost conserved at A–D as expected from the validity of $n_1=D$. This decrease of n_1 will be due to the increase of the energy gap as far as $n_1-n_2=D$ is assumed. In fact, the σ_e and θ curves in the figure show that the bottom of the conduction band shifts to the right by $1.5\,kT$ on this figure while the $d(eD)/dE$ curves show that the top of the valence band shifts to the left by about $0.7kT$.

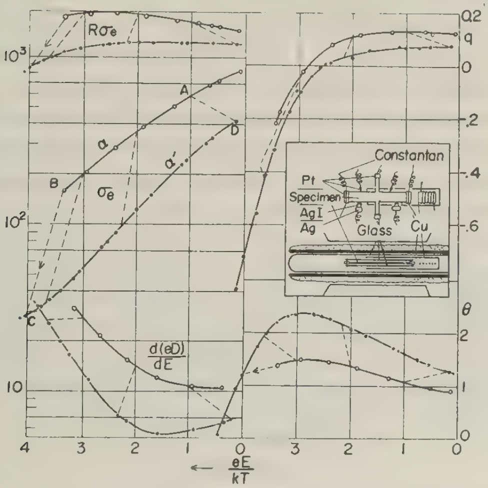

Fig. 10. An example of the $\alpha-\alpha'$ transition. $R\sigma_e$ ($cm^2\,s^{-1}\,v^{-1}$), σ_e($\Omega^{-1}\,cm^{-1}$), $d(eD)/dE$ ($C\,cm^{-3}\,v^{-1}$) in logarithmic scale and q, θ in linear scale are plotted against eE/kT at about 185°C for $Ag_2Te_{0.9}Se_{0.1}$. The schematic diagram to illustrate sample-holding is also shown.

Then the increase of the energy gap will be, summing them, about $2.2kT=\sim 90$ mv. Thus we conclude that the α–α' change is a kind of phase transition accompanying the change of the energy gap. It is also accompanied by the decrease of the electron mobility and of $\zeta_e{}^0$ or Ag-solubility. The experimental plots in Fig. 10 can not, to be regret, be satisfactorily accounted for under the assumptions taken above and so their detailed analysis will be left to the future. We only note here that the q-value and the η-dependence of $R\sigma_e$ in the small η range (0~2, where the hole contribution is negligible) decrease at $\alpha\to\alpha'$, suggesting that this transition is also accompanied by the decrease of a-value or the change of energy-dependence of τ, or both.

(d) *σ_e and $d(eD)/dE$ vs eE/kT for β_S*

As mentioned in Introduction, if the chemical potential of Ag ion ζ_i is composition-dependent, the comparison between theory and experiment as done in the preceding sections becomes impossible unless E is properly corrected. The physical meaning of this correction is in general not clear. In this respect, the β phase is more difficult to study than the α phase. This composition-dependence of ζ_i, however, decreases as the temperature is raised, and becomes negligible at sufficiently high temperatures except the β_{Se} phase, as expected from the composition-independence of σ_i in β_S and β_{Te} in contrast to the composition-dependence of σ_i in β_{Se}, as mentioned in § 2 (d). Then the comparison is possible again. As an example of such a case we shall describe the eE/kT plots for Se–S system in the β_S phase.

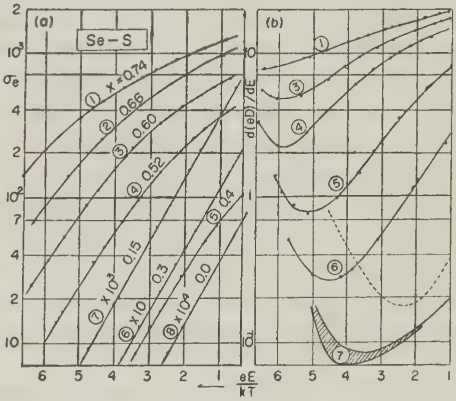

Fig. 11. (a) σ_e($\Omega^{-1}\,cm^{-1}$), (b) $d(eD)/dE$ ($C\,cm^{-3}\,v^{-1}$) vs eE/kT at 75°C for the β_S phase of Se–S. The corresponding plots for β_{Se} are very Ag_2Se-like though not shown.

Fig. 11 shows σ_e and $d(eD)/dE$ at 75°C for this case. The values of $R\sigma_e$ are almost composition- or eE/kT-independent though not shown. These curves show clearly that the non-degenerate feature of S-rich sample changes gradually to the degenerate features as seen in the α phase. In the non-degenerate case, σ_e is of course proportional to $\exp\eta$ and $d(eD)/dE$ is to be given by

$$-\frac{d(eD)}{dE}=\frac{e^2}{kT}(N_1\exp\eta_1+N_2\exp\eta_2)\,, \quad (7)$$

which is illustrated by the dotted line in (b) in the figure, showing the similarity to the experimental curves (No. 5 and 6). When x is as small as 0.15, the gradual change at supply or removal of Ag becomes ramarkable as in Ag_2S, making the value of $d(eD)/dE$ undefinite as shown by hatching (No. 7).

When the degeneracy is not very high, the position of $\eta=0$ can not determined from the curves of σ_e or $d(eD)/dE$. Therefore, it is determined from the θ (reduced thermoelectric power) vs eE/kT plots where the value of a is temporarily assumed as 0.03 which can account for the η-dependence of $d(eD)/dE$ for high degenerate case as $x=0.74$ (No. 1). The ζ_e^0-values thus determined are shown in Fig. 9, repsesenting its considerable lowering in comparison with ζ_e^0 in the α phase. To be regret, the position of $\eta=0$ estimated from θ is somewhat displaced from that obtained by the σ_e-curve in the degenerate case, showing the experimental systematic error or invalidity of our assumptions or both. Overlooking such a discrepancy, the effective mass of electron is estimated as $0.1\sim0.14m$. Next, the energy gaps are roughly estimated from Fig. 11 (b) assuming $m_2=m$, which are also shown in Fig. 9. On the other hand, the energy gap at 20°C is estimated, as the case of α Te–S, from the absorption edge at the infrared transmission in non- or slightly-degenerate samples, as 0.4 ev ($x=0.6$), 0.45 (0.52), 0.56 (0.40), and 0.65 (0.30). They have the same x-dependence with those shown in Fig. 9, although they are considerably larger than those.

Finally, we shall give a short comment about the β_S–β_{Se} transition as seen in Fig. 2 (c). The change of σ_e in this case indicates that the energy gap decreases at $\beta_S\rightarrow\beta_{Se}$. In the case of $x=0.6$, both phases are stable at 20°C; β_S is stable when the temperature is lowered down to 20°C while β_{Se} is stable when it is raised up from below 0°C as known from the phase diagram. Making use of this fact, the infrared transmission at 20°C is compared between two phases for a specimen of $x=0.6$. The result is just as expected; as the cooling time is longer, the transmission decreases remarkably. This decrease is obviously due to the shift of the absorption edge and the increase of the free carrier absorption.

We have so far tried to show how the electrical properties of Ag_2VI's are varied from one to the other by mixing two of them. As mentioned already the assumption of constant τ has no convincing theoretical basis at the present stage. We can only say which energy dependence leads to better agreement with experiment. At such a choice of the energy dependence, the introduction of the a-value makes the definite choice very difficult. For example, the η-dependence of $R\sigma_e$ and the positive q-value observed in α-Ag_2Se can not be accounted for by constant τ but fairly well accounted for by constant l[1)] as far as the a-value is assumed zero. If the assumption of $a=0$ is abandoned, however, the situation becomes quite different, that is, constant τ is better than constant l under proper a-value, as seen already. For Ag_2Te and Ag_2S, the ambiguity in such a choice is more profound, since the a-value can not exactly determined in these cases. Thus we see that we should have more detailed informations for our systems in order to proceed farther.

The author wishes to express his sincere thanks to Mr. Suzuki, Mr. Yokota, and Mr. Haga in our Department of Physics for their kind advices and discussions. The present work was supported by the Scientific Research Fund of the Ministry of Education.

Appendix

Every expression in the reference (3), treating two-band semiconductor under the assumptions of $a=0$ and $l=l_0y^r$ ($y=\mathcal{E}/kT$), keeps its validity for the more general case where $y=y(\kappa^2)$ and $\tau=\tau_0t(y)$, κ being defined in Eq. (5), if

$$\left\{p\left(r-\frac{1}{2}\right)+\frac{3}{2}+n\right\}F_{p\{r-(1/2)\}+(1/2)+n};\quad p=1,2,3\,,\quad n=0,1\,,\tag{8}$$

used there is replaced by its generalized expression given by[5,6,7]

$$K_{pn}=-\int\kappa^{3-p}\left(\frac{t}{2}\frac{dy}{d\kappa}\right)^p y^n\frac{\partial f}{\partial y}dy\,.\tag{9}$$

The μ defined there by $el_0(2m^*kT)^{-1/2}$ is to be taken here as $e\tau_0/m^*$ and α, β, γ, δ, φ and ψ are accordingly generalized as

$$\left.\begin{aligned}\alpha=\frac{K_{20}}{K_{10}}\,,\quad\beta=\frac{K_{11}}{K_{10}}\,,\quad\gamma=\frac{K_{21}}{K_{10}}\,,\\ \delta=\frac{K_{13}}{K_{10}}\,,\quad\varphi=\frac{K_{30}}{K_{10}}\,,\quad\psi=\frac{K_{31}}{K_{10}}\,.\end{aligned}\right\}\tag{10}$$

It is easily seen that the expression (9) is reduced to (8) if $t=y^{r-(1/2)}$, and $y=\kappa^2$. As another special case, if $t=1$ and $y=\kappa^2(1-a\kappa^2/2)$ as Eq. (5), K_{pn} is reduced to L_{pn} expressed as

$$L_{pn}=-\int\left(\frac{1-z}{a}\right)^{3/2}z^p y_n\frac{\partial f}{\partial y}dy;\qquad z=\sqrt{1-2ay}\,. \tag{11}$$

Then we have, for single carrier,

$$-\frac{d(eD)}{dE}=\frac{e^2}{kT}\frac{2}{\sqrt{\pi}}N_1G_n';$$

$$G_n'=\int\left(\frac{1-z}{a}\right)^{1/2}\frac{1}{z}\frac{\partial f}{\partial y}dy\,, \tag{12}$$

$$\sigma_e=\frac{4e\mu N_1}{3\sqrt{\pi}}L_{11}\,,\quad R\sigma_e=\mu\frac{L_{20}}{L_{10}}\,,\quad q=\frac{L_{11}}{L_{10}}-\frac{L_{21}}{L_{20}}\,. \tag{13}$$

Rewritting L_{11} and L_{20}/L_{10} in Eq. (13) as G_σ and $G_{R\sigma}$, we have Eq. (6).

These integrals G_n', G_σ, etc. can be evaluated, the a-value being chosen properly, by expanding the integrands in terms of y and using the numerical table of F_r (r: half integer)[7] for small η-values (<5), while by using the high degeneracy approximation for large η-values (>5)[5]. Fig. 12 shows various theoretical curves thus obtained together with the special cases of (1) $a=0$, τ=constant and (3) $a=0$ and l=constant. Further, it shows two examples of experimental q-value at 170°C, indicating the better applicability of curve (2) or (2′) in comparison to (1) or (3).

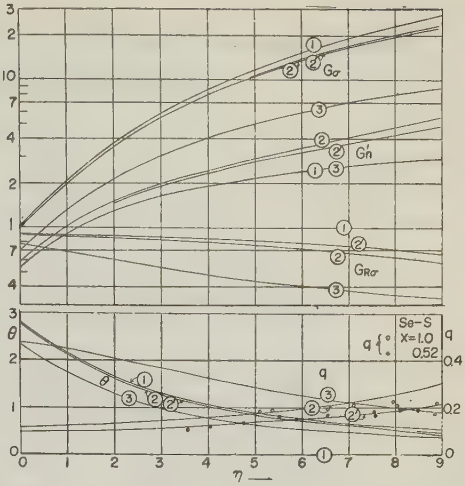

Fig. 12. Theoretical curves; (1) $a=0$, (2) $a=0.035$, (2′) $a=0.03$, where τ is energy-independent, while (3) $a=0$ and the mean free path is energy-independent, or $\tau=\tau_0y^{-1/2}$. The examples of experimental q-value are also shown.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 15, No. 9, SEPTEMBER, 1960

Temperature Dependence of the Optical Absorption Edge of Tungsten Trioxide Single Crystal

By Tsuruji IWAI

Faculty of Science, Osaka University, Osaka

(Received March 4, 1960)

The optical absorption edge of WO_3 single crystal has been measured with polarized light over the temperature range from −100°C to 900°C. From 0°C to about 700°C, the absorption edge shifts linearly toward red with increasing temperature, the temperature coefficients being -9.0×10^{-4} ev/deg for the case of light polarized in the direction parallel to the a-axis (a-polarized light) and -6.5×10^{-4} ev/deg for the case of light polarized in the direction parallel to the c-axis (c-polarized light), respectively.

In the vicinity of −50°C, an anomalous shift of the absorption edge takes place. This is attributed to the phase transition. In the low temperature phase, the extinction position is different from that in the high temperature phase. In addition, when the temperature is raised through 740°C, a sudden red shift takes place for the case of a-polarized light, the magnitude being about 0.35 ev, while no anomaly occurs for c-polarized light.

§ 1. Introduction

A report has previously been published on the optical absorption edge of WO_3 single crystals[1]. But it is limited to the case in which natural light falls on a platelike crystal having its c-axis perpendicular to the plate (c-crystal). According to the measurements of the optical indices of refraction[2], the optical anisotropy of WO_3 is larger than that of other perovskite-type ferroelectrics. Furthermore, it has been observed that WO_3 shows pleochroism at room temperature[3]. Judging from these facts, it may be desired that the temperature dependence of the optical absorption will be measured by use of the polarized light corresponding to the symmetry of the crystal.

The color of WO_3 crystals becomes deeper when the temperature is raised as seen in many other polar crystals. When the orthorhombic-to-tetragonal transition takes place at 740°C, the color shows an abrupt change from reddish yellow to dark red. According to the visual observation of a b-plane by S. Sawada *et al.*[4], this sudden change occurs only in the case of observations with the light polarized in the direction parallel to the a-axis (a-polarized light).

WO_3 has several transition points at about −50°C, (or −40°C and 17°C)[5], 330°C, 740°C, and 910°C etc. The optical absorption edge has been measured with polarized light over the temperature range covering almost all of these transition points. Above 900°C, however, no measurement has been done because of strong radiation from the background. Furthermore, when WO_3 is kept above 700°C for a long time, its surface becomes pitted and dirty owing to sublimation. Therefore, the measurements at temperatures above 700°C was possible only in the heating procedure.

§ 2. Experimental

The greater part of the WO_3 single crystals prepared with a sublimation method were c-crystals. From among them, several c-crystals about 50 μ thick were chosen and used as specimens. Some b-crystals about 100 μ thick were also obtained by cleaving the larger c-crystals. These samples had not the so-called 90° domains i.e. a-b or a-c domains.

1) b-plane: When a- or c-polarized light was incident perpendicularly upon the b-plane of WO_3, the light transmitted through the crystal was examined with the aid of a small quartz prism spectrograph. A tungsten lamp was used as a continuous light source and polarized light was obtained with Nicols. In Fig. 1, (a) is the continuous spectrum of the light source, while (b)- and (c)-series are the absorption spectra of a thin crystal at room temperature for a- and c-polarized light. Each series shows the dependence of the spectrum on the exposure time. As seen in Fig. 1, if an exposure time is sufficiently long, the end of the continuum at the shorter wavelength side is hardly changed for any longer exposure. At any temperature, the wavelength of the terminal for such a long exposure is adopted as the absorption edge. This value may correspond to that at the steep part of the usual absorption curves. The temperature dependence of the absorption edge was measured over the range from −100°C to 900°C. The result obtained is shown in Fig. 2.

At any temperature, the wave-length of the absorption edge for *a*-polarized light is a little longer than that for *c*-polarized light. However, the absorption edge shifts linearly toward red simlarly in both cases, as the temperature is raised from room temperature to about 700°C, and we can not observe any anomaly associated with the monoclinic-to-orthorhombic transition at 330°C. In this linear region, the temperature coefficients of the shifts are as follows:

-9.0×10^{-4} ev/deg for *a*-polarized light,

and

-6.5×10^{-4} ev/deg for *c*-polarized light.

Around the transition point at −50°C, anomalous shifts are observed for both polarized light cases. In each case, the shift occurs along a different path on heating and cooling. The most remarkable shift takes place at 740°C, the orthorhombic-to-tetragonal transition point. Namely, for *a*-polarized light, the absorption edge suddenly shifts far into the near infrared, the magnitude being about 0.35 ev, while, for *c*-polarized light, such a sudden shift does not take place.

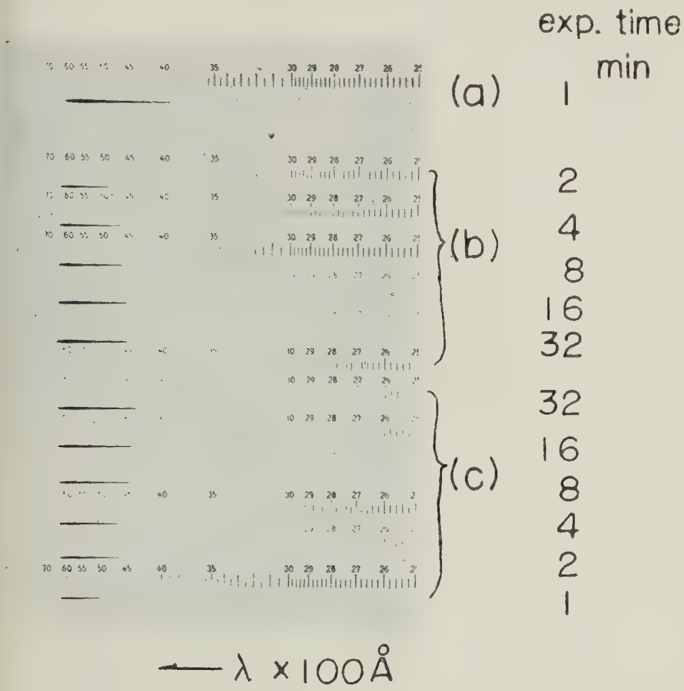

Fig. 1. Optical absorption in *b*-crystal

2) *c-plane*: By use of *a*- and *b*-polarized light, the same experiments as in the case of *b*-plane were carried out. The results are shown in Figs. 3 and 4. Roughly speaking, the temperature dependence of the absorption edge is in agreement with the result for *b*-plane with *a*-polarized light. However, there seems to be some difference between the two cases

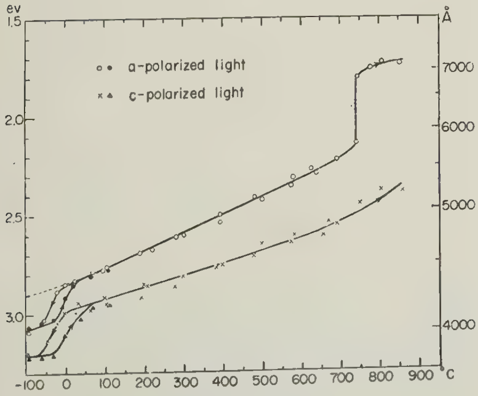

Fig. 2. Optical absorption edge *versus* temperature in *b* plane

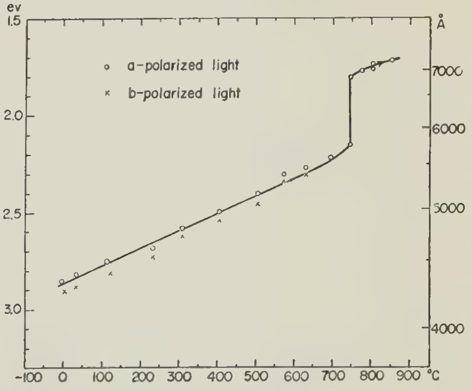

Fig. 3. Optical absorption edge *versus* temperature in *c*-plane

with *a*- and *b*-polarized light. In the temperature range from room temperature to about 700°C, the absorption edge for *a*-polarized light always appears on the longer wave-length side than that for *b*-polarized light, though the difference is small (about 50 Å~100 Å), while they coincide with each other below −50°C as shown in Fig. 4.

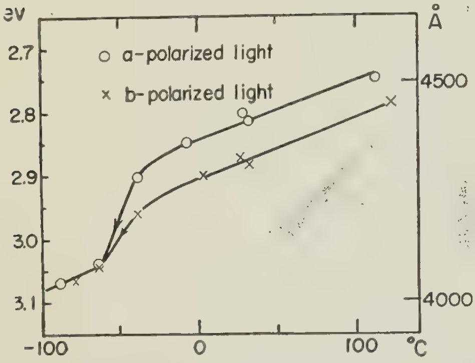

Fig. 4. Optical absorption edge *versus* temperature in *c*-plane

§3. Discussions

1) *From 0°C to 700°C*: In this temperature range, the absorption edge shifts toward longer wave-lengths for any polarized light, as the temperature is elevated. The red shift of the absorption edge has been investigated theoretically[6], and explained by the interactions between the lattice vibrations and the electrons in the crystal. These theories show that the shift is represented qualitatively by

$$E=\alpha-\beta T \quad (T\gg\Theta),$$

where E is the energy of the absorption edge, α and β are the constants characteristic to the crystal, T is the absolute temperature of the crystal, and Θ is the Debye temperature of the crystal. Since the symmetry of WO_3 is not cubic, and several physical constants (*e.g.* Debye temperature etc.) are unknown, the experimental results can not be compared with the theory directly. At any rate, the experimental curve is satisfied with the above expression, qualitatively. The values of α and β estimated in this temperature region are as follows:

$\alpha=3.1_1$ ev, $\beta=9.0\times10^{-4}$ ev/deg,
for *a*-polarized light,

and

$\alpha=3.1_5$ ev, $\beta=6.5\times10^{-4}$ ev/deg,
for *c*-polarized light.

These temperature coefficients are close to the values which have been well known in normal ionic crystals[7] and $BaTiO_3$[8]. Thus, these linear shifts may be due to the interactions between the lattice vibrations and the electrons in the crystals.

2) *Below 0°C*: According to the measurements with $BaTiO_3$ single crystals[8], at the orthorhombic-to-rhombohedral transition point the transparency decreases very much, and the absorption edge shifts suddenly toward red in appearance, because of multidomains in the low temperature phase (rhombohedral phase). When WO_3 is cooled, the multidomain structure as shown in Fig. 5 appears at about −50°C, at the same time as the transition to the low temperature phase happens. Therefore, the anomalous shifts about this transition point might be apparent as in the case of $BaTiO_3$. If so, the shifts should take place toward longer wave-lengths in contradiction to the experimental curves. Therefore the shifts of the absorption edge accompanied with this transition can not be attributed to the multidomain effect. In fact, by the microscopic inspection, the color of WO_3, light green just above this transition point, becomes pale, as soon as the multidomains have appeared.

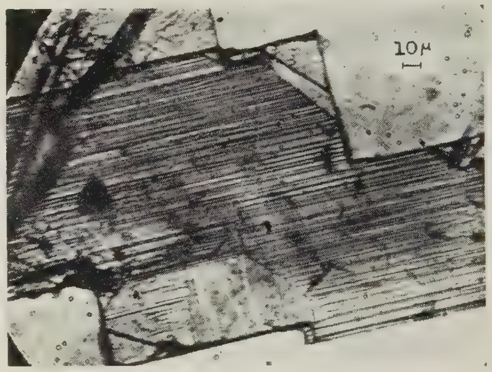

Fig. 5. The domain structure of WO_3 below −50°C

The extinction position of a *c*-plane changes abruptly with this transition. In the low temperature phase it makes an angle of about 45° with the monoclinic *b*-axis, while it is parallel or perpendicular to the *b*-axis in the high temperature phase. Then the direction of a- or b-polarized light is no longer parallel to anyone of the optic elasticity axes in the low temperature phase. This may be the reason why any distinction of the absorption edge between a- and b-polarized light cases is not observed in the low temperature phase as shown in Fig. 4. On the other hand, such an abrupt change in regard to the extinction position of a b-plane does not occur, and the discrepancy of the absorption edge between the a- and c-polarized light cases is also seen in the low temperature phase.

According to T. Muto *et al.*[6], the shift of the absorption edge due to the interactions between the lattice vibrations and the electrons at low temperatures is expressed by

$$E=\alpha'-\beta' \exp(\Theta/T) \quad (T \ll \Theta) .$$

This means simply a deviation from the linear dependence on temperature. The experimental curves, however, are not so simple, but exhibit obviously the temperature hysteresis loops. Thus, it is difficult to believe that the anomalous shift is a deviation from the linear dependence as mentioned above*. Then, it is natural to suppose that the shift should be attributed to the phase transition. Such an anomalous shift related to the phase transition has not yet been observed in the case of $BaTiO_3$.

3) *From 700°C to 900°C*: Accordingly to S. Sawada *et al.*[4], a polydomain structure appears in the tetragonal phase above 740°C, and then vanishes at about 810°C. Therefore, in the range from 740°C to 810°C, the incident ray of light may be refracted or reflected at plenty of domain walls. As a result, there is some possibility that the absorption edge may suddenly shift in appearance at 740°C just as in the case of the low temperature phase of $BaTiO_3$. However, such an apparent absorption should disappears above 810°C. Moreover, any abrupt shift is not observed for c-polarized light. From these facts, the sudden shift observed in the case of a-polarized light can not be considered to be a mere apparent phenomenon.

Then, some other mechanisms should be taken into consideration to explain this anomaly. There are two mechanisms at least that must not be neglected. The first is based on migrations of some oxygen atoms. When WO_3 single crystals are kept in vacuum above 740°C for a long time, they are likely to be reduced and the surfaces assume metallic luster. Magnèli and Hagedüs *et al.*[9] have shown that there are several kinds of reduced forms of tungsten oxides. Judging from this situation, it may be supposed that some oxygen atoms in the interior of WO_3 are apt to move from their normal sites at high temperatures. Therefore, if one assumes that the concentration of oxygen vacancies increases when the phase changes from orthorhombic to tetragonal, the optical absorption due to such a lattice imperfection is expected to be much more intense in the tetragonal phase than in the orthorhombic phase[1]. This optical absorption band might appear on a little longer wavelength side than the intrinsic absorption band edge. Accordingly, the superposition of the intrinsic absorption with the absorption band due to such a lattice imperfection in the tetragonal phase may give rise to the optical anomaly at 740°C. Such being the case, the anisotropic character of the absorption edge, that is, the fact that the sudden shift takes place only for the case of a- or b-polarized light may be attributed to the anisotropic character of a lattice imperfection**.

---

* According to S. Sawada[10] the value of specific heat begins to decrease gradually at about 0°C, when the temperature is lowered. Then assuming $\Theta=300°K$, and using the temperature coefficients of the linear red shift, the calculated curve on the low temperature side is a dotted line in Fig. 2 for the case of a-polarized light.

** If oxygen ions lining up in the direction of the a-, b-, and c-axes are called O_a, O_b, and O_c respectively, as discussed in the previous paper[1], it may be expected that the O_a is especially movable in the tetragonal phase. Then, suppose that any one of O_a-site becomes vacant, and two electrons will be trapped around the vacancy to keep the electrical neutrality. Since two W ions always close to the vacancy, the trapped electrons may roughly be considered to move around the two W ions. Such a model resembles a hydrogenlike molecule. When the electron in such a hydrogenlike molecule makes the optical transition from its ground state to the first excited state, the dominant component of the transition matrix element of the dipole moment will be that along the direction joining the two nuclei. Since this direction coincides with the a-axis in the present case, such optical absorption can be observed for a-polarized light case, but not for c-polarized light in the dipole transition approximation.

The second is based on energy band considerations. The energy band scheme would depend on the nature of the crystalline field and vary with the symmetry of the crystal. Then, the energy band structure of WO_3 can be expected to change with the phase transition. As many authors[11] pointed out in wurtzite structure materials, the optical transition between the valence and conduction bands follows the proper selection rule for the crystal structure, which depends on polarization of the incident light in the anisotropic crystal. In tetragonal $BaTiO_3$, R. C. Casella *et al.*[12] have observed the dichroic effect at the absorption edge, which disappears in the cubic phase. They also treated this phenomenon in terms of band-band transitions. Therefore, energy band considerations would lead one to expect the anisotropy of the optical absorption edge (pleochroism) and also the sudden shift of the absorption edge associated with the phase transition in WO_3 without assuming any lattice defect***. From this point of view, the intrinsic absorption edge itself would be expected to show a shift, owing to the change of the band structure, when the phase changes from orthorhombic to tetragonal.

At the present stage, however, it may be too early to decide which one of the two mechanisms mentioned above is more important, because the low resolving power of the spectrograph used prevented the author from getting information about any detailed structure of the absorption edge.

This work has been carried out under the guidance of Professor T. Horie, to whom the author wishes to express his sincere gratitude. The author wishes to express his sincere thanks to Professor S. Sawada of Tokyo Institute of Technology for valuable suggestion and kind advice. The author also wishes to express his gratitude to Lect. K. Kawabe of Kobe University, Dr. T. Kojima of Osaka City University and Mr. T. Kojima of Kinki University for their valuable discussions and criticisms. He wishes to thank Mr. E. Hirota and Mr. A. Tsubaki for their valuable assistance.

*** Going along this line, the pleochroism of WO_3 may be attributed to the splitting of the electronic state, of which the energy band is composed, due to the crystalline field. If the wave-lengths of the absorption edge for *a*-, *b*-, and *c*-polarized light are called λ_a, λ_b, and λ_c respectively, from the experimental result it follows:

$\lambda_a-\lambda_b\approx100$ Å (0.05 ev), $\lambda_a-\lambda_c\approx700$ Å (0.3 ev) in the orthorhombic phase, $\lambda_a=\lambda_b$, $\lambda_a-\lambda_c\approx1800$ Å (0.6 ev) in the tetragonal phase. This value is considerably larger than that roughly estimated from the dichroic data in tetragonal $BaTiO_3$[12] (0.02～0.03 ev) in the region where the dichroic peak is located.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 15, No. 9, SEPTEMBER, 1960

Association of Vacancies with Calcium Impurities in Potassium Chloride Crystals

By Tosiyuki NINOMIYA

The Institute for Solid State Physics, the University of Tokyo, Tokyo

(Received June 4, 1960)

Measurements are made on the dc conductivity and dielectric loss in quenched KCl crystals doped with small amount of $CaCl_2$. The evidence for formation of higher complexes is obtained from the decay of the conductivity during annealing after quenching. It is also found that there exists a relation between the number of free vacancies, n_v, and that of impurity-vacancy associated pairs, n_p, during the decay at a fixed temperature,

$$n_p = K' n_v^{1.92}.$$

The number of the free vacancies is found to decay exponentially with time. The activation energy for the decay is estimated to be 0.63 ± 0.1 eV.

§1. Introduction

One of the conventional methods of investigation of atomic defects in ionic crystals is to add small amount of divalent impurities to the host crystals[1]. Results obtained are usually analysed on the assumptions that these impurity ions are dissolved substitutionally in the lattice and there exist free vacancies and impurity-vacancy associated pairs in it besides isolated impurity ions. On the other hand, Haven suggested the existence of higher complexes, that is, impurity-vacancy clusters[2]. He measured dielectric loss in NaCl containing $CaCl_2$ at 110°C and estimated the concentration of the free vacancies from the low frequency conductivity and that of the pairs from the height of the loss peak. A sum of these two concentrations was found to be smaller than the concentration of the added impurity. It seems, however, to remain some ambiguity in his analysis, because we have neither reliable knowledge about the mobility of the free vacancies at these low temperatures nor about the dipole moment of the pairs[3].

The purpose of the present paper is to investigate the state of the impurities in KCl and provide a new evidence for formation of the aggregates of calcium impurities in the crystal.

§2. Theory

In ionic crystals the addition of divalent cation impurities leads to the formation of cation vacancies. These vacancies tend to associate with isolated impurity ions owing to the Coulomb interaction between these opposite charges. The degree of association decreases with increasing temperature. Then, in a quenched crystal an excess concentration of free vacancies and isolated impurity ions is retained and they migrate to form impurity-vacancy associated pairs and higher complexes, when the crystal is held at a fixed temperature after quenching.

Under the condition that crystals are quenched from a temperature, in which positive ion vacancies introduced with divalent impurities are predominant, a sum of the number of the free vacancies, $n_v(t)$, and that of the pairs, $n_p(t)$, should remain constant during annealing after quenching unless precipitates or higher complexes are created. Then,

$$n_v(t) + n_p(t) = N. \qquad (1)$$

Eq. (1) gives a straight line as shown in curve *a* of Fig. 1, when plotted in a n_v versus n_p curve.

In the case in which the formation of higher complexes occurs during the annealing process, a sum of the numbers of the vacancies and the pairs decreases with time and a trajectory becomes curvilinear. (Fig. 1 curve *b* or *c*) Curve *c* can be expected if a rate of formation of higher complexes is slower than that of formation of simple associated pairs.

So long as quenching strain has no influence on the mobility of free vacancies, their number is proportional to dc conductivity or ac conductivity at low frequencies. The existence of associated pairs gives rise to dielectric loss in a crystal and its peak height is proportional to their number. Therefore, if observed dc conductivity is plotted against tan δ due to the pairs, a valuable information about the higher complexes or precipitates may be obtained from the shape of the obtained curve.

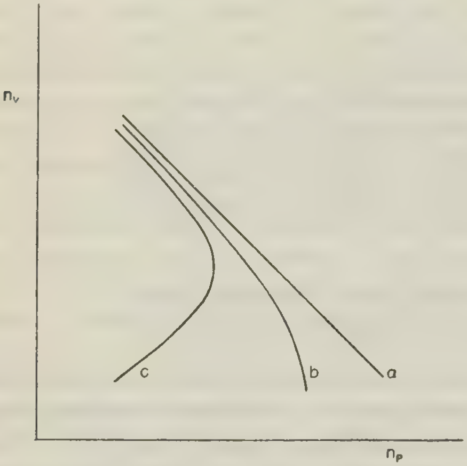

Fig. 1. Trajectory of the numbers of defects after quenching.

§ 3. Experimental Procedure

KCl crystals used as source material were purified beforehand by normal freezing of powder of Wako reagent grade purity. These pure crystals show neither dielectric loss of Debye type due to associated pairs, nor change in their conductivity after quenching.

Specimen crystals were grown from the melt of the above source material, into which $1\times10^{-2}\sim5\times10^{-2}$ mole per cent of $CaCl_2$ had been added, by the normal freezing method using a platinum boat in the atmosphere of purified nitrogen. The end of crystals solidified in a boat was turbid and milky looking, when cooled slowly to room temperature. Only transparent portions were used in the measurements.

The concentration of Ca^{++} impurities was estimated from the dc conductivity at 372°C by making reference to the data given by Kelting and Witt[4] for KCl-$CaCl_2$ system. Those for pure crystals were also estimated to be about 2×10^{-4} mole per cent.

The crystals were cleaved into pieces about $4\times5\times2$ mm for quenching experiments. After heating these crystals at about 530°C, which is still in the impurity range, in a vacuum vessel for several hours, quenching was done by removing the vessel from a furnace and making air flow into it. Most of the quenched crystals were cleaved into three pieces as shown in Fig. 2, and the hatched section was used for measurements in order to avoid an effect of inhomogeneity. Some crystals were measured after all surface layers of about 0.8 mm thickness were removed by cleavage in order to investigate an effect of surface contamination. These gave the same results as those crystals shown in Fig. 2.

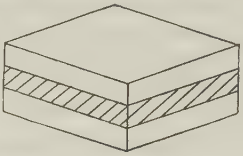

Fig. 2. Cleavage of a quenched crystal. The hatched section was used for measuremets of conductivity.

The ac conductivity was measured with the ac bridge.[5] Measurements of the dc conductivity were made with the $\mu\mu$-A meter which has a time constant of 1 second. Electrodes were applied with silver paints. Colloidal graphite was also used for the measurements of the dc conductivity up to high temperatures.

The decay of the conductivity was measured at various selected temperatures after keeping quenched crystals for about 20 hours

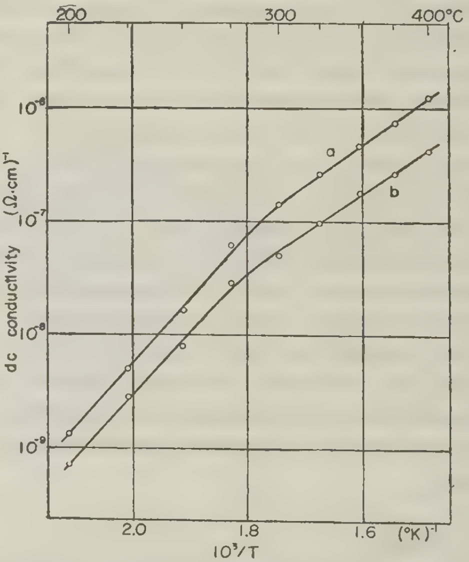

Fig. 3. Dc conductivity of annealed crystals doped with Ca^{++}. Impurity concentration
a: 0.01 mole per cent
b: 0.003 mole per cent

at room temperature. It took 30~60 minutes to raise the temperature of crystals to the selected one from room temperature. Therefore, we could not observe a change which took place during the resting and the temperature increasing.

§ 4. Experimental Results

a) *Dc conductivity of annealed crystals*

The dc conductivity of the doped crystals, which were annealed in the atmosphere of nitrogen at 650°C for 11 hours and cooled to room temperature at a rate of 10 deg/hr, were shown in Fig. 3. The curve for a crystal containing 0.01% Ca^{++} shows a portion of steeper slope below 300°C and, when the measurements were made while the crystal was cooled from 400°C at a more rapid rate than 150°C/hr, an increasing cooling rate results in a larger conductivity in this temperature range.

b) *Dielectric loss in annealed and quenched crystals*

The dielectric loss curve plotted against frequency for annealed crystals shows one peak, which is 1.25 times wider than a simple Debye type loss as shown in Fig. 4. This peak is supposed to be the loss due to impurity-vacancy associated pairs in comparison with the results by Dryden.[6]

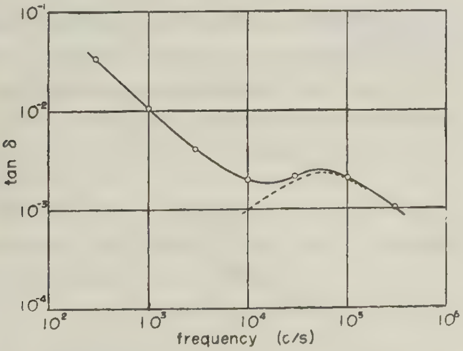

Fig. 4. Dielectric loss in an annealed crystal containing 0.01% Ca^{++} at 143°C.

Dielectric loss in a quenched crystal was also measured. Curve *a* and *b* in Fig. 5 show losses which were measured 10 min. and 5.5 hours after the beginning of decay observation, respectively. Curve *b* is shifted down to make the figure distinctive. The magnitude of the loss peak of curve *b* is smaller than that of curve *a* by 22%. Changes of neither the position nor the shape of the loss peak due to the pairs were observed during annealing at 144°C.

From those results we may conclude that we can follow a change of the number of the pairs during a decay if we measure a magnitude of dielectric loss at a fixed frequency. We chose 100 kc/s as the measuring frequency.

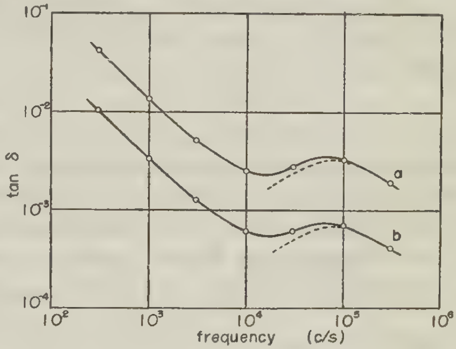

Fig. 5. Dielectric loss in a quanched crystal containing 0.006% Ca^{++} at 144°C. Curve *b* is shifted down to make the figure distinctive. (see text)

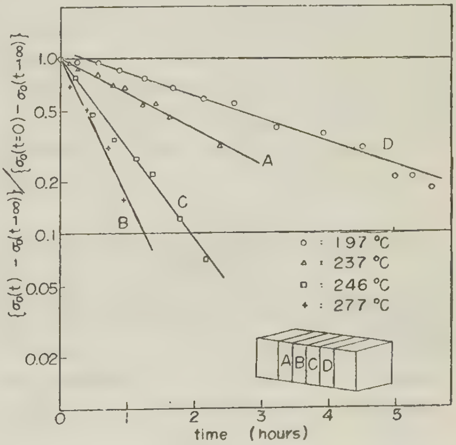

Fig. 6. Decay of dc conductivity after quenching.

c) *Decay of dc conductivity*

The dc conductivity was found to decay exponentially with time. The temperature dependence of the relaxation time for decay was investigated on the four pieces A, B, C and D, which were obtained by cleavage from one quenched crystal containing 0.01% Ca^{++}, as shown in Fig. 6. The origin of time was the time at which the temperature of crystal reaches the selected one. The activation energy for the decay was obtained to be 0.63±0.1 eV. (Fig. 7) Decay could not be observed above 200°C for a crystal containing 0.003% Ca^{++}, but at 144°C the conductivity decayed slightly (a few per cent).

d) *Ac conductivity decay*

Simultaneous measurements were made on dc conductivity, ac conductivity at 300 c/s and dielectric loss at 100 kc/s during annealing at 144°C for a quenched crystal containing 0.01% Ca^{++}. The dc conductivity, σ_0, and the conductivity at 300 c/s, σ_{300}, decayed, keeping a relation

$$\sigma_{300}=K_1\sigma_0 \qquad (2)$$

as shown in Fig. 8. K_1 was about 1.6 and this suggests that the measured value of the dc conductivity was affected by polarization. But, at the same time, this relation shows that the magnitude of the dc conductivity is proportional to the number of the free vacancies in spite of polarization effect.

To the dielectric loss at 100 kc/s both the simple associated pairs and the free vacancies contribute. The magnitude of the contribution from the latter can be estimated from the conductivity at 300 c/s. This was only 3~4% of the total loss. By subtracting this value from the observed loss, the contribution from the former could be obtained. Fig. 9 shows a curve of the logarithum of $\sigma_0(t)$ versus the logarithum of $\tan\delta$ due to the pairs, $\tan\delta_{\rm pair}$. This curve can be fitted by a relation

$$\tan\delta_{\rm pair}=K_2\ \sigma_0^{1.92}. \qquad (3)$$

The nearly same value of K_2 was obtained for crystals containg Ca^{++}, the concentration of which is 0.003% to 0.02%, at the same temperature.

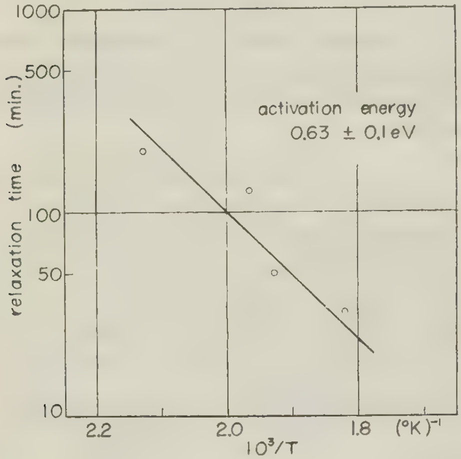

Fig. 7. Relaxation time for decay of dc conductivities.

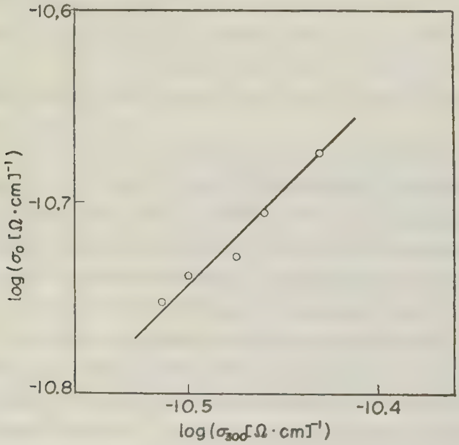

Fig. 8. Relation of dc conductivity and ac conductivity at 300 c/s during decay at 144°C.

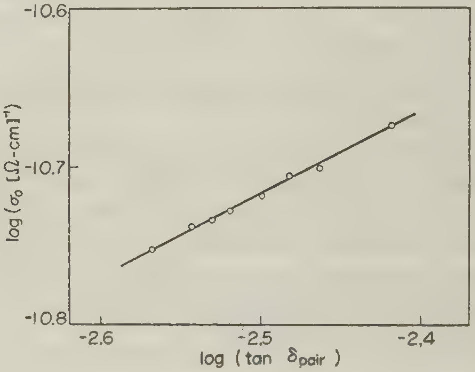

Fig. 9. Trajectry of conductivity during annealing at 144°C.

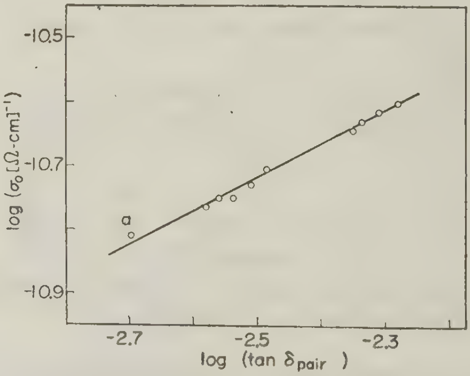

Fig. 10. Trajectory of conductivity during annealing at 144°C.

A quenched crystal containing 0.02% Ca^{++} was cooled slowly to room temperature after the decay of the conductivity was measured at 144°C for several hours, and was again heated to 144°C after keeping at room temperature for 19 hours and the measurement was continued. The result is shown in Fig. 10. The point *a* is that obtained in the measurement after resting at room temperature. The other points are those in first annealing. A straight line could be drawn through all these points and the same relation as the formula (3) was obtained.

For another crystal we made a similar measurement, but by heating the crystal for several hours up to higher temperature by 10 degrees in the course of annealing instead of cooling. The same relation was also available.

§ 5. Discussion

a) *Possible influence of quenching strains on the conductivity*

In ionic crystals the thermal conductivity is very small and thermal stresses cause plastic deformations. If quenching strains had an influence on the jump frequency of the bound vacancy around a Ca^{++} ion, its change would result in a shift of the peak frequency of loss. As shown in Fig. 5, we could not find any change either in the peak frequency or in the shape of the curve of loss due to the simple associated pairs during annealing. This implies that the observed decay of the loss is not affected by quenching strains, but is due to the decrease of the number of the pairs.

As for the free vacancies, we may conclude that quenching stains have little influence on their mobility, when we take into account the fact that measurements of ionic conductivity of pure crystals after quenching by air cooling reveal no change in either the ac or dc values.

Therefore, a relation between the free vacancies, n_v, and of the pairs, n_p, can be deduced from the formala (3),

$$n_p = K'_2 \, n_v^{1.92}. \tag{4}$$

b) *Association of vacancies with the impurity ions*

In quenched crystals, there exists an excess of the free vacancies and the isolated impurity ions. They will attract each other and form simple associated pairs. These pairs also tend to form precipitates or higher complexes.

These reactions can be formulated in terms of the following equations:

Reaction I [free vacancy]+[isolated imprity ion] $\leftrightarrows$ [simple associated pair], (5)

Reaction II $n \times$[simple associated pair] $\rightleftarrows$ [precipitate or higher complex]. (6)

Charged higher complexes may also be formed.

From the experimental results shown in Fig. 9 and 10, following conclusions can be obtained:

1) The deviation of the curve in Fig. 9 from the curve *a* in Fig. 1 is the direct evidence for the formation of higher complexes or precipitates during the annealing.

2) Reaction I can reach an equilibrium in a short time at 144°C, but for the other reaction the time required to reach equilibrium is long. In this situation an expected curve of n_v *vs.* n_p is curve *c* in Fig. 1. We, however, observed only a part of the trajectory because of our experimental condition that it took about one hour to raise the temperature of crystals to the selected one.

From the present experiment, we can not decide which are formed during the annealing, precipitates or higher complexes. But, the formation of higher complexes seems more likely, because the density of KCl crystals containing small amount of $CaCl_2$ changes linearly with the concentrations of the impurity.[7)]

Since the reaction 1 reaches equilibrium in a short time, the following relation may be expected between the concentrations of the defects:

$$K \, n_v \cdot n_i = n_p, \tag{7}$$

where n_i is the number of isolated impurity ions. K is slightly dependent on the concentration of unassociated defects, because there exist long range Coulomb interactions among these defects.

Unless charged complexes are formed,

$$n_v = n_i, \tag{8}$$

and Eq. (7) is reduced to an explicit form as[1),8)]

$$x_p = 12 \, x_v^2 \exp\left[\frac{T_0}{T} - \frac{2(2\pi\sqrt{2})^{1/2} (T_0/T)^{3/2} x_v^{1/2}}{\{1+4(\pi\sqrt{2})^{1/2} (T_0/T)^{1/2} x_v^{1/2}\}} \right], \tag{9}$$

where x_p and x_v are the molar fractions of the pairs and of the vacancies respectively and T_0 is a binding energy of the pairs divided by Boltzmann's constant. In the derivation of this equation, purely Coulombic interactions among the defects are assumed at all separations and only nearest association is considered as pair.

The experimental results in NaCl containing $CdCl_2$ agree well with the prediction of Eq. (9), if we take the binding energy as 0.34 eV.[8] This value is in fairly good agreement with the calculated one by Bassani and Fumi.[9] They obtained the value of the binding energy of 0.32 eV for Ca^{++} in KCl.[9] When a sum of the concentrations of free vacancies and pairs is $1\times10^{-3}\%$, $5\times10^{-3}\%$ and $1\times10^{-2}\%$, $d(\log x_p)/d(\log x_v)$ is estimated to be 1.8, 1.7 and 1.6 respectively from Eq. (9), using the binding energy of 0.32 eV. In these estimations, the long range interactions are somewhat underestimated, because the energy value of 0.32 eV is smaller by a factor of about 2 than that obtained on the assumption of purely Coulombic interactions, and correction of this will further reduce the value of $d(\log x_p)/d(\log x_v)$.

On the other hand, from the experiment of the conductivity decay, we obtained the formula (4), where $d(\log x_p)/d(\log x_v)=1.92$. The disagreement between the experiment and the above estimation suggests that the number of free vacancies may not be equal to that of isolated impurity ions or the distribution of defects may not be homogeneous.

In the former case charged complexes or charged dislocations will be formed. Owing to the lack of information about the concentration of isolated Ca^{++} ions, we can make no further discussion. If similar experiments as above are made for crystals containing manganese impurities, more definite conclusions may be obtained, because we expect to have detailed information about the behaviors of manganese ions from electron spin resonance.

As to the existence of heterogeneity in crystals, we may conclude that quenching strains do not play important role, taking into account that both crystals cleaved as shown in Fig. 2 and those, for which all surface layers were removed, showed the same results.

The author wishes to express his sincere thanks to Professor H. Kanzaki and Professor T. Suzuki for their encouragement and many valuable discussions. He is also much indebted to Mr. K. Kido for his help and to Profesor J. Yamashita for his advice.

Measurement of the Intensity in Electron Diffraction by a CdS Single Crystal

By Satio TAKAGI and Fuminori FUJIMOTO

Institute of Physics, College of General Education,
University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received May 7, 1960)

A method of measuring the intensity of electron in electron diffraction patterns by the electron-bombardment-induced-current (EBIC) in a CdS single crystal is described. The CdS detector is moved in the diffraction camera by a screw which is driven by a synchronous motor. EBIC is measured directly by a automatic recording millivoltmeter. EBIC properties of good crystals selected from those prepared by Frerichs' method are given. It is shown that the intensity can be measured within 2–3% error, if suitable precautions are made. An example of the measurement on TlCl is also given.

§1. Introduction

The photographic method is usually employed for the intensity measurement in electron diffraction. For the purpose of precise measurement, however, this method requires rather elaborate procedures and for all these procedures an accuracy better than a few percent cannot be expected. In X-ray diffraction, the direct method of intensity measurement with a G–M or other counters is widely used with satisfactory results. Lennander[1] has developed the G–M counter method in electron diffraction and succeeded in obtaining on accuracy as high as that in X-ray diffraction. However, the resolving time of the G–M counter is too long for the beam intensity conveniently used in electron diffraction experiment and moreover the detector is not suitable to be put in the ordinary diffraction camera.

One of the authors and his collaborator[2] have pointed out that the electron-bombardment-induced-current (EBIC) in CdS crystal can be utilized for the intensity measurement in electron diffraction, and Simon[3] applied this method to X-ray diffraction. It was pointed out in the electron case, that drawback of this method were relatively long response time (1 min.) of, and the hysteresis effect in EBIC. By proper choise of the CdS crystal, the characteristics of the detector are now greatly improved, the response time and the hysteresis effect being reduced to a negligible extent.

Characteristic of the photoconduction[4] and of EBIC[5] have been studied by many authors. However, the results obtained are not always satisfactory for the present purpose.

Experimental results on the EBIC characteristics of CdS detector for use in electron diffraction are presented in this paper together with an example of the intensity measurement.

§2. Preparation of CdS Detector

The CdS single crystals were prepared by Frerichs' method, no impurity being added purposely. Crystals suitable for the detector of electron beam were selected under the following directions: i) the stick-like crystals 0.5–1.0 mm in diameter and about 3 mm in length, ii) with orange colour, iii) no luminescence with ultra-violet irradiation, iv) with extremely small dark current and v) with relatively large photocurrent induced with daylight.

Indium metal which makes ohmic contact with CdS was evaporated directly onto the crystal surface with a narrow gap at the centre of the crystal. The gap was made by placing a fine wire on the crystal during the evaporation. Deposited indium served as electrodes and the gap as the slit of the detector. Suitable thickness of indium electrode is 1500–3000 A, for 0.03 mm gap. Thicker electrodes made electrical contact with each other and with thinner ones the effective width of the slit became larger than the true width of the gap. This is probably due to the fact that the conductivity of thin electrodes is comparable with the conductivity of CdS crystal induced by electron beam which can penetrate through thin electrode and reach the crystal underneath.

The crystal detector prepared by the above procedures was set between two copper electrodes, making electrical contact with them with conductive paste.

§ 3. Apparatus

The diffraction camera used in this experiment is of a usual type with a focussing coil. CdS detector is placed in front of a box containing the photographic plates and can be driven perpendicular to the incident beam by a screw which is rotated either by hand or by a synchronous motor. The maximum stroke is 9 cm. The driving system of the detector is shown in Fig. 1. D is the detector composed of a insulator base, two copper electrodes and an CdS crystal, P is a metal shield which protect the insulator base from being charged up by electron beam, S is the driving screw, C is the incident beam stop and F is a Faraday cylinder, 6.5 mm in diameter, which is used in obtaining the characteristic curve (i.e. EBIC vs. electron intensity curve) of the crystal.

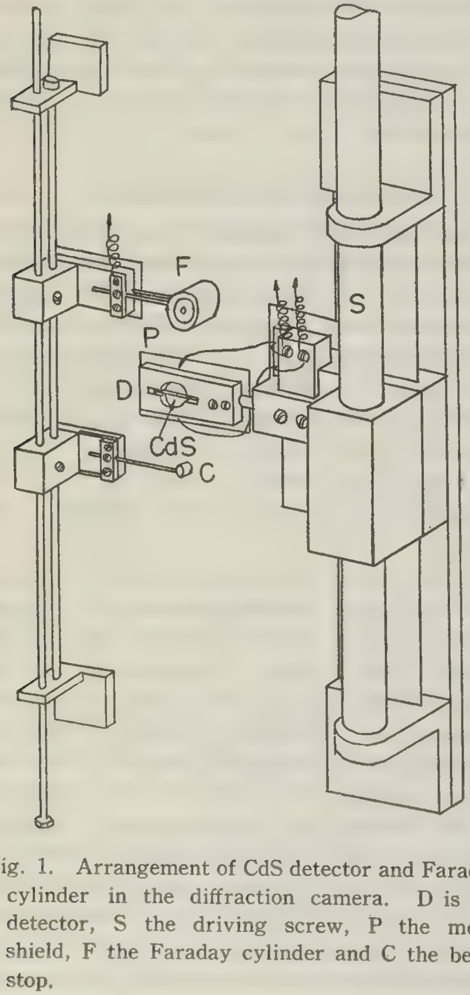

Fig. 1. Arrangement of CdS detector and Faraday cylinder in the diffraction camera. D is the detector, S the driving screw, P the metal shield, F the Faraday cylinder and C the beam stop.

The detector D is connected in series with a battery and an automatic recording millivoltmeter which are placed outside the camera and F with a DC amplifier of maximum sensitivity 10^{-13} A.

Photographic plates can be stored in a box not shown in the figure and the diffraction pattern can be photographed whenever desired.

The primary voltage of the high-tension transformer was kept constant by an automatic stabilizer which was controlled by a variable impedance connected in series with the primary circuit of the transformer. No especials tabilizer of the electron current was used, but following precautions were taken: i) the voltage on the Wehnelt cylinder was applied by self-biasing, ii) tungsten filament with fresh surface was used as the cathode which was heated by a battery, iii) the residual pressure in the diffraction camera was kept as low as

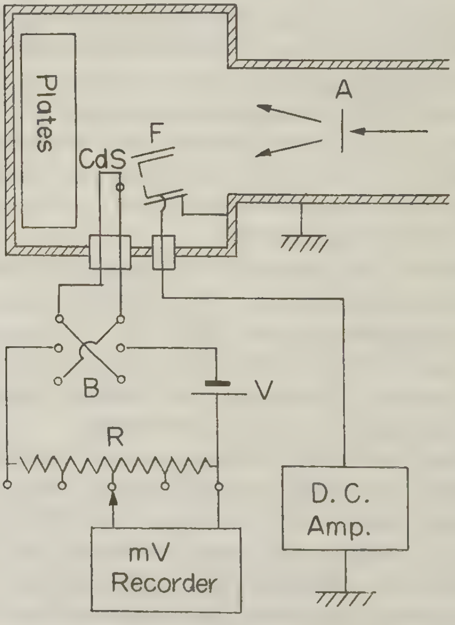

Fig. 2. Schematic diagram showing the arrangement of obtaining the EBIC vs. electron intensity curve.

8×10^{-5} mmHg. Under these conditions the fluctuation in the total electron current was less than 1%.

§ 4. Characteristics of the CdS Detector

i) *EBIC vs. electron intensity curve*

Fig. 2 schematically shows arrangement of obtaining the sensitivity curve and measuring EBIC and the electron current. The scatterer A is a thick film of amorphous substance such as glass, which gives diffraction pattern of almost uniform intensity distribution, the incident spot disappearing in the pattern. The Faraday cylinder is set at high scattering angle where the intensity distribution of electrons over the openning of the cylinder is sufficiently constant, and the CdS crystal is held behind the hole at the bottom of the cylinder. The electron current onto the crystal is calculated from the current onto the Faraday cylinder assuming the proportionality between the beam current and the cross section. The voltage applied to the crystal and the mean electric field in the crystal are given in Table I.

Table I. Properties of CdS detectors.

Dector No.	Slit width mm	Cryst. width mm	Applied voltage Volt (kV/cm)	n*	Gain*
1	0.2	0.70	45 (2.25)	0.82	4.8×10^6
2	0.08	1.00	6 (0.75)	0.90	1.2×10^7
3	0.08	0.69	6 (0.75)	0.97	5.1×10^7
4	0.03	0.68	1.5 (0.50)	0.87	1.3×10^7
5	0.03	0.75	45 (15.0)	0.90 ($>3.1\times10^{-10}$ A/cm²) 0.98 ($<3.1\times10^{-10}$ A/cm²)	2.3×10^7
6	0.03	0.74	1.5 (0.50)	0.82	4.3×10^7
7	0.03	0.53	6 (2.0)	0.96	4.9×10^7
8	0.03	0.67	1.5 (0.50)	0.97	4.3×10^7

* for 41.3 keV electrons.

The results for 41.7 keV electrons are shown in Fig. 3, Fig. 9 (a) and (b). Dark current for each crystal was negligibly small. The relation between EBIC and the electron current is given by the well known formula

$$i\propto I^n\,,$$

where i and I are EBIC and the electron current, respectively. Values of n are given in Table I, which are constant in the whole range of measurement except in the case of Dectector No. 5 for which n is 0.9 for intensities higher than 3.1×10^{-10} A/cm² and 0.98 for lower intensities. The deviation of the individual points from the curve is within 3%, except a few points which show larger deviations. These larger deviations might arise not from the error in the measurement of the intensity of EBIC but from that in the measurement of the electron current. The measurement of the latter is more difficult owing to the stray electrons scattered or se-

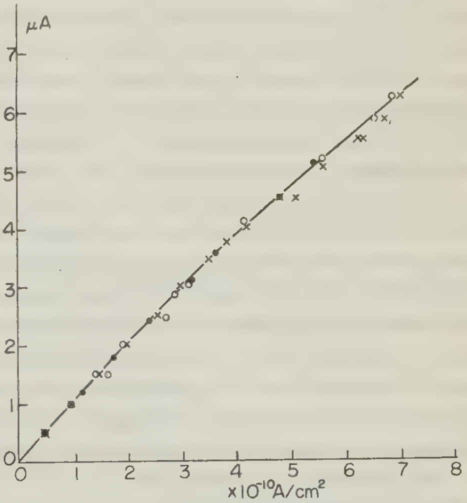

Fig. 3. Characteristic curve for Detector No. 2. The ordinate is EBIC and the abssisa is the electron intensity. Electron energy=41.3 keV.

○: the measurement on the 2nd day,

×: the measurement on the 3rd day.

condarily emmitted from the surroundings of the Faraday cylinder.

The characteristic curve did not change for 48 hours so long as the crystal was kept in vacuum. When, however, the crystal was exposed to air, the characteristic curve changed. An example is shown in Fig. 4.

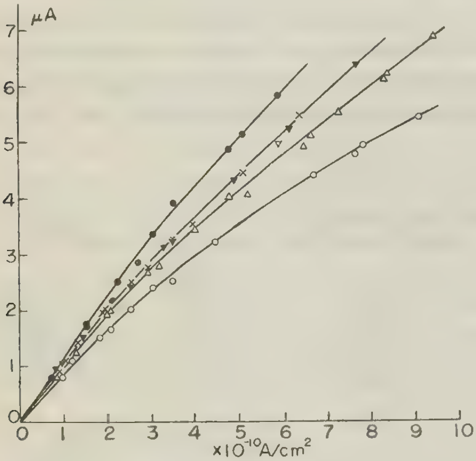

Fig. 4. Change of the characteristic curve upon exposure to air and subsequent evacuation. Electron energy=41.3 keV.

●: before the exposure,
○: 1^h 30′ after the exposure,
△: 3^h 00′ after the exposure,
×: 4^h 30′ after the exposure,
▼: 24^h after the exposure.

Black circles represent results before the exposure to air, and white circles those 1.5 hours after 15 minutes exposure to air and subsequent evacuation, triangles and crosses those of later measurements. The time of measurement after the exposure is given in the legend. It is shown in the figure that after 4.5 hours the curve did not change any more, but it did not coincide with the initial curve, while for Detector No. 8 the characteristic curve coincided with the initial one about 20 minutes after the exposure. After repeated exposure to air, not only the gain but also the value of n changes. So it is necessary to check the characteristic curve for each intensity measurement.

The sensitivity of CdS crystals changed on irradiation with very strong electron beam. The EBIC then gradually increased with constant beam intensity. When the direction of the applied voltage was reversed by B in Fig. 2, the EBIC suddenly decreased and then gradually increased.

The irradiation with such a strong beam must be avoided, hence use was made of beam stop C in Fig. 1. By the irradiation with diffracted electrons used in this experiment none of the crystals showed such decrease of EBIC on reversing of the field, except Detector No. 1 which showed a slight decrease at the beam intensity higher than 5×10^{-10} A/cm².

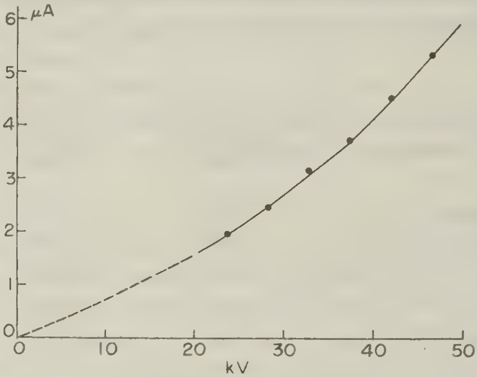

Fig. 5. Change of sensitivity with electron energy for Detector No. 2. Electron intensity=3.5 $\times 10^{-10}$ A/cm².

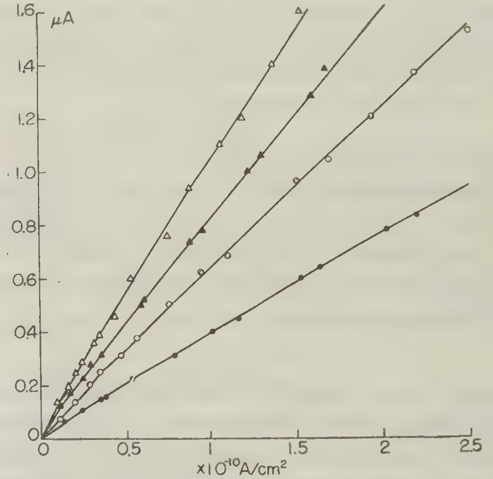

Fig. 6. Characteristic curves for Detector No. 8 with various electron energy. ●: 23.5 keV; ○: 32.4 keV; ▲: 41.3 keV; △: 50.2 keV.

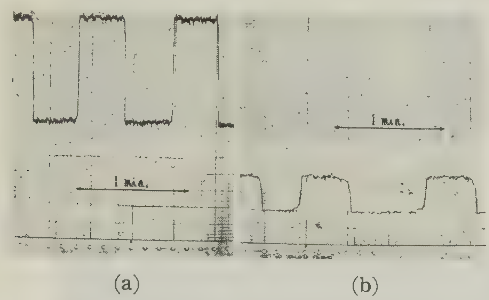
Fig. 5 shows the variation of EBIC with the accelerating voltage at constant electron current for Detector No. 2 and Fig. 6, the characteristic curve of Detector No. 8 for 23.5, 32.4, 41.3 and 50.2 keV electrons. The change of the characteristic curve was reversible with the change of the accelerating voltage.

ii) *Response time*

The speed of response of EBIC is an important factor in the present method. It has been reported[4] that the response of photoconduction consists of two distinct parts: an initial rapid portion and a much slower portion of which response times are several μ sec. and several sec., respectively.



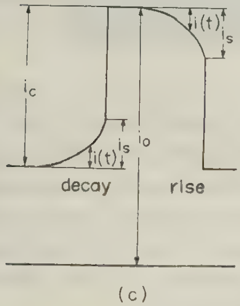


Fig. 7. Response of EBIC on Detector No. 8, (a) for $I_0=1.2\times10^{-10}$A/cm², (b) for $I_0=3.2\times10^{-12}$A/cm², (c) showing the meaning of symboles used in the text.

Fig. 7 shows the results of the experiment on EBIC. The electron intensity was instantaneously reduced to about half of the initial value and then increased to the initial value. (a) and (b) show the results for strong and weak irradiation, respectively. (c) shows schematically two portions of response time and the meaning of symbols used in the text and in Table II where values of response time T in rising case are given. The value of T, which is here refered to as "the response time" is defined as the time required for $i(t)$ to become $i_s/2$ (see Fig. 7(c)). Note that T does not mean the time required for $i(t)$ to become $i_c/2$. The value of T for decaying case is generally a little smaller than that for rising case. In Table III, values of T and i_s/i_0 of Detector No. 8 are shown for various change of the irradiation intensities in the case of medium and weak irradiations. EBIC reaches to the constant value within a few second even with very weak irradiation, and the response time is the shorter, the smaller the variation of irradiation intensity.

Table II. Values relating to the response of detectors in the rise case. $I_c/I_0=1/2$ and electron energy=41.3 keV.

Detector No.	i_s/i_0 (%)	T (sec.)	I_0 (A/cm²)

	3	1	2.4×10^{-11}
	5	1.5	1.1×10^{-11}
	15	1.5	3.2×10^{-12}

The response time was smaller than the response time of the recorder for the intensity variation usually met with in practical diffraction work.

iii) *Other Properties*

a) *Noise of EBIC.* For the detector with slit width larger than 0.08 mm, the noise of EBIC was less than the fluctuation in the incident electron intensity and was negligible. For smaller slit width, e.g. 0.03 mm, the magnitude of noise was often larger than 10% of the EBIC for weak irradiation, and did not decrease with decrease of the electron intensity, though the fluctuation in the

	1	9	2.5	6	2.5

electron intensity became smaller with the decrease of the electron intensity. After prolonged use with large noise, the crystal was often broken down and became conductive.

When there is a large noise, it is better to reduce the applied field and diminish the noise. For this reason the strength of the applied field to the crystal is limited.

b) *The infra-red quenching.* It was reported in the previous note, that the illumination with infra-red light improved the hysteresis effect in the sensitivity curve. This method, however, was not adopted in the present experiment, because (1) the hysteresis effect in the sensitivity curve was not observed so long as the electron intensity was kept less than a reasonable value, (2) the response of EBIC was not improved, (3) the sensitivity decreased and (4) the variation of the EBIC increased probably by the fluctuation in the infra-red intensity.

§ 5. Measurement of Debye Ring for Electron Diffraction

Fig. 8 (a) and (b) show the intensity curves of electron diffraction pattern from a polycrystalline TlCl which was preparated in the camera by vacuum evaporation onto collodion film. CdS Detector No. 8 with slit width 0.03 mm was used. (a) and (b) show the intensity curves for which the divider resistance R shown in Fig. 2 were 1 kΩ and 10 kΩ, respectively. (c) shows the photograph which was taken subsequently. Fig. 9 (a) and (b) show the characteristic curves for Fig. 8 (a) and (b) respectively, by which the absolute values of electron intensity of (a) and (b) can be obtained.

The detector speed was 2 mm/min. and the time required for the measurement was 7 min. This time is determined by the line width (0.08 mm for 110-reflection in this case) and the pen speed of the recorder (2 sec. for full scale). If we measure more broad line or use the high speed recorder, we can shorten the time of measurement.

§ 6. Discussion

The main cause of error in the present method are as follows: (1) slow response of EBIC, (2) the shift of EBIC, (3) the noise and (4) the shift and fluctuation of the intensity of scattered electrons. The former three of these are concerned with the properties of crystals, and can be avoided by proper choise of the crystal and of the intensity of electrons. Detector No. 8, for example, can safely be used with current density from 5×10^{-12} A/cm^2 to more than 2.5×10^{-10} A/cm^2. This range covers the whole range of current densities in usual diffraction pattern. The change of the characteristic curve of the crystal on exposure to air is a troublesome problem, because it necessitates frequent calibration of the characteristic curve. This will be avoided, however, by employing suitable air lock for the replacement of specimens and photographic plates used in ordinary electron microscopes.

(4) arises from the fluctuation of the inci-

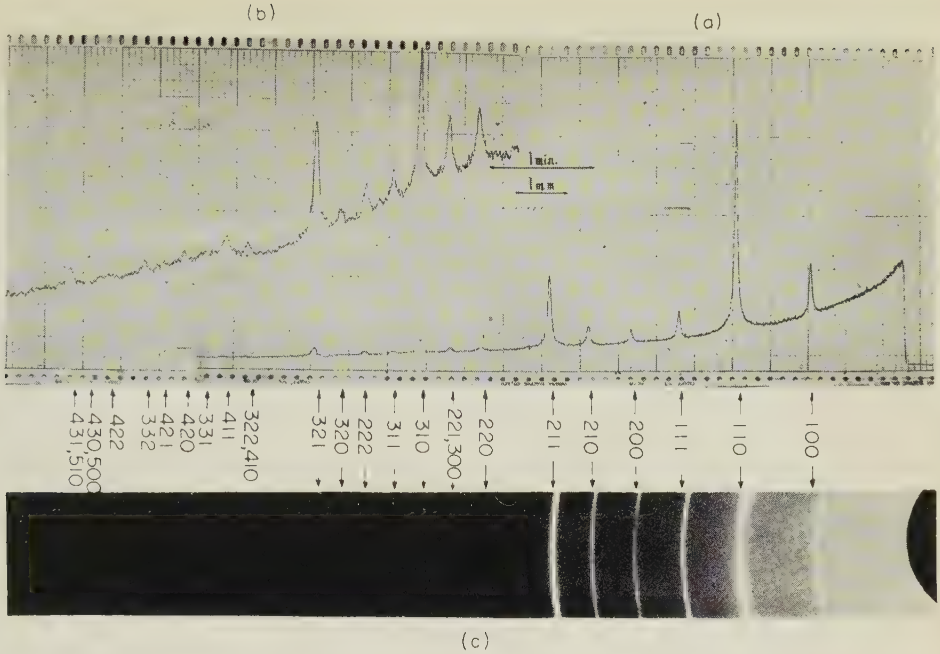

Fig. 8. Example of the measurement on TlCl. The distance in the acctual pattern and the time of measurement are indicated in the figure. Electron energy=41.3 keV.

(a) for R (Fig. 2)=1 kΩ, (b) for R=10 kΩ, (c) the diffraction pattern.

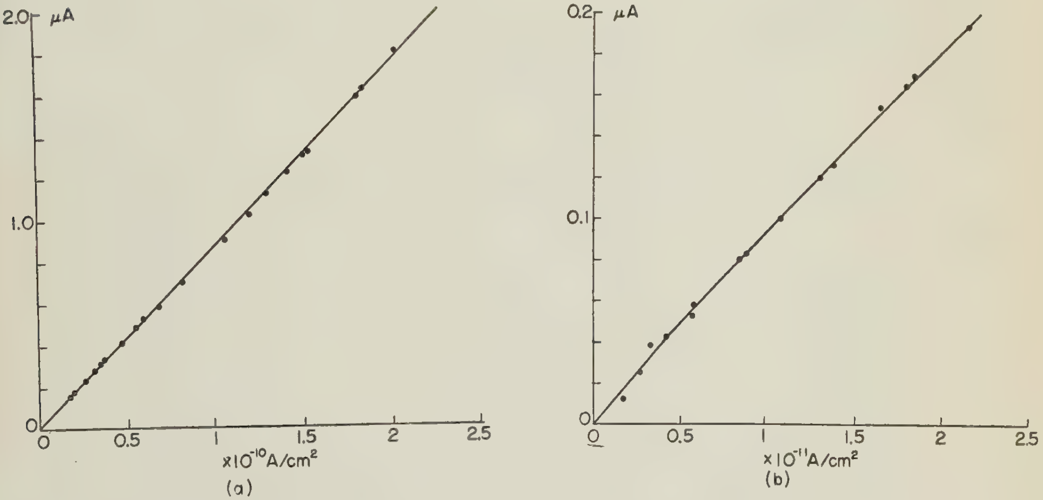

Fig. 9. Characteristic curves of Detector No. 8. (a) and (b) are those corresponding to Fig. 8 (a) and (b), respectively.

dent beam and the change of the specimen on irradiation with electron beams. The fluctuation of the intensity of the total electron current from the cathode to the anode can easily be kept constant within 1%, so long as suitable precautions stated in § 3 are taken into account. The fluctuation in the intensity of actual incident beam, i.e. the beam passed through slits, is somewhat larger and is 2–3% in ordinary conditions. The intensity of the diffracted beam, however, sometimes changed gradually, even if the incident beam intensity was kept constant. This may be due to the change in specimen: e.g. the contamination of the specimen, the vapourization in the case of volatile speci-

mens and the chemical change in the case of chemically unstable substances. To avoid this effect, weak electron beam should be used which, however, is limited by rather slow response of EBIC and relatively large noise for weak electron beams. The present method is not adequate for the diffraction by unstable substances.

In the present study, we do not considered in detail the mechanism of EBIC, but merely quote the data on properly selected crystals and show that these crystals can be used for the present purpose. The study of photoconductivity of CdS and other crystals has made a progress in recent years, and the production of good crystals suitable for the detection of electron beam i.e. crystals with short response time, small noise and with n nearly equal to 1 etc. may be expected.

This work was partly supported by a research grant of the Ministry of Education.

Elektronische Wechselwirkung zwischen Wasserstoff und aufgedampften Nickelfilmen

Von Yoshihiko Mizushima

Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Musashino-shi, Tokyo

(Recived December 28, 1959)

Adsorption of hydrogen on nickel film was measured, which was evaporated under an ultra-high vacuum condition. The relation between the adsorption and the change of electrical resistance of the film was closely studied to find apparently complicated results, which were very different from those of the previous reports. The effect of film thickness, measuring temperature and annealing temperature were separately examined. Adsorption kinetics were also regarded. From the experimental facts it was concluded that the adsorbed species were: (1) negatively charged atom, (2) positively charged atom and (3) molecule. The charge is, however, relatively small. An explanation for the resistance change was suggested.

§ 1. Problemstellung

Die Adsorption von Wasserstoff an Übergangsmetallen ist wegen ihrer grundlegenden Bedeutung für die heterogene Katalyse in den letzten Jaharzehnten besonders weitgehend untersucht worden. Seit 20 Jahren gewinnt die Messung an im Hochvakuum aufgedampften Metallschichten[1),2)] wegen der Sauberkeit solcher Filme zunehmend an Interesse.

Das Verhalten der elektrischen Leitfähigkeit von Metallfilmen bei der Adsorption von Fremdmolekeln[3)] wird neuerdings vielfach und mit Erfolg für die Untersuchungen herangezogen. Die von den verschiedenen Autoren erhaltenen Ergebnisse bezüglich des Systems Ni/H_2 sind aber noch nicht in guter Übereinstimmung[3),4),5)], was zur Folge hat, daß der Mechanismus der Adsorption von Wasserstoff an Nickel noch nicht restlos geklärt ist.

Das Ziel der vorliegenden Arbeit ist, das Verhalten der elektrischen Leitfähigkeit von im Ultrahochvakuum[6)] aufgedampften Nickelschichten bei der Adsorption von Wassestoff unter saubersten Bedingungen zu verfolgen und den Einfluß der Meßtemperatur, der Aufdampf- und Temperungsbedingungen zu studieren, um damit Aufschluß über den Adsorptionsmechanismus zu gewinnen. Ein Teil der experimentellen Ergebnisse ist kurz mitgeteilt[7)].

§ 2. Experimentelles

In Abb. 1 ist die Versuchsapparatur dargestellt. Meßzelle Z und Ionisationometer I.M. können mit elektrischem Ofen auf über 400°C, alle anderen Teile, mit Ausnahme des McLeodschen Manometers, mit Hilfe einer Heizbandumwickelung auf 300°C geheizt werden. Das Quecksilber ist vorher mit kleiner Flamme gut entgast worden. Nach einer 20 Stunden dauerunden Ausheizung und Elektronenbombardment der nicht heizbaren Metallteile des Ionisationsmanometers ist ein Endvakuum von 10^{-11} Torr erreichbar. Als Kriterium für die Vakuumdichtigkeit soll die gesamte Apparatur über Nacht Klebvakuum halten, d.h. der Leckwert soll kleiner als 3.10^{-12} l. Torr/Sek. sein.

Der Verschluß S_6 ist mit einem Schliffeinsatz versehen, damit keine Rückdiffusion von Gas, das langsam vom Quecksilber abgegeben wird, in den Meßteil stattfindet. Dadurch kann der Meßteil beliebig lange unter gutem Vakuum gehalten werden. Solange das Ionisationsmanometer läuft, bleibt dieser Teil im Bereich von 10^{-10} Torr. Wenn das Ionisationsmanometer nicht eingeschaltet ist, nimmt der Druck dieses Teils langsam zu (über Nacht 10^{-9} Torr).

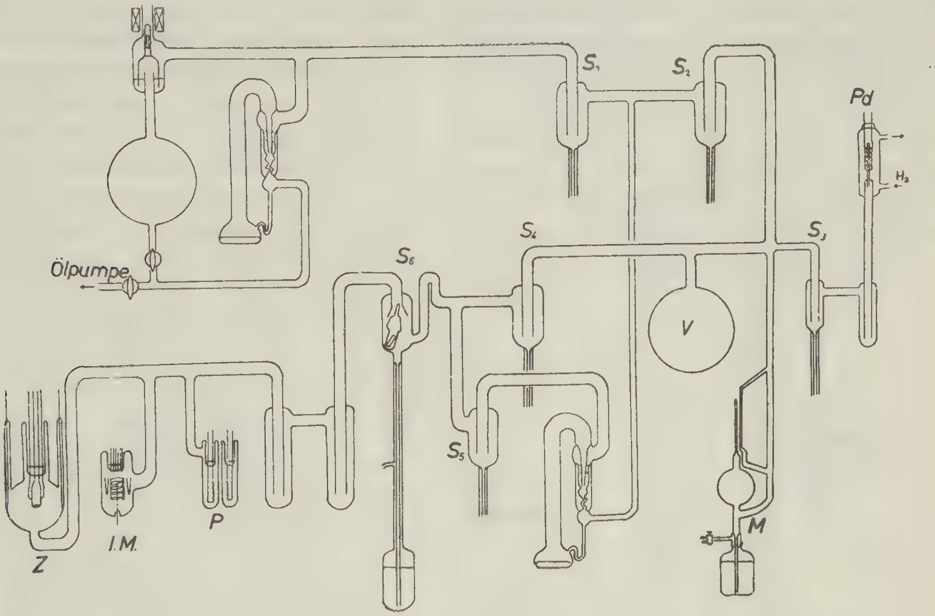

Abb. 1. Versuchsapparatur

Bei der Durchführung der Versuche muß das Vakuum beim Glühen der Nickelwendel gerade vor dem Äufdampften 10^{-10} Torr erreichen. Dann wird die Meßzelle auf 90°K abgekühlt, und der Nickelfilm wird aufgedampft bis zum gewünschten Widerstandswert, normalerweise 100 Ω (Schichtdicke ca. 100 Å), innerhalb 15 Min. Danach wird die Zelle auf Zimmertemperatur erwärmt und weiter im kochenden Wasserbad eine Stunde lang getempert. Nach Sennett u. Scott[8)] und Reynolds u. Stilwell[9)] ist die Kristallstruktur des aufgedampften Films umso kompakter, je größer die Aufdampfgeschwindigkeit ist. Es ist aber in diesem Falle wichtiger, daß die aufgedampfte Oberfläche gasfrei bleibt. Deshalb wird die geringere Wendeltemperatur gewählt, zumal bei Übergangsmetallen die Gefahr einer Koagulation nicht so groß ist.

Bei der Entkühlung der Zelle nach dem Aufdampfen kann man einen kurzzeitigen Druckanstieg beobachten, der bei ungenügender Entgasung der Nickelwendel über 10^{-7} Torr erreichen kann. Wendet man jedoch die Methode mit vier Zuführungsdrähten[5] an, so tritt dieses Druckmaximum nicht mehr auf, soweit die Wendel gut entgast wurde.

Durch die einstündige Temperung bei 373°K erreicht man, daß der Widerstand bei Zimmertemperatur konstant bleibt, daß also kein Ordnungsvorgang mehr festzustellen ist.

Dann wurde die Messung begonnen.

Nach der Messung wird die aufgedampfte Schicht in verdünnter Salpetersäure gelöst und nach einer Methode von Sandell[10] photometrisch bestimmt.

Das in den meisten Fällen zum Versuch benutzte Nickel hat etwa 1.7% Verunreinigungen, wie Co, Al, Si. Um einerseits die Verunreinigung der Schicht möglichst gering zu halten und anderseits did Entgasung möglichst vollkommen durchzuführen, wurde bei Verwendung einer neuen Nickelwendel zunächst ein Film aufgedampft, der nicht zu einer Messung diente. Erst nach Herauslösen dieses ersten Films und Reinigung der Zelle wurde der richtige Versuch mit einem neuen aufgedampften Film begonnen. Der versuch mit spektroskopisch reinem Nickel zeigte, daß die vorliegende Meßergebnisse bei beiden Nickelproben fast dieselben sind, solange die Entgasung sehr vorsichtig durchgeführt wird.

§ 3. Experimentelle Ergebnisse

Soweit nicht besonders erwähnt, sind die Bedingungen der Schichtherstellung: Aufdampfen bei 90°K unter 10^{-10} Torr, Schichtdicke ca. 100 Å und Temperung bei 373°K 1 Stunde lang.

3–1. *Adsorption bei 273°K*

Ein typischer Verlauf des Widerstandes und

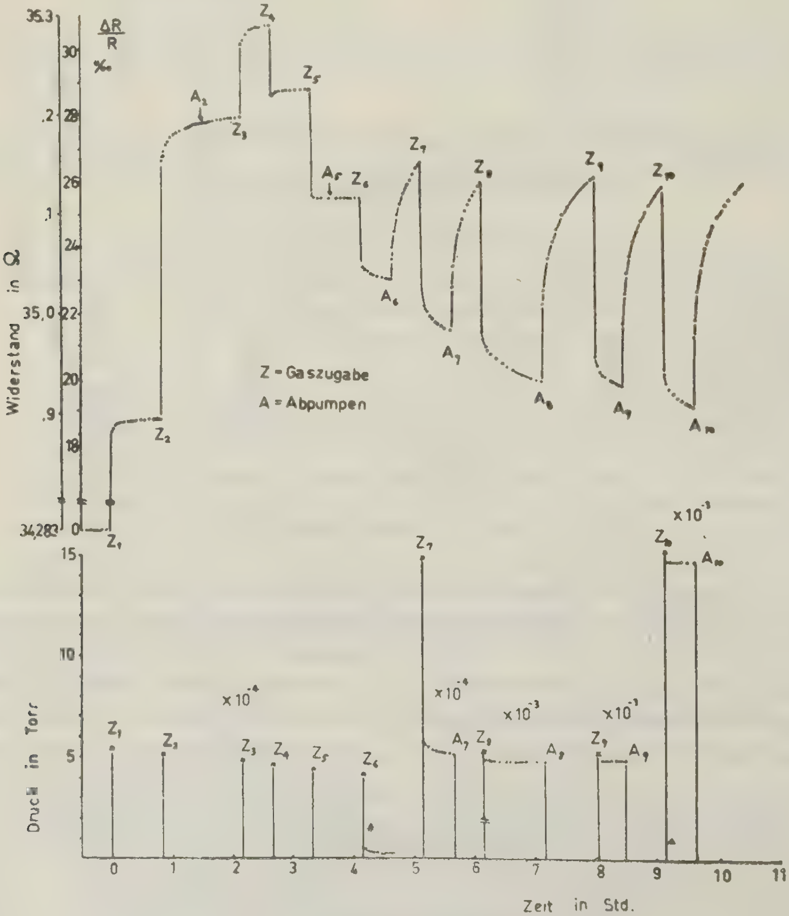

Abb. 2. Adsorption bei 273°K

des Drucks bei 273°K als Funktion der Zeit nach verschiedenen Zugaben von Wasserstoff ist in Abb. 2 dargestellt. Bei der jeweiligen Zugaben Z_1 bis Z_5 ist nach 20 Sek. kein Druck mehr festzustellen. Der Widerstand steigt nach der Gaszugabe zunächst sehr rasch an, dann langsamer. Die geringfügige zeitliche Widerstandszunahme dauert auch dann noch an, wenn der Druck praktisch auf Null abgesunken ist. Das läßt auf irgeneinen Vorgang schließen, der unabhänging ist vom Gasdruck. Nach der Zugabe einer gewissen Wasserstoffmenge erreicht der Widerstand schließlich ein Maximum (Z_3) und nimmt dann bei weiteren Zugaben ab. Die langsame Widerstandszuanhme nach jeder Zugabe bleibt jedoch erhalten. Der Druck fällt immer noch rasch innerhalb einer halben Minute bis auf Null ab. Bei weiteren Gaszugaben wird die langsame Widerstandszunahme schwächer. Schließlich erreicht man einen Punkt, von dem ab nicht mehr die ganze abgegebene Gasmenge adsorbiert wird. Nach diesem Punkt ist das Adsorptionsgleichgewicht so langsam, daß man mit dem Piranimanometer verfolgen kann.

Der Druck- und Widerstandsverlauf ist jetzt mit einem beträchtlichen Zeitbedarf verknüpft. Der Sättigungswert wird innerhalb einiger Stunden nicht erreicht. Während vor diesem Grenzpunkt durch Abpumpen kein Gas desorbiert werden kann und der Widerstand sich folglich beim Abpumpen auch nicht ändert, läßt sich nach dem Grenzpunkt durch Abpumpen innerhalb der Fehlergrenze die gesamte (nach diesem Grenzpunkt) adsorbierte Gasmenge desorbieren, wobei die Widerstandsänderung rückläufig ist. Dieser Grenzpunkt ist also eine wichtige Größe und wird im folgenden als irreversible Grenze bezeichnet. Die Gasmenge, die bis zu dieser Grenze adsorbiert ist und nicht mehr desorbiert werden kann, wird n_{irr} genannt. Die reversibel, unter dem Druck 5.10^{-3} Torr und in 1 Stunde adsorbierte Menge wird n_{rev} genannt. Unter $n_{\max}$ versteht man die Menge, die bis zum Erreichen des Widerstandsmaximum adsorbiert ist. Die entsprechende Widerstandsänderung vom Anfangswert R_0 wird $\Delta R_{\max}$ genannt.

Wird eine genügend große Wasserstoffmenge auf einmal zugegeben, so erreicht die Adsorption innerhalb einer halben Minute die irreversible Grenze, nach der die Adsorption langsam vor sich geht, wie in Abb. 3 dargestellt ist. Der Widerstand erreicht also das Maximum sehr rasch, so daß nur der reversible Teil der Beobachtung zugänglich wird.

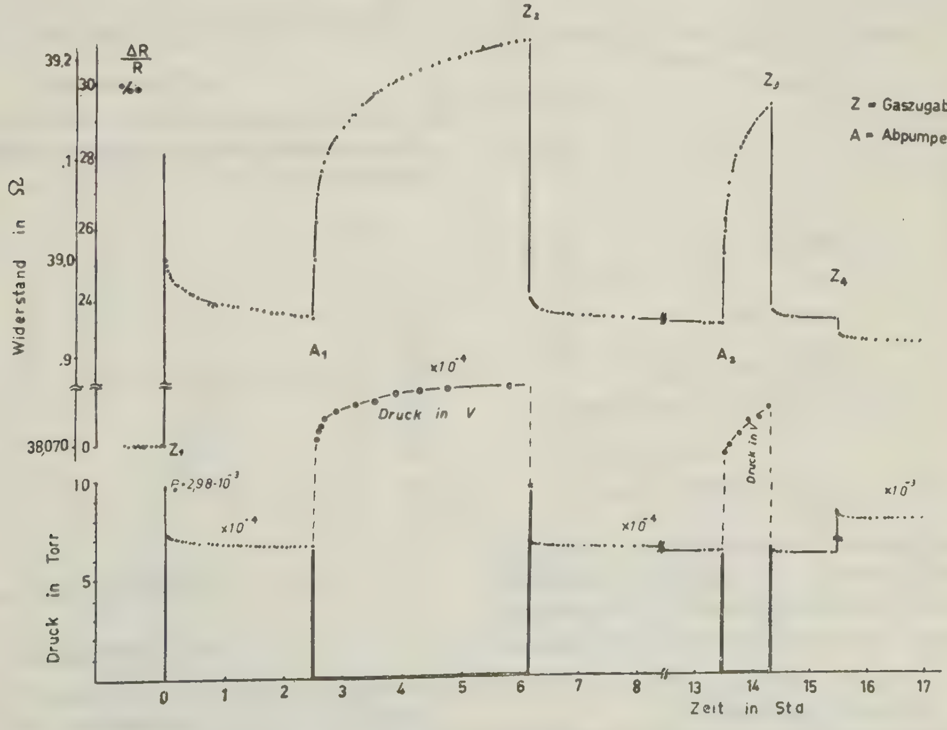

Abb. 3. Adsorption bei 293,5°K

Die Widerstandsänderung ist durchaus proportional der adsorbierten Menge.[7] Diese Tatsache deutet darauf hin, daß der gemessenen Widerstandsänderung und gemessenen Adsorption ein und derselbe Mechanismus zu Grunde liegt.

In Abb. 4 sind die Werte für die Widerstandsänderungen aus Abb. 2 über log $(t+t_0)$ aufgetragen. Alle Kurven, die bei der Desorption erhalten werden, folgen ohne Ausnahme und bis zum Ende der sogenannten Zeldovich-Gleichung[11]

$$n=\frac{1}{\alpha}\,[\log (t+t_0)+\text{const}] \tag{1}$$

oder

$$R=\frac{1}{\alpha}\,[\log (t+t_0)+\text{const}]\,. \tag{2}$$

Die Abb. 5 gibt den Zusammenhang zwischen der relativen Widerstandsänderung $\Delta R/R$ und der adsorbierten Menge pro Makrooberfläche mit den aus Abb. 2 zu entnehmenden Werten.

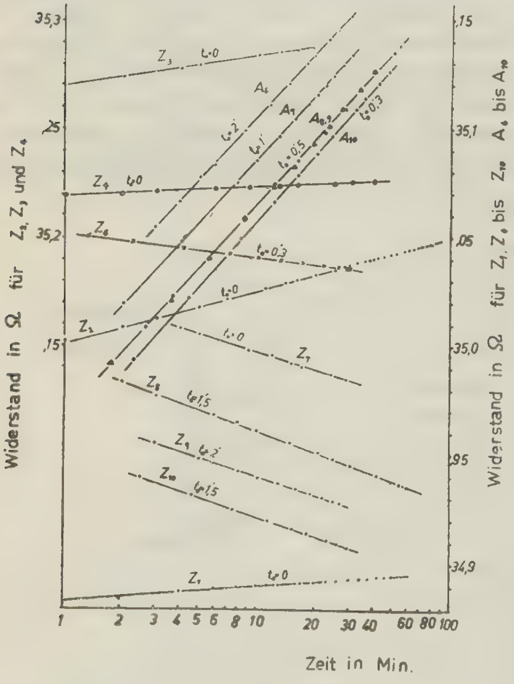

Abb. 4. Kinetik bei 273°K in Abb. 2

Die Meßpunkte entsprechen noch nicht ganz dem Gleichgewicht, da sich der Widerstand noch weiter entsprechend der Zeldovich'schen Gleichung ändert wie aus Abb. 3 zu ersehen ist.

3–2. *Adsorptionsisotherme*[7]

Die isotherme Widerstands- bzw. Druckänderung wurde bei Zimmertemperatur und bei tiefer Temperatur untersucht. Die Absorptionsenthalpie ΔH wird im reversiblen Bereich errechnet und in Abb. 6 als Funktion der Belegung pro Makrooberfläche aufgetragen.

Bei der Temperaturänderung im Isothermenversuch läßt sich die Aktivierungsenergie der Chemisorption bei Zimmertemperatur ermitteln. Die Aktivierungsenergie nimmt mit jeder Zugabe schwach zu. Sie ist im irreversiblen Bereich nicht zu berechnen und beträgt wahrscheinlich Null, da sowohl bei Zimmertemperatur als auch bei tiefer Tem-

Abb. 6. Die aus Isothermen berechnete Adsorptionswärme ΔH in Abhängigkeit von der Besetzung mit Wasserstoff

peratur die irreversible Adsorption ohne Zeitbedarf vor sich geht.

3–3. *Adsorption bei 90°K*

Der typische Adsorptionsverlauf—durchgeführt genau wie bei 273°K—ist in Abb. 7 dargestellt. Am Anfang finden sehr schnelle Adsorptionen mit irreversibler Widerstandszunahme statt. Bis zum Widerstandsmaximum sind die Verhältnisse sehr ähnlich wie bei 273°K. Der einzige Unterschied besteht darin, daß die ständige langsame Widerstandszunahme, die nach jeder Zugabe unabhängig vom Gasdruck verläuft, bei 90°K nicht der Zeldovich-Gleichung gehorcht, sondern nahezu linear ist. Nach dem Maximum nimmt der Widerstand—auch wie bei 273°K—ab. Bei jeder Zugabe ist ein kleiner Widerstandspeak vorhanden, der jedoch schnell durch eine Widerstandsabhahme überkompensiert wird. Nach einigen weiteren Zugaben nimmt der Widerstand wie vorher zu, doch erfolgt die Abnahme bedeutend langsamer und in so geringem Maße, daß als Endeffekt eine geringe Widerstandszunahme resultiert. Der irreversible Grenzpunkt wird dann (Z_{10}) erreicht und der Druckverlauf ist meßbar.

Bei weiterer Zugabe ändern sich die Verhältnisse wieder. Der Peak bei der Zugabe

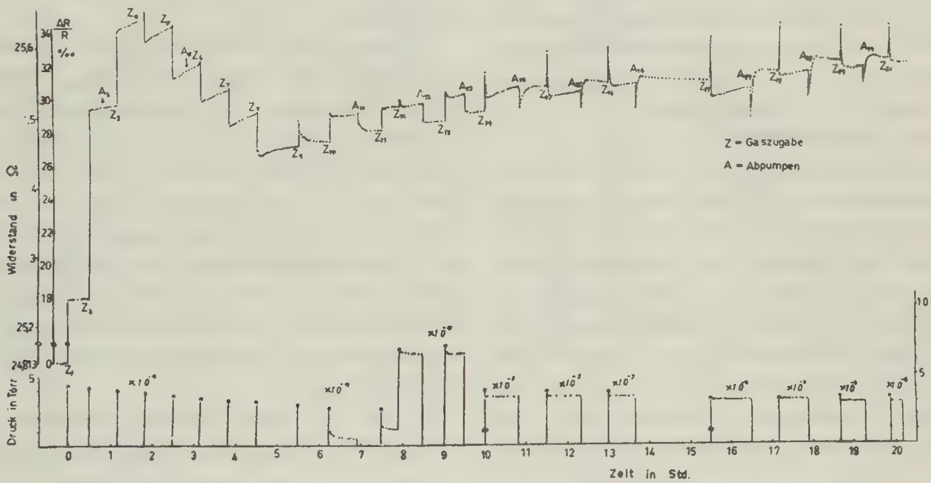

Abb. 7. Adsorption bei 90°K

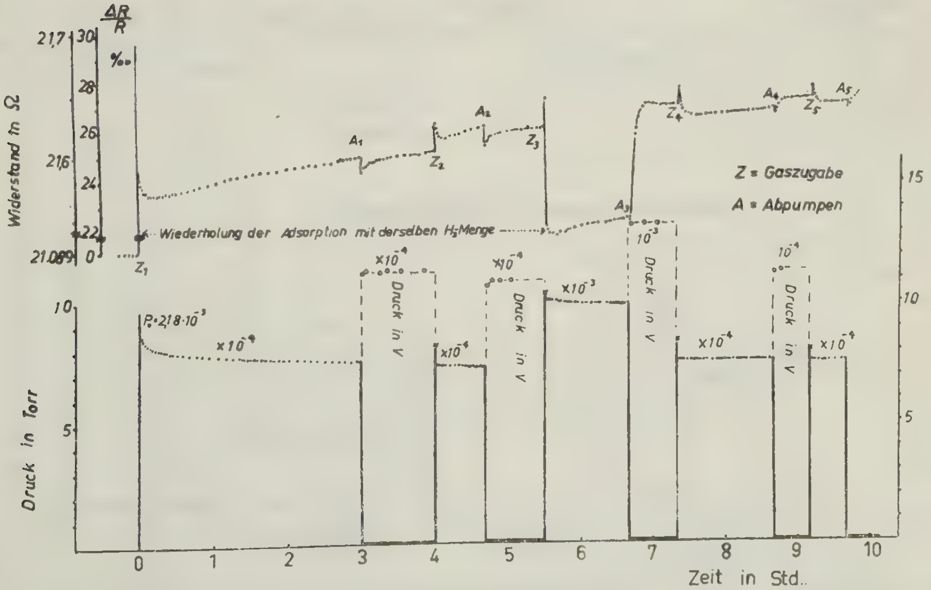

Abb. 8. Durch zwischenzeitliche Druckerhöhung bewirkte Umkehr des Widerstandseffktes bei 90°K

bleibt, doch ist die nachfolgende Widerstandsabnahme so groß, daß sie die Zunahme überwiegt. Beim Abpumpen geht dieser reversible Teil nach Auftreten eines umgekehrten Peaks wieder zurück. Je höher der Zugabedruck wird, desto stärker diese Umkehr der Widerstandsänderung.

Wenn auf einmal eine hinreiched große Gasmenge zugegeben wird, erhält man eine Kurve, wie sie in Abb. 8 und 9 dargestellt ist. Die Adsorption erreicht schon in einer halben Minute über Maximum und Minimum des Widerstandes die irreversible Grenze. Danach findet eine langsame, teilweise reversible Adsorption statt. Beim Abpumpen desorbiert nur wenig. Der Obserflächenprozeß geht immer—auch während des Abpumpens—unabhängig vom Gasdruck weiter, so daß lei der nochmaligen Zugabe der abgepumpten Gasmengen der Druck weiter abnimmt.

Um die Umkehr (Inversion) der Widerstandseffekte eingehender zu prüfen, wurden folgende Versuche unternommen. In Abb. 8 ist der Einfluß des Gasdrucks auf die Inversion gezeigt. Mit kleinem Zugabedruck wurde zunächst die Reversibilität geprüft. Danach wurde ein großer Druck zugegeben (Z_3). Nach dem Abpumpen wurde nochmals wie vorher ein kleiner Druck zugegeben. Es zeigt sich, daß nun die Inversion stattgefunden hat, d.h., daß die Widerstandsabnahme nach dem Peak bei der Zugabe diesen überkompensiert und daß beim Abpumpen die Widerstandszunahme stärker als die Widertsandsabnahme ist.

Bei dem andern Versuch (Abb. 9) wurde zunächst die Reversibilität geprüft. Dann wurde die Zelle auf 273°K erwärmt, ohne daß vorher abgepumpt war. Dabei erfolgte eine merkliche Adsorption wie am Gleichgewichtsdruck und am Widerstand zu erkennen war. Nach Abkühlung auf 90°K wurde wiederum die Reversibilität geprüft. Durch die zwischenzeitliche Temperaturerhöhung ist die Umkehr der Widerstandsänderung eingetreten und macht sich auch bei dem kleinen Druck bemerkbar.

Eine proportionalität zwischen Widerstandsänderung und adsorbierte Menge ist nicht mehr vorhanden. Der Druckverlauf folgt der Zeldovich'schen Gleichung unabhängig vom zwischenzeitlichen Abpumpen wie in Abb. 10 (aus Abb. 8) dargestellt ist. Der Widerstandsverlauf ist dagegen sehr kompliziert. Es gilt die Zeldovich-Gleichung bei der Desorption nicht mehr, da die Desorption nach wenigen Minuten endet. Diese Tatsachen deuten darauf hin, daß mehrere Adsorptionsmechanismen bei 90°K vorliegen.

In Abb. 11 ist die relative Widerstandsänderung aufgetragen als Funktion der Zahl von

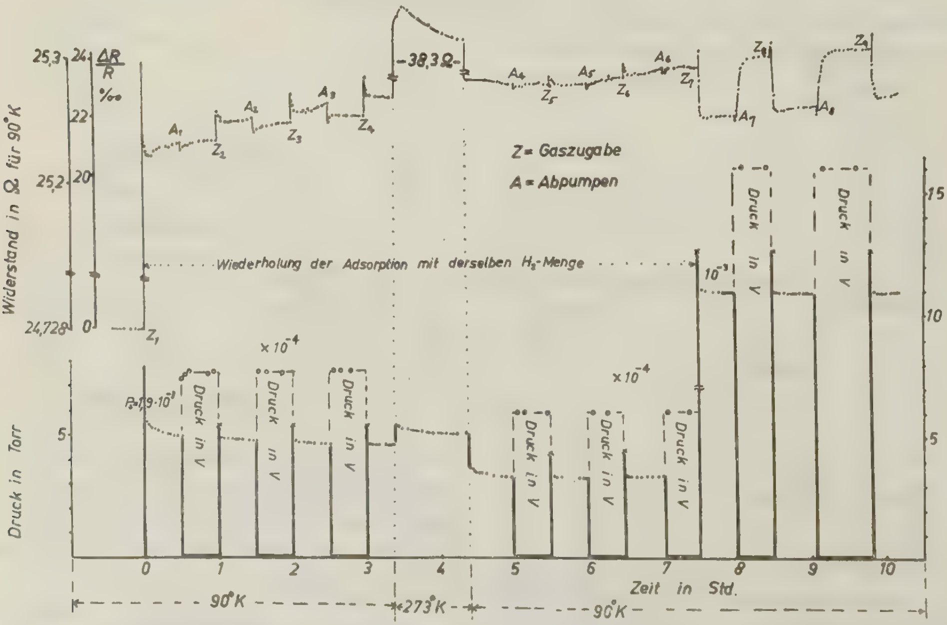

Abb. 9. Durch zwischenzeitliche Temperaturerhöhung bewirkte Umkehr des Widerstandseffektes bei 90°K

bei 90°K adsorbierten Wasserstoffmolekeln unter Zugrundelegung des in Abb. 7 dargestellten Versuchs.

3–4. *Einfluß der Schichtdicke*

Es wurden Schichten mit einer Dicke d von 25 Å bis 500 Å aufgedampft. Die Adsorption wurde jeweils unter gleichen Bedingungen durchgeführt. In Abb. 12 sind die Widerstände der Schichten als Funktion der Schichtdicke bei 273°K und 90°K angegeben. Wie ersichtlich ist, gilt für dickere Schichten ungefähr die Gesetzmäßigkeit

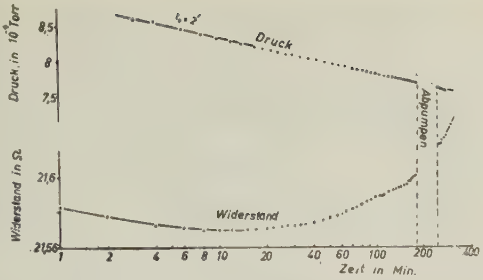

Abb. 10. Beziehung zwischen der zeitlichen Änderung von R und p in Abb. 11 zwischen Z_1 und Z_2

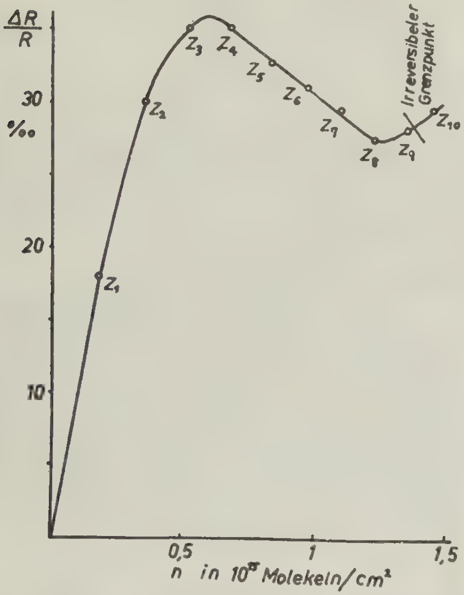

Abb. 11. Widerstandsänderung in Abhängigkeit von der adsorbierten Zahl von Wasserstoffmolekeln bei 90°K nach Abb. 10

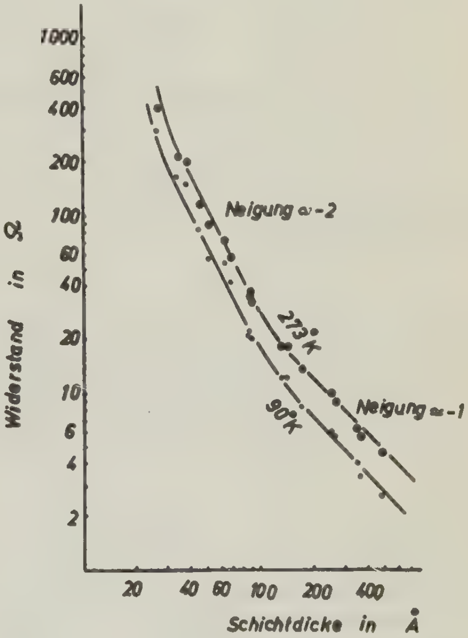

Abb. 12. Widerstand und Schichtdicke unbelegter Ni-Schichten

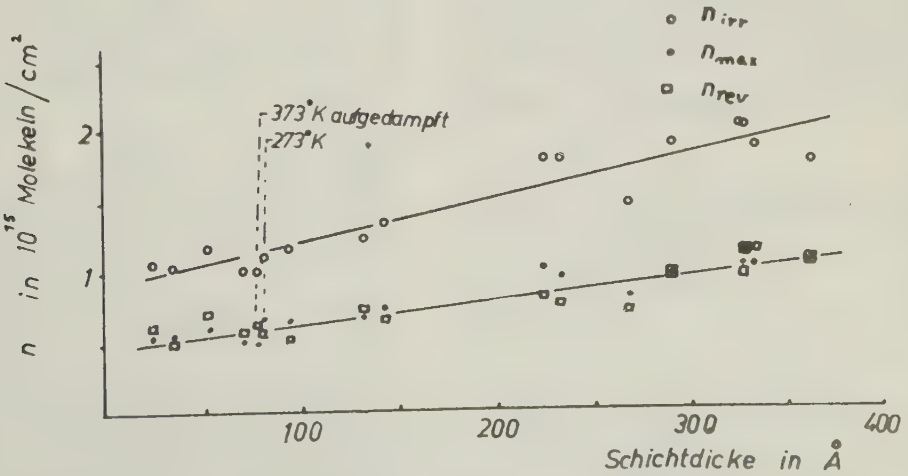

Abb. 13. Adsorbierte Menge H_2 in Abhängigkeit von der Schichtdicke, 273°K

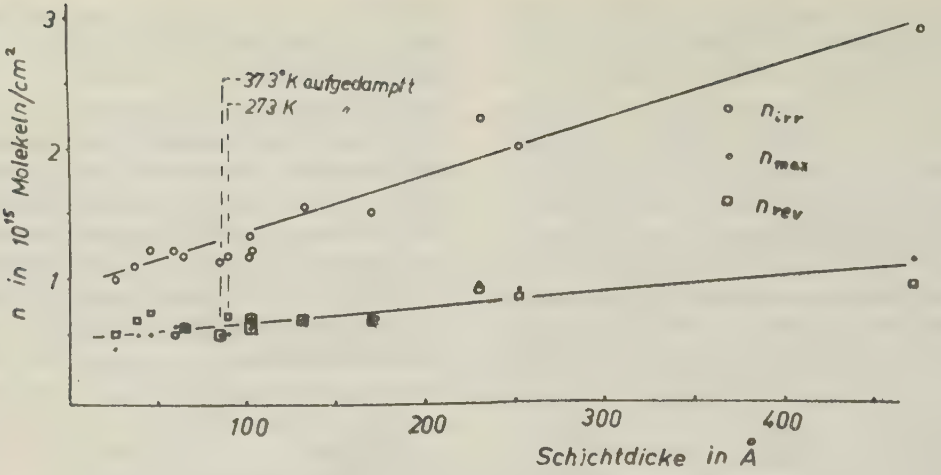

Abb. 14. Adsorbierte Menge H_2 in Abhängket von der Schichtdicke, 90°K

$$1/R = \text{const}\,(d - \text{const}), \tag{3}$$

sowie für dünnere Schicht näherungsweise im gemessenen Bereich

$$1/R = \text{const} \cdot d^2. \tag{4}$$

Exakt liegt hier natürlich keine Linearität zwischen log R und log d vor. Grenzdicke zwischen beider Gleichungen liegt etwa bei 100Å.

Die charakterischtischen Größen n_{max}, n_{irr} und n_{rev} sind für verschiedene Schichtdicken in Abb. 13 und 14 dargestellt. Die Meßwerte ergeben eine Gerade, die nicht durch den Ursprung geht. Diese Tatsache deutet darauf hin, daß die Adsorption an dünne Schicht auf Oberfläche stattfindet. Es gibt nur wenige Mitteilungen[12),13)], die besagen, daß die Gerade nicht durch den Koordinatenanfangspunkt geht. Extrapoliert man die in Abb. 13 und 14 angegebenen Werte nach größeren Schichtdicken hin, so erhält man eine ungefähre Übereinstimmung mit anderen in der Literatur angegebenen Werten[2),14)].

In Abb. 15 ist $\Delta R_{\text{max}}/R$ gegen log d aufgetragen. Die Kurve zerfällt in zwei Teile. Bei dünneren Schichten ist $\Delta R_{\text{max}}/R$ unabhängig von Meß-temperatur und von Schichtdicke, bei dickeren dagegen abhängig von Temperatur und von Schichtdicke.

3–5. *Einfluß der Temperaturbedingung*

Alle Nickelschichten wurden bei 90°K bis 100 Ω aufgedampft und später bei verschiedener Temperatur 1 Stunde lang getempert. In Abb. 16 sind n_{max}, n_{irr}, n_{rev} sowie $\Delta R_{\text{max}}/R$ für die gleiche Schichtdicke (ca. 100 Å) dargestellt. Der Ordnungszustand nimmt mit steigender Tem-

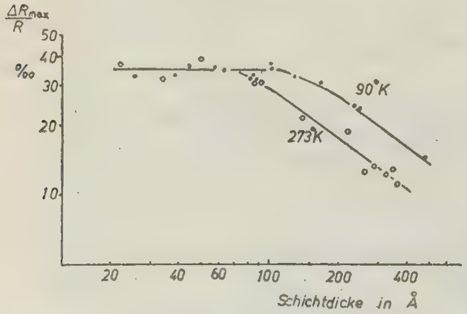

Abb. 15. Maximale Widerstandsänderung als Funktion der Schichtdicke

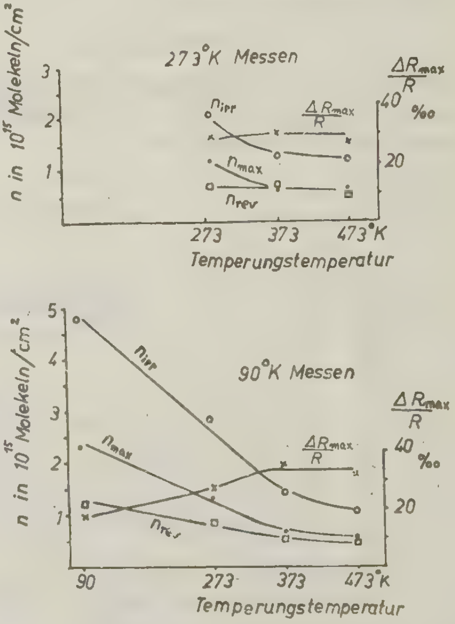

Abb. 16. Einfluß der Temperung auf die adsorbierte Menge H_2 und auf die maximale Widerstandszunahme

erungstemperatur zu und die Oberflächenrauhigkeit nimmt entsprechend ab. Infolgedessen werden die absorbierten Mengen $n_{\max}$, n_{irr}, n_{rev} kleiner, die relative Widerstandsänderung $\Delta R_{\max}/R$ dagegen größer. Aus Abb. 17 ist zu entnehmen, daß die Verhältnisse $n_{\text{rev}}/n_{\text{irr}}$ bzw. $n_{\max}/n_{\text{irr}}$ unabhängig von der Temperungstemperatur sind.

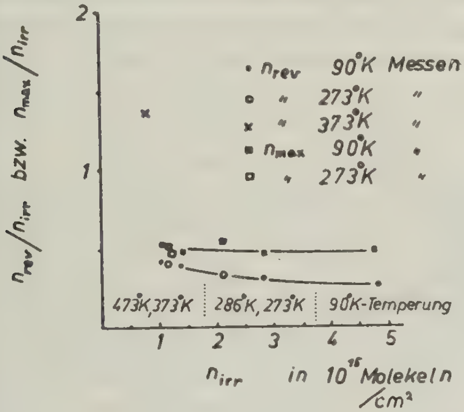

Abb. 17. Einfluß der Temperung auf das Verhältnis $n_{\text{rev}}/n_{\text{irr}}$ bzw. $n_{\max}/n_{\text{irr}}$

Während die Änderung des elektrischen Widerstandes bei allen getemperten Schichten ähnlich verläuft, ist bei ungetemperten Schichten die zweite Widerstandszunahme (molekular) viel größer als bei den getemperten.

Die Temperung bei 473°K ruft keine wesentliche Änderung gegenüber der Temperung bei 373°K hervor.

3–6. *Einfluß der Aufdampftemperatur*

Die Abb. 13 und 14 zeigen, daß beim Aufdampfen bei 273°K oder 373°K die charakteristischen Werte, $n_{\max}$, n_{irr} und n_{rev}, nicht von denen bei normaler Aufdampftemperatur (90°K) verschieden sind. Der Verlauf der Widerstandskurve zeigt auch keine Abweichung vom üblichen Verhalten. Die Adsorption von Wasserstoff ist also unabhängig von der Aufdampftemperatur, jedoch abhängig von der höchsten Temperatur, auf der die Schicht erwärmt wurde, d.h. von der Temperungstemperatur.

3–7. *Einfluß der Sauberkeit der Arbeitsbedingungen*

Versuche, bei denen die Vorentgasung nicht vollkommen durchgeführt war, zeigen; (1) Auch *bei 273°K* ein negativer Widerstandspeak beim Abpumpen auftritt. (2) $\Delta R_{\max}$ erfolgt weniger und von Mal zu Mal verschieden[15] (Durch Vorbelegung ist der Widerstand vor der Messung schon erhöht, wodurch $n_{\max}$ entsprechend weniger wird.). (3) Die langsame, vom Gasdruck unabhängige Widerstandszunahme ist verschwunden. (4) Im irreversiblen Bereich bei tiefer Temperatur zeigt sich keine Inversion, und bei der Gaszugabe nimmt der Widerstand lediglich zu, beim Abpumpen ab.

§ 4. Diskussion

4–1. *Sauberkeit der Schichten*

Nach Becker[16] erhält man zuverlässige Ergebnisse nur, wenn die Partialdrucke von O_2 und H_2O unter 10^{-10} Torr liegen. Das ist wahrscheinlich der Grund dafür, daß die vorhergehenden Arbeiten[3,4,5,15,17,18,19,20] nicht übereinstimmten und widersprechende Ergebnisse zeigten. Oda et al.[21] haben gezeigt, daß der Sauerstoff im Restgas eine wichtige Rolle auf Meßergebnisse spielt. Die beschriebene Resultate sind innerhalb der Meßfehler gut reproduzierbar, welcher Erfolg nur durch die Methode der vier Zuführungsdrähten erreicht wurde, denn das Gas, das während des Aufdampfens herausgetrieben wird, an die neu aufgedampfte Schicht sofort adsorbiert und nicht mehr desorbiert, dessen Effekt durch Ionisationsmanometer auch nicht zu beobachten ist.

4–2. *Diskussion einer Diffusion in das Innere der Schicht*

Beeck[2] hat für aufgedampfte Nickelschichten eine anfängliche sehr rasche Adsorption von Wasserstoff und eine nachfolgende langsame Druckabnahme gefunden. Diese langsame Adsorption ist nach seiner Deutung eine Diffusion in das Kristallgitter. Später haben Porter u. Tompkins[12] am System Fe/H_2 und Gundry u. Tompkins[22] am System Ni/H_2 diese Annahme genau nachgeprüft und geschlossen, daß die langsame Adsorption eine Art von Oberflächenadsorption sei.

Auch in der vorliegenden Arbeit sind diese Verhältnisse mit einer anderen Methode nachgeprüft, Wie aus Abb. 17 hervorgeht will, das Verhältnis $n_{\max}/n_{\text{irr}}$ bzw. $n_{\text{rev}}/n_{\text{irr}}$ bei Messungen unterhalb Zimmertemperatur nicht so stark geändert wie die Mengen $n_{\max}$, n_{irr} und n_{rev} selbst. Ferner zeigen Abb. 13 und 14, daß dieses Verhältnis fast unabhängig von der Schichtdicke und auch von der Meßtemperatur ist. Mit Änderung der Schichtdicke ändert sich die Oberflächenrauhigkeit und dadurch auch das Verhältnis Oberfläche zu Volumen. Übrigens, wenn eine Diffusion in Filminnere stattfindet, so muß sie bei 273°K stärker als bei 90°K sein. Adsorptionsverhalten bei beider Temperatur sind bis zu dem Punkt sehr ähnlich, der etwa $n_{\min}$ bei 90°K entspricht. All diese Tatsachen deuten darauf hin, daß den vorliegenden Versuchen unterhalb Zimmertemperatur und unter 5.10^{-8} Torr keine innere Diffusion stattfindet. Bei 373°K nimmt jedoch das Verhältnis $n_{\text{rev}}/n_{\text{irr}}$ sehr stark zu. Hier liegt wahrscheinlich eine innere Diffusion vor.

4–3. *Adsorptionssisotherme und Rauhigkeitsfaktor*

Die Adsorptionsisothermen im reversiblen Bereich bei Zimmertemperatur ergibt sich gegen $\sqrt{p}$ ein geradeliniger Verlauf.[7] Erfolgt die Langmuir'sche Adsorption mit Dissoziation in zwei verschiedenen Zuständen, so gilt allgemein:

$$n=b_1\sqrt{a_1p}/(1+\sqrt{a_1p})+b_2\sqrt{a_2p}/)(1+\sqrt{a_2p}) \tag{5}$$

Wenn eine der Adsorptionswärmen bzw. eine der Konstanten a sehr groß ist, hat Gl. (5) folgende Näherung für *niedrige* Drucke:

$$n=b_1+b_2\sqrt{a_2p} \tag{6}$$

Diese Gleichung erklärt die Lage wobei die obengenannte Gerade nicht durch den Koordinatenanfangspunkt geht. Der irreversible Anteil b_1 liegt vor, wenn die Adsorptionswärme dieses Anteils so groß ist, daß das Gas nicht mehr desorbiert. In Abb. 18 wird die Langmuir'sche Gerade für reversible Mengen geprüft. Man erhält eine Gerade, aus deren Neigung der Wert b_2 zu errechen ist. Die Summe b_1+b_2 entspricht der Menge der Sättigungsadsorption 3, 7.10^{15} Molekeln/cm². Wenn man annimmt, daß die drei kristallographischen Flächen, (110), (111), (100), für nicht orientierte, dünne Schicht gleichäufig sind, bekommt man einen Oberflächen-ranhig-keitsfaktor von 4.8.

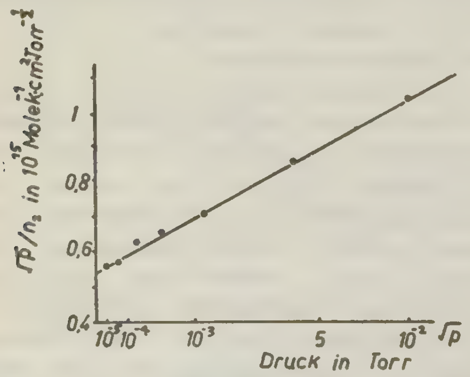

Abb. 18. Langmuir-Gerade bei 273°K nach Abb. 7

Wenn man eine Annahme von Trapnell[23] als Kriterium für $\theta=1$ übernimmt, dann beträgt die adsorbierte Menge bis 2,5 kcal, physikalische Adsorptionswärme, bei Zimmertemperatur nach Abb. 6 $2{,}5.10^{15}$ Molekeln/cm², entsprechend einem Rauhigkeitsfaktor von 3 für die Schichtdicke von ca. 100 Å.

4–4. *Molekulare Adsorption bei tiefer Temperatur*

Die Adsorptionsisotherme bei tiefer Temperatur und die daraus ermittelte Adsorptionsenthalpie (Abb. 6) lassen sich eine Schlußfolgerung herausziehen, daß die molekulare Adsorption bei tiefer Temperatur und im reversiblen Bereich voliegen[7] wobei im Widerstandsverlauf eine zweite Widerstandszunahme vorhanden ist. Somit ist anzunehmen, daß diese zweite Widerstandszunahme von der molekularen Adsorption versursacht wird. Eine Deutung der Ergebnisse geht davon aus, daß die H_2-Molekel im Oberflächenfeld des Metalls als Dipol polarisiert ist, dessen positives Ende nach außen gerichtet ist[24]. Für den Schichtwiderstand wird sich das negative Ende stärker auswirken, da es näher an der Oberfläche sitzt. Damit $\Delta R>0$.

Bei Gaszugabe bei tiefer Temperatur treten viele Peaks auf, besonders im Falle der ungetemperten Schichten. Das hat seinen Grund im folgenden. Bei stärker Besetzung wird die Wahrscheinlichkeit kleiner, daß zwei leere Plätze nebeneinander vorhanden sind, auf denen eine Molekel sofort dissozieren kann. Deshalb muß die Molekel zunächst auf einem leeren Platz molekular adsorbieren ($\Delta R>0$). Später, wenn durch Oberflächendiffusion ein zweiter benachbarter leerer Platz in der günstigen Richtung entsteht, kann die Molekel langsam auch diesen besetzen und dissozieren ($\Delta R<0$). Bei tiefer Temperatur ist die Rotationsschwingung kaum angeregt, und außerdem die Geschwindigkeit der Oberflächendiffusion geringer.

4–5. *Eigenschaften der atomaren Adsorption*

Die Adsorption von Wasserstoff an sauberem Ubergangsmetall ist zuerst von Roberts[25] untersucht worden, der fand, daß der Wasserstoff bei Zimmertemperatur in Atome dissoziert und daß die Adsorptionsgeschwindigkeit sehr groß ist. Später wurde diese Annahme auch an aufgedampften Schichten weiter bestätigt2),16),26). Die anfängliche rasche Adsorption wird als ein Charakteristikum für Sauberkeit betrachtet27),28),29),30).

Bei der Wasserstoffadsorption auf Nickel nimmt die Photoemission ab7),31), und das Oberflächenpotential wird negativ24). Dieser Befund deutet darauf hin, daß der adsorbierte Wasserstoff auf Nickel negativ polarisiert ist. Die größe des Dipolmomentes läßt sich aus verschienenen Meßergebnissen berechnen. Es wurde gefunden4), daß sie viel kleiner ist, als zu erwarten wäre, wenn der Wasserstoff als Ion adsorbiert ist. Die Adsorptionswärme ist trotzdem sehr hoch32) und auch die Widerstandsänderung ist sehr stark. Es wurde eine Theorie33),34) entwickelt, daß der Wasserstoff hauptsächlich kovalent adsorbiert ist. Man kann annehmen, daß sich eine negative Polarisation teilweise überlagert. Nach einer Theorie von Higuchi *et al*35) ist der ionische Anteil etwa 26% zu berechnen.

4–6. *Atomare Adsorption und Widerstandsänderung*

Bei atomarer Adsorption nimmt der Widerstand zunächst stark zu, dann schwächer ab. Für die Deutung dieser Erscheinung sind folgende Ursachen zu diskutieren.

a) Es findet eine Adsorption an aktiven Zentren bzw. an Gitterstörungen statt36). Solche Zentren sind sehr empfindlich gegenüber Sinterung. Die erhaltenen Meßkurven und charakteristischen Größen sind aber sämtlich ähnlich, unabhängig von der Temperung und von der Aufdampftemperatur. Aus dem Grunde ist diese Möglichkeit abzulehnen.

b) Einfluß verschiedener Kristallflächen. Aus demselben Grunde wie bei a) und deshalb, weil die Vehältnisse $n_{\max}/n_{\mathrm{irr}}$ bzw. $n_{\max}/n_{\min}$ unabhängig von der Temperung konstant bleiben, ist nicht anzunehmen, daß die verschiedenen Kristallflächen einen so verschiedenen Einfluß auf die Wasserstoffadsorption an Nickel ausüben, wie das beim Wolfram der Fall ist. Diese Differenz der Austrittsarbeiten kann nur eine untergeordnete Rolle spielen, da die atomare Adsorption hauptsächlich kovalent ist. Wortmann *et al*32) haben bei sehr sauberen Bedingungen mit dem Feldelektronenmikroskop gearbeitet und mitgeteilt, daß die Adsorption von Wasserstoff an Nickel-Einkristallen bei sehr tiefer Temperatur, anders als beim System W/H_2, sehr homogen verläuft, und daß ein Effekt durch die verschiedenen Kristallflächen nicht zu bemerken ist30).

c) Zunächst findet eine Adsorption an der äußeren Oberfläche statt, dann an der inneren, d.h. an der Grenzoberfläche der einzelnen Kristallkörnchen5). Wenn die Widerstandszunahme auf eine Adsorption an der äußeren Oberfläche, und die Abnahme auf eine Adsorption an der inneren zurückzuführen wäre, dann ist es nicht zu verstehen, daß nach dem Maximum der Widerstand bei Gaszugabe sofort abfällt und nachher langsam zunimmt.

d) Temperaturerhöhung infolge Adsorptionswärme15). Die angeführten Versuche zeigen, daß die Zunahme lange Zeit erhalten bleiten, unabhängig davon, ob die Schicht abgekühlt oder nicht. Diese Theorie kann also nicht bestätigt werden.

e) Es gibt zwei Arten der atomaren Adsorption, eine gibt die Widerstandszunahme; die andere die Abnahme. Nur diese Deutung erscheint möglich. In folgenden Paragraphen werden alle experimentellen Ergebnisse mit dieser Annahme gedeutet.

Bis zum Widerstandsmaximum ist der Wasserstoff teilweise negativ aufgeladen, da der Widerstand zunimmt und die Photoemission abnimmt7). Die Elektronen werden aus dem Metall in die Adsorptionsschicht gezogen. Dieser teilweise negativ aufgeladene Zustand sei mit $H^{(-)}$ bezeichnet. Nach dem Wider-

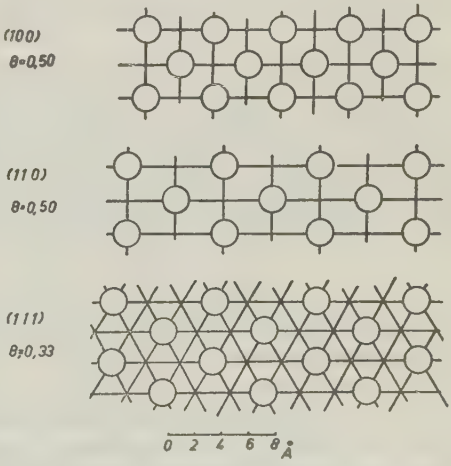

Abb. 19. Atomare Adsorption von $H^{(-)}$ auf den Ni-Kristallflächen (100), (110) und (111)

tandsmaximum soll der Wasserstoff entsprechend mit $H^{(+)}$ bezeichet werden, da der Widerstand abnimmt. In diesem Falle aber ändert sich die Photoemission wenig oder sogar nicht7). Von der Vakuumseite gesehen, wird sich das Oberflächenpotential nicht so stark ändern wie der Widerstand, denn $H^{(+)}$ ist kleiner als $H^{(-)}$ und haftet dichter an der Oberfläche.

Weil der Wasserstoff auf der Oberfläche beweglich ist32), wird sich $H^{(-)}$ am Anfang so gleichmäßig verteilen, daß die Repulsion gegeneinander möglich klein ist. Am Widerstandsmaximum liegt eine Verteilung der $H^{(-)}$ auf den einzelnen Flächen vor wie in Abb. 19 dargestellt ist. Der mittlere θ—Wert beträgt $\theta=0{,}44$, wenn alle 3 Kristallflächen als gleich häufig angenommen werden. Dieser Wert ist ein Sättigungswert und, wie nachher erklärt wird, nicht zu erreichen. Aus dem Grunde ist der beobachtete Wert $\theta(R_{\max})$ kleiner. $n_{\max}$ entspricht einer Oberflächenbelegung von ca. $\theta=0{,}2$, unter der Annahme, daß der Rauhigkeitsfaktor 4 ist.

Nach diesem Maximum folgt stärkere Repulsion zwischen den adsorbierten Atomen. Von diesem Moment an wird die Adsorption für $H^{(+)}$ günstiger, weil einerseits die elektrostatische Energie damit verringert wird und anderseits $H^{(+)}$ kleiner ist. Dann kann es auch im Gegensatz zu $H^{(-)}$ leichter in die feinen Spalten eindringen und dort adsorbieren. Deshalb ist bei Zimmertemperatur weitere Adsorption von $H^{(+)}$ möglich, während bei 90°K beim Überschreiten einer gewissen Belegung molekulare Adsorption stattfindet.

4–7. *Elektronische Begründung der Adsorption*

In Abb. 20 ist das Potentialprofil des System Ni/H_2 dargestellt, dessen Berechnung auf Morse'scher Kurve und auf Literaturenwerte erfolgt. Die Abb. 20 zeigt, daß die Wasserstoffmolekel keine Aktivierungsenergie braucht, um zu dissozieren und zu chemisobieren27).

Dowden37) hat auf Grund theoretischer Überlegungen auf die Möglichkeit hingewiesen, daß zwei Adsorptionstypen für Waserstoff am Nickel vorliegen können. Diese Theorie ist später von Gundry u. Tompkins38) zur Deutung ihrer Ergebnisse aufgegriffen worden. Eine Deutung erfolgt mit kombinierten d-s-p-Orbitals, die andere lediglich mit d-Orbital. Im folgenden wird eine vorläufige Annahme gemacht, daß $H^{(-)}$ der d-s-p-Bindung und $H^{(+)}$ der d-Bindung entspricht. Es ist nicht unbedingt nötig, aber dient zur Veranschaulichung.

In Abb. 21 ist das gesamte Schema der Potentialkurven dargestellt. Es ist zu beachten, daß die Potentialkurven für die d-s-p-Bindung und für die d-Bindung auf der Abszisse getrennt dargestellt sind. Das bedeutet nicht, daß die Bindungsabstände so verschieden sind, sondern nur, daß die d-s-p-Bindung nach der d-Bindung erreicht wird und deshalb von der Gasphase weiter entfernt dargestellt ist. Die zunächst stattfindende einfache d-Bindung kann in die stärkere d-s-p-Bindung übergehen ohne daß ein Platzwechsel erfolgt.

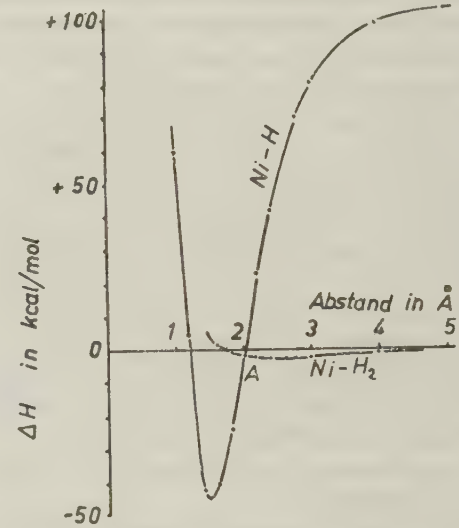

Abb. 20. Potentialprofil des Systems Nickel-Wasserstoff

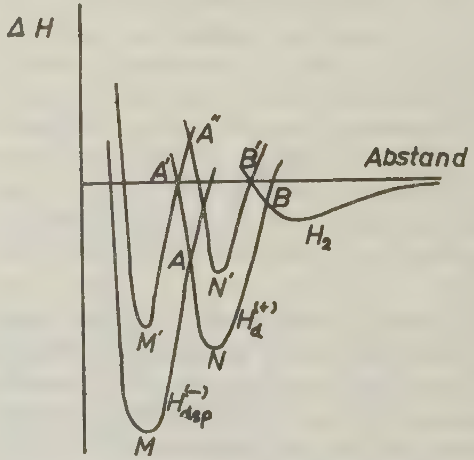

Abb. 21. Potentialprofil nach der Theorie von Dowden

Wenn eine Molekel auf die Schicht trifft, wird sie sofort dissozieren und in die tiefste Mulde M fallen. Dabei ist $\Delta R>0$ und die Adsorptionsenthalpie am größten. Mit der Besetzung wird die d-s-p-Kurve angehoben, bis der Schnittpunkt A die Nulllinie erreicht (A'). Danach adsorbiert Wasserstoff zum größten Teil als $H^{(+)}$ mit d-Bindung aber noch ohne Aktivierungsenergie; denn B liegt unter der Nulllinie. Mit der Besetzung steigt auch diese Kurve an, bis der Schnittpunkt B mit der Kurve für die van der Waal'schen Adsorption (H_2) die Nulllinie erreicht (B'). Danach wird bei 90°K der Wasserstoff nur noch zunächst molekular adsorbiert (H_2). Bei Zimmertemperatur kann wegen der thermischen Energie der Wasserstoff über die Potentialmauer in die d-Bindung gelangen. Der Schnittpunkt zwischen den Potentialkurven für $H^{(-)}$ und $H^{(+)}$ ist nun sehr stark gestiegen (A'') und sehr schwer übersteigbar. Bevor der tiefste Punkt M der d-s-p-Kurve und der tiefste N der d-Kurve die Nullinie nicht erreichen, ist keine wahre Sättigungsadsorption anzunehmen. Diese ist wegen der hohen Potentialmauer sehr schlecht erreichbar.

Die Aktivierungsenergie für die Desorption ist anfänglich sehr hoch und viel größer als für die Adsorption. Desorption findet deshalb noch nicht statt, auch wenn abgepumpt wird. Beim Auftreten der reversiblen Adsorption sind die Rotentialkurven so weit gestiegen, daß die Aktivierungsenergie für die Desorption bedeutend kleiner geworden ist. Bei 90°K ist die thermische Energie aber so klein, daß praktisch nur Molekeln desorbiert werden, während bei Zimmertemperatur immerhin die Atome über den molekularen Zustand langsam desorbieren, wie es aus Abb. 3 und Abb. 9 entnommen kann.

Bei allen Meßkurven ist eine stets zunehmende Tendenz des Widerstandes vorhanden. Solange M niedriger als N und N niedriger als die Nulleinie liegt, wird $H^{(+)}$ aus der d-Binding nicht desorbieren, sondern langsam in die d-s-p-Bindung übergehen. Dieser Übergang ist der langsamen, ständigen Widerstandserhöhung zuzuschreiben, die bei Zimmertemperatur relativ schnell zu einem Abschluß kommt (Abb. 2), während sie bei tiefer Temperatur lange Zeit benötigt.

Die Verhältnisse betreffs der Widerstandsänderung sind bei 90°K recht kompliziert. Bei der Gaszugabe überschreitet der Widerstand einen Peak (H_2), bevor er abnimmt. Bei noch größeren Zugabedrucken tritt die Inversion ein. Diese Inversion wird, wie in Abb. 8 und 9, verstärkt durch großen Druck und durch Temperaturerhöhung. Durch die beiden Effekte geht die Umwandlung $H_2\rightarrow H_d^{(+)}\rightarrow H_{dsp}^{(-)}$ schneller. Wenn die für die d-s-p-Bindung in Frage kommenden Plätze alle besetzt sind, wird die langsame Widerstandszunahme geringer. Die Stellen, die bei niedrigem reversiblem Druck von H_2 besetzt waren, sind jetzt von stärker gebundenen $H_{dsp}^{(-)}$ eingenommen. Nach dieser Druck- bzw. Temperaturerhöhung sind im reversiblen Bereich unter niedrigem Druck nur noch sehr wenig Stellen für stabiles H_2 verfügbar. Bei weiteren Gaszugaben entsteht der instabile Peak, aber es schließt sich der folgende, reversible Vorgang an $H_2\rightleftarrows H_d^{(+)}$. Der Widerstand nimmt bei der Zugabe nach dem Peak ab. Es ist also Inversion eingetreten.

Das Oberflächenpotential im reversiblen Bereich und bei Zimmertemperatur wird bei der Zugabe durch den Übergang $H_d^{(+)}\rightarrow H_{dsp}^{(-)}$ etwas negativer, und damit wird die Photoemission verringert, da der Effekt von $H_{dsp}^{(-)}$ stärker als der von $H_d^{(+)}$ ist. Bei der Zugabe von noch höheren Drucken wird der Adsorptionszustand von $H_{dsp}^{(-)}$ allmählich gesättigt, und nun bleibt der Wasserstoff meistens als $H_d^{(+)}$. Das Oberflächenpotential wird somit etwas positiv, wie auch bei Photoemission7) gefunden worden ist.

4–8. *Reaktionskinetik*

a) Zimmertemperatur

Erst im reversiblen Bereich ist die Geschwindigkeit dn/dt bzw. dR/dt meßbar. In diesem Falle ist, wie Abb. 21 zeigt, die Potentialkurve nach oben zu verschoben. Die Aktivierungsenergie E ist entsprechend höher7), ihre Zunahme ΔE in erster Näherung proportional der adsorbierten Menge. Diese Proportionalität ist theoretisch und experimentell bestätigt worden26),39),40).

$$\Delta E=\mathrm{Const}\cdot n \tag{7}$$

$$dn/dt=\mathrm{Const}\cdot\exp\left(-\frac{E+\mathrm{Const}\cdot n}{kT}\right)=a\cdot e^{-\alpha n} \tag{7'}$$

Daraus folgt durch Integration

$$n=\frac{1}{\alpha}[\ln(t+t_0)-\ln \alpha a] \tag{8}$$

$$t_0=\frac{e^{\alpha n_0}}{\alpha a},\quad n_0=n_{(t=0)},$$

also Zeldovich-Gleichung. In diesem Falle spielt eine Reaktionsordnung eine untergeordnete Rolle. Die Gesetzmäßigkeit gilt sowie bei Widerstandsänderung, da sie proportional der adsorbierten Menge ist, als auch bei der Desorption, da die Aktivierungsenergie für Desorption auch zunimmt.

b) 90°K

b–1) Adsorption als Molekel

Wie an dem Peak im reversiblen Bereich zu erkennen ist, geht die Adsorption als Molekel sehr rasch vor sich. Die molekulare Adsorption geht beim Abpumpen sofort zurück.

b–2) Dissoziation in Atome

Die Molekel kann sich zersetzen und $H^{(+)}$ bilden soweit noch ein benachbarter leerer Platz verfügbar ist. Der zeitliche Verlauf des Peaks bei einer jeden Zugabe ist nicht genau zu verfolgen, da der Vorgang sehr schnell ist. Bei ungetemperter Schicht jedoch ist der Peak größer und der Gang verfolgbar. Nach Eliminierung des Ordnungsvorgangs der Schicht selbst ist die Kurve in Abb. 22 dargestellt.

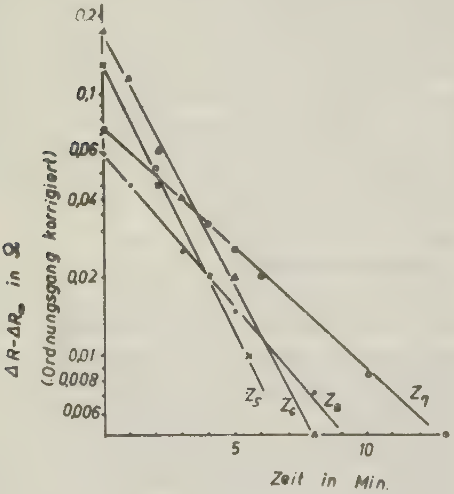

Abb. 22. Zeitlicher Verlauf der Dissoziation bei einer ungetemperten Schicht

Die Reaktion 1. Ordnung ist für die beiden Mechanismen möglich, die in § 4–4 vorgeschlagen waren.

Auch der Peak im zweiten Widerstandszunahmebereich (Z_9 in Abb. 7) kann untersucht werden. Hier ist die atomare d-Bindung bereits stark besetzt, so daß der Schnittpunkt B fast zur Nullline angehoben ist. Die Molekel kann nicht mehr sofort dissozieren und zunächst als polarisierte Molekel adsorbiert. Die für die molekulare Adsorption in Betracht kommenden Stellen sind aber noch nicht ganz besetzt, weshalb die Adsorption immer noch rasch vor sich geht. Die Dissoziation wird in dem Falle bestimmt durch die Geschwindigkeit, mit der der Punkt B überwunden wird. Die Analyse ergibt also eine Zeldovich-Gleichung, die experimentell bestätigt werden kann.

b–3) Stets zunehmende Tendenz des Widerstandes

Wie vorher häufig erwähnt wurde, gibt es bei 90°K eine lineare Widerstandszunahme. Bei tiefer temperatur geht die Überwindung der Potentialmauer zwischen d- und d-s-p-Bindung langsam vor sich. Die Zeldovich-Gleichung wird dann für die Bedingung: kleines T bzw. großes α umgeformt

$$n=\frac{1}{\alpha}\left[\frac{t}{t_0}+\ln t_0-\ln\frac{1}{\alpha a}\right]. \tag{9}$$

Das besagt; die d-Bindung wandelt sich mit der Zeit linear in die d-s-p-Bindung um. Der gesamte Widerstand nimmt linear zu, denn es ist $|\varDelta R_{asp}|>|\varDelta R_d|$. Der lineare Vorgang wird durch eine Druckerhöhung und eine Temperaturerhöhung zur Sättigung beschleunigt (vgl. Abb. 9).

b–4) Schlußfolgerung für 90°K

Die H_{dsp}-Bindung wird am Anfang des Versuchs zuerst besetzt, dann H_d und H_2. In den späteren Versuchsstufen ist wegen der Anhebung der Potentialkurven diese Reihe umgekehrt, nämlich zuerst wird H_2 besetzt, dann H_d und langsam H_{dsp}. Diese Tatsache ist nur durch die Wechselwirkungstheorie mit zwei Bindungstypen zu verstehen.

4–9. *Elektronische Begründung der Widerstandsänderung*

Die folgenden Ausführungen beziehen sich auf die Widerstandsänderung bis zum Erreichen der maximalen Widerstandszunahme. Nach der semi-klassischen Sommerfeld'schen Theorie gilt die Gleichung

$$R=\frac{1}{\sigma}=\frac{\text{Const}}{N.1.d}\,, \tag{10}$$

wobei σ die Leitfähigkeit, N die Zahl der effektiven Leitungselektronen pro cm³, l die mittlere freie Weglänge der Leitungselektronen bedeuten.

Für die Leitfähigkeit σ bei Schichtdicken, die Größer als die freie Weglänge sind, gilt theoretisch folgende Formel[41],

$$\frac{\sigma}{\sigma_\infty}=1-\frac{3}{8}\frac{l}{d}\,, \qquad (11)$$

wobei σ_∞ sich auf unendlich dicke Schichten bezieht. Sie entspricht der empirischen Formel Gl. (3). Nach dieser Gleichung beträgt die freie Weglänge ca. 110 Å (umgerechnet aus Abb. 12), während in der Literatur[42] für massives Nickel 266 Å angegeben ist. Für aufgedampfte, feinkörnige Schichten ist 110 Å plausibel.

Für Widerstandsänderung infolge der Adsorption folgt es aus Gl. (10):

$$-\frac{\Delta R}{R}=\frac{\Delta N}{N}+\frac{\Delta l}{l}+\frac{\Delta d}{d}\,. \qquad (12)$$

Zu erster Näherung wird $-\Delta R/R=\Delta N/N$ angenommen[3]. Die Widerstandsänderung wird in Elektronenzahländerung umgerechnet und in Einheiten pro adsorbiertes Wasserstoffatom in Abb. 23 dargestellt. Dabei wird angenommen, daß ein Nickelatom 0,6 freie Leitungselektronen liefert. (Die unteren Kurven stellen die für $H^{(+)}$ berechnete Werte dar.).

Die Elektronenbeanspruchung ist temperaturabhängig, wie aus Abb. 15 und 23 hervorgeht. Wenn die Widerstandsänderung durch Beanspruchung bzw. Lieferung von Leitungselektronen besteht, ist die Tatsache sehr schwierig zu verstehen; denn die Leitungselektronenzahl ist temperaturunabhängig. Der berechnete Wert von ca. 3 Elektronen pro H-Atom für dicke Schichten ist auch viel zu groß, sowohl bei kovalenter als auch ionischer Bindung.

In Abb. 24 ist der Absolutwert $\Delta R/_{\max}$ gegen

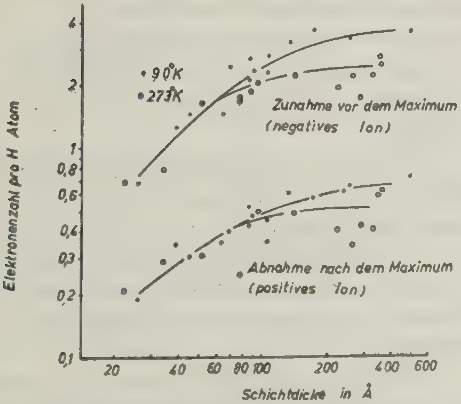

Abb. 23. Elektronenbeanspruchung pro Wasserstoffatom in Abhängikeit von der Schichtdicke

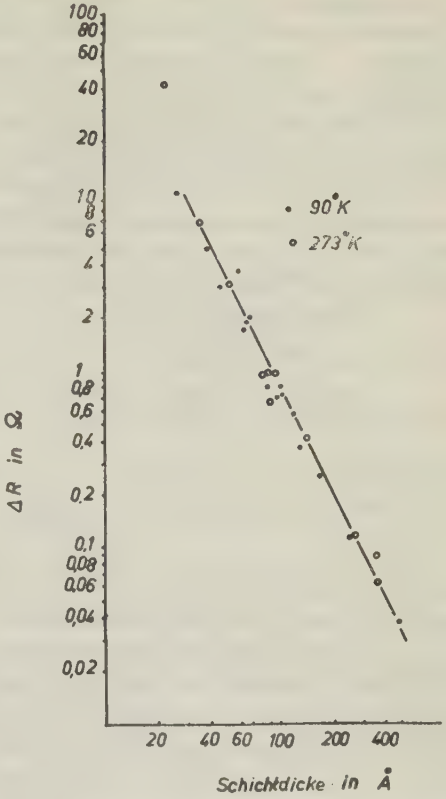

Abb. 24. Maximale absolute Widerstandszunahme bei 90°K und 273°K als Funktion der Schichtdicke

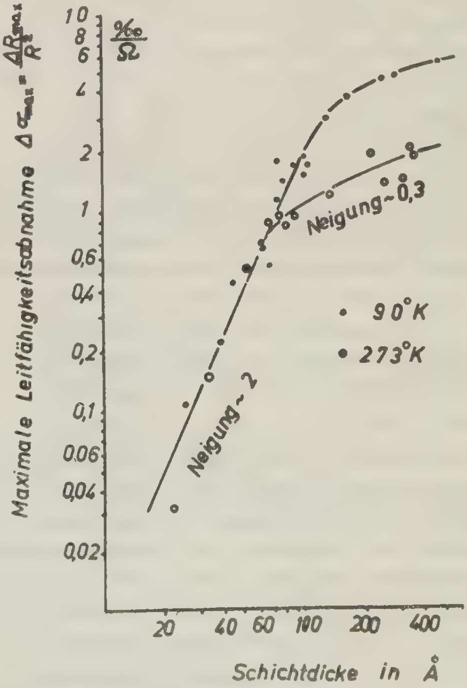

Abb. 25. Maximale Leitfähigkeitsabnahme bei 90°K und 273°K als Funktion der Schichtdicke

d aufgetragen. Der durch Adsorption hervorgerufene Zusatzwiderstand ist temperaturunabhängig. Diese Tatsache deutet genau wie bei der Matthiessen'schen Regel daraufhin, daß die Widerstandsänderung durch eine Behinderung der Leitung verursacht wird und nicht durch die Änderung der Elektronenzahl.

In Abb. 25 ist $\Delta\sigma_{\max}$ gegen d aufgetragen. Nach Abb. 15 kann man näherungsweise folgende Gleichung erhalten

$$1/R=\mathrm{Const}\cdot N.l.d^m \tag{13}$$

wobei $m\geq 1$. Daraus folgt

$$-\frac{\Delta R}{R}=\frac{\Delta N}{N}+\frac{\Delta l}{l}+m\frac{\Delta d}{d} \tag{14}$$

und ferner

$$\Delta\sigma=-\frac{\Delta R}{R^2}=\Delta N.l.d^m+\Delta l.N.d^m+md.N.l.d^{m-1} \tag{15}$$

Aus Abb. 12 erhält man für dickere Schichten einen Wert $m\gtrsim 1$, und für dünnere $m\simeq 2$.

Zur Deutung des Kurvenverlaufs in Abb. 25 für *dickere* Schichten, bei denen $\Delta\sigma$ temperaturabhängig ist und die Neigung etwas größer als 0 ist, kann nur das letzte Glied der rechten Seite in Gl. (15), $\Delta d.N.l.d^{m-1}$, herangezogen werden. Das Auftreten von Δd im letzten Glied könnte in folgender Weise gedeutet werden. Durch die Wechselwirkung werden die s-Elektronen teilweise in die d-Lücken[4)18)] und teilweise für die Aufladung des Wasserstoffs übergehen, um damit eine Bindung aufzuführen, was zur Folge hat, daß die Oberflächennickelschicht freie Elektronen verliert und eine Elektronenmangelschicht sich bildet. Als Endeffekt wird diese unmittelbare Oberflächennähe für die Stromleitung unwirksam. Die effektive Dickenänderung beträgt ca. 4Å, also 1∼2 Nickelatomschichten.

Bei *dünneren* Schichten (<110Å) gilt $m\simeq 2$ und dann kommt als einzige Möglichkeit für eine Deutung des Kurvenverlaufs in Abb. 25 das Glied $\Delta l.N.d^2$, bei dem einerseits die Neigung ca. 2 ist und das anderseits temperaturunabhängig ist. Bei dünneren Schichten spielt die Oberflächenrauhigkeit eine wichtige Rolle. Die Streuung der Leitungsselektronen durch das in Spallen sleckende $H^{(-)}$ wirkt viel stärker aus, als auf einer glatten Schicht. Dabei sollte man den Effekt nicht als gleich mäßige Querschnittänderung betrachten, denn in der Schicht, bei der die Schichtdicke kleiner als die freie Weglänge ist, ändert sich der Widerstand durch die Querschnittänderung nicht.

Der Effekt beruht also auf eine Änderung der freien Weglänge. In Analogie zur Matthiessen'schen Regel bei Legierungen kann die wahre Elektronenbeanspruchung bei einer dünnen Schicht sehr grob abschätzen. Massive Legierung und Oberflächenadsorption sind natürlich nicht dasselbe, doch in dem Punkte ähnlich, daß jede freie Weglänge von der zusätzlichen Streuung beeinflußt wird. Da $n_{\max}$ ca. $1{,}10^{15}$ Atome/cm² beträgt, und da auf ein Ni-Oberflächenatom 1 H-Atom kommt [2),12),22)], werden ebenso viele Nickelatom aufgeladen. Man nimmt also an, daß ebenso viele zusätzlich geladene Gitterbausteine gleichmäßig verteilt sind. Die effektive geänderte Ladungszahl ΔZ ist wie folgt abzuschätzen: Bei Gültigkeit der Gleichung[44)]

$$\Delta R=\mathrm{Const}\ (\Delta Z)^2 n\,, \tag{16}$$

in der n der prozentuale Zusatz an Störatomen ist, beträgt ΔZ für Adsorption ca. 0,3, denn die Widerstandsänderung bei einer Schichtdicke von 50Å beträgt ca. 3%, und ein Zusatz von 1 Atom—% Cu eine Widerstandsänderung ergibt von 15% bei einer Ladungsdifferenz[42)]. Die Aufladung des Wasserstoffs ist somit nicht so stark.

§ 5. Zusammenfassung

1. Sehr saubere Ni-Schichten wurden im Ultrahochvakuum hergestellt. Die Wasserstoffadsorption wurde im Temperaturbereich von 77°K bis 373°K gemessen.

2. Die Adsorption ist im wesentlichen eine Oberflächenerscheinung, wenn die Adsorption unter Zimmertemperatur stattfindet.

3. Der elektrische widerstand wird bei dem Adsorption zunächst vergrößert.

4. Bei tiefer Temperatur gibt es ein Widerstandsmaximum und anschließend ein Minumum, bei Zimmertemperatur nur ein Maximum.

5. Es findet anfänglich eine rasche irreversible Adsorption statt, danach eine langsame reversible Adsorption.

6. Die Adsorption bei Zimmertemperatur ist atomar, die bei tiefer Temperatur ist ein Gemisch von atomarer und molekularer Adsorption.

7. Unter der Annahme, daß bei atomarer Adsorption zwei Bindungstypen möglich sind, lassen sich alle komplizierten Erscheinungen

und die Kinetik erklären.

8. Die Widerstandsänderung wird durch eine Störung des Leitungszustandes im Metall verursacht, d. h. durch eine Änderung des wirksamen Querschnittes oder Streuung der Elektronen.

9. Die Polarisation des adsorbierten Wasserstoffs ist verhältnismäßig gering, obgleich der Effekt auf Elektronenleitung ausgeprägt ist.

Der Deutsche Akademische Austauschdienst und die Deutsche Forschungsgemeinschaft haben die Arbeit durch Stipendien unterschützt. Herrn Prof. Dr. R. Suhrmann möchte ich für die Anregung zu dieser Arbeit, die Bereitstellung der nötigen Mittel und die sorgfältigen Diskussionen meinen herzlichen Dank aussprechen. Herr T. Ichimiya, der ein Stipendium ermöglichte, sei auch bestens gedankt.

The Binding Energy of the σ Bond. IV.
Discussion on the Higher Order Terms

By Kiyosi O-OHATA

Physics Department, Tokyo Institute of Technology,
Oh-okayama, Meguro-ku, Tokyo

(Received March 5, 1960)

It has been shown in the previous report that the bond orbital method gives the total energy of the molecule as the expanded power series of the overlap integrals between the bond orbitals. It is here shown that the contribution of the third order terms of these overlap integrals, which are neglected hitherto, to the binding energy of the σ bond is by no means negligible though smaller than that of the second order terms. In the case where the third order terms are taken into account, the validity of the additivity rule of the binding energies of the saturated hydrocarbons is discussed.

§1. Introduction

In the previous report[1] we considered the binding energy of the saturated molecules with only σ bonds, assuming that the total energy of these molecules can be obtained in good approximation if we take into account the terms up to the second order of the overlap integrals between orbitals involved in the different bonds. It is very difficult to discuss generally the contribution of the higher terms than the third order to the binding energy of the σ bond. We here propose a method to discuss this problem with the use of the bond orbital method. In the bond orbital method the ground electronic state of the saturated molecule is expressed by a closed shall like structure, in which individual orbitals are filled with two electrons with the opposite spins. There arises no difference in the expectation value of the total energy whether we use, as bond orbitals, a set of nonorthogonal orbitals or that of the mutually orthogonal bond orbitals constructed by the linear combinations of the former orbitals. We follow the method of orthogonalization due to Landshoff and Loewdin.[2] Then we can easily obtain the expression of the total energy of the molecule which takes into account the higher order terms of the non-orthogononality between the different bonds. We shall particularly discuss the magnitude of the contribution of the third order terms to the binding energy of the saturated molecule.

§2. The Bond Orbitals

We consider a chemical bond A-B, which binds the atoms A and B in the saturated molecule. The bond orbital τ_α, which is in charge of the bond A-B, is given by a linear combination of ϕ_i the atomic valence orbitals of the atom A and ϕ_j that of the atom B, namely,

$$\tau_\alpha=\frac{1}{\sqrt{N_\alpha}}(\lambda\phi_i+\mu\phi_j)\ , \tag{2.1}$$

where $N_\alpha=\lambda^2+\mu^2+2\lambda\mu S_{ij}$, λ and μ are the parameters, and S_{ij} is the overlap integral between the orbitals ϕ_i and ϕ_j. The electronic ground configuration of the molecule is given by

$$\tau_\alpha)^2\tau_\beta)^2\tau_\gamma)^2\cdots\tau_\zeta)^2\ . \tag{2.2}$$

We here exclude the lone-pair and core electrons, but even if we include them to the configuration (2.2), it is still valid that the electronic configuration is given by a closed shell like structure. We shall assume that the bond orbitals are orthogonal to the lone-pair and core orbitals. If it is not the case, we can follow the orthogonalization process to make the valence orbitals to be orthogonal to the core orbitals, as discussed in §2 of I.

We here apply the Loewdin method of orthogonalization to the set of bond orbitals (2.2) to make them mutually orthogonal. According to Loewdin, the relation between the column matrix of the orthogonal bond orbitals (τ^0) and the one of the non-orthogonal bond orbitals (τ) is given by

$$(\tau^0)=(\mathbf{1}+\boldsymbol{T})^{-1/2}(\tau)\ , \tag{2.3}$$

where $\mathbf{1}$ is the unit matrix, $\boldsymbol{T}$ is the matrix constructed from the overlap integrals $T_{\alpha\beta}$

between the bond orbitals τ_α and τ_β, and $T_{\alpha\alpha}$ is assumed to be zero. As the state is given by a closed shell like structure the wave function constructed from the configuration (2.2) is the same as that from the configuration

$$\tau_\alpha{}^o)^2\tau_\beta{}^o)^2\tau_\gamma{}^o)^2\cdots\tau_\zeta{}^o)^2 \tag{2.4}$$

and the electronic energry of the molecule obtained by the former function is the same as that by the latter one.

The detailed form of the orthogonal bond orbital $\tau_\alpha{}^o$ is

$$\begin{aligned}\tau_\alpha{}^o=&\left\{1+\frac{8}{3}\sum_\xi T^2_{\alpha\xi}-\frac{5}{16}\sum_\xi T_{\alpha\xi}\left(\sum_\eta T_{\alpha\eta}T_{\xi\eta}\right)\right\}\tau_\alpha\\&-\sum_\beta\left\{\frac{1}{2}T_{\alpha\beta}-\frac{3}{8}\sum_\xi T_{\alpha\xi}T_{\beta\xi}\right.\\&\left.+\frac{5}{16}\sum_\xi T_{\alpha\xi}\left(\sum_\eta T_{\beta\eta}T_{\xi\eta}\right)\right\}\tau_\beta\,,\end{aligned} \tag{2.5}$$

where we neglect the terms of the higher than the fourth order in the powers of the overlap integrals, the subscripts denote the individual bonds and the summation is taken over all the constituent bonds. The total energy of the molecule is expressed as

$$E=2\sum_\alpha I^o_{\alpha\alpha}+\sum_\alpha\sum_\beta(2C^o_{\alpha\beta}-K^o_{\alpha\beta})+\sum_{(XY)}\frac{Z_XZ_Y}{R_{XY}}\,, \tag{2.6}$$

where

$$I^o_{\alpha\alpha}=(\tau_\alpha{}^o|h|\tau_\alpha{}^o)=\int\tau_\alpha{}^o(1)h(1)\tau_\alpha{}^o(1)dv_1\,,$$

$$\begin{aligned}C^o_{\alpha\beta}&=(\tau_\alpha{}^o\tau_\alpha{}^o;\tau_\beta{}^o\tau_\beta{}^o)\\&=\iint\tau_\alpha{}^o(1)\tau_\beta{}^o(2)\frac{1}{r_{12}}\tau_\alpha{}^o(1)\tau_\beta{}^o(2)dv_1dv_2\,,\end{aligned}$$

and

$$\begin{aligned}K^o_{\alpha\beta}&=(\tau_\alpha{}^o\tau_\beta{}^o;\tau_\beta{}^o\tau_\alpha{}^o)\\&=\iint\tau_\alpha{}^o(1)\tau_\beta{}^o(2)\frac{1}{r_{12}}\tau_\beta{}^o(1)\tau_\alpha{}^o(2)dv_1dv_2\,.\end{aligned}$$

$h(1)$ is a part of the total Hamiltonian which depends on only one electron, and we assumed all the orbitals to be real. The last term in Eq. (2.6) shows the nuclear repulsion. If we substitute the relation (2.5) into Eq. (2.6) and omit the terms higher than fourth order of the overlap integrals, we obtain an approximate formula for the total energy. Based on the order of the overlap integrals we can devide the total energy as follows:

1. The zeroth order terms:

$$\sum_\alpha E_0(\alpha)=\sum_\alpha\left(2I_{\alpha\alpha}+C_{\alpha\alpha}+2\sum_{\beta\neq\alpha}{}'C_{\alpha\beta}\right)+\sum_{(XY)}\frac{Z_XZ_Y}{R_{XY}}\,, \tag{2.7}$$

2. The second order terms:

$$\begin{aligned}\sum_{(\alpha\beta)}E_2(\alpha\beta)=2\sum_{(\alpha\beta)}&\Big[T^2_{\alpha\beta}\Big\{I_{\alpha\alpha}+I_{\beta\beta}+C_{\alpha\alpha}+C_{\beta\beta}+3C_{\alpha\beta}+2\sum_{\xi\neq\alpha,\beta}{}''(C_{\alpha\xi}+C_{\beta\xi})\Big\}\\&-2T_{\alpha\beta}\Big(I_{\alpha\beta}+D_{\alpha,\alpha\beta}+D_{\beta,\alpha\beta}+2\sum_{\xi\neq\alpha,\beta}{}''C_{\xi,\alpha\beta}\Big)-K_{\alpha\beta}\Big]\,,\end{aligned} \tag{2.8}$$

3. The third order terms:

$$\begin{aligned}\sum_{(\alpha\beta\gamma)}E_3(\alpha\beta\gamma)=-4\sum_{(\alpha\beta\gamma)}&\Big[T_{\alpha\beta}T_{\beta\gamma}T_{\gamma\alpha}\Big\{I_{\alpha\alpha}+I_{\beta\beta}+I_{\gamma\gamma}+C_{\alpha\alpha}+C_{\beta\beta}+C_{\gamma\gamma}\\&+3(C_{\alpha\beta}+C_{\beta\gamma}+C_{\gamma\alpha})+2\sum_{\xi\neq\alpha,\beta,\gamma}{}'''(C_{\alpha\xi}+C_{\beta\xi}+C_{\gamma\xi})\Big\}\\&-T_{\beta\gamma}T_{\gamma\alpha}\Big(I_{\alpha\beta}+D_{\alpha,\alpha\beta}+D_{\beta,\alpha\beta}+D_{\gamma,\alpha\beta}+2\sum_{\xi\neq\alpha,\beta,\gamma}{}'''D_{\xi,\alpha\beta}\Big)\\&-T_{\gamma\alpha}T_{\alpha\beta}\Big(I_{\beta\gamma}+D_{\alpha,\beta\gamma}+D_{\beta,\beta\gamma}+D_{\gamma,\beta\gamma}+2\sum_{\xi\neq\alpha,\beta,\gamma}{}'''D_{\xi,\beta\gamma}\Big)\\&-T_{\alpha\beta}T_{\beta\gamma}\Big(I_{\gamma\alpha}+D_{\alpha,\gamma\alpha}+D_{\beta,\gamma\alpha}+D_{\gamma,\gamma\alpha}+2\sum_{\xi\neq\alpha,\beta,\gamma}{}'''D_{\xi,\gamma\alpha}\Big)\\&+T_{\alpha\beta}L_{\gamma,\alpha\beta}+T_{\beta\gamma}L_{\alpha,\beta\gamma}+T_{\gamma\alpha}L_{\beta,\gamma\alpha}\Big]\,.\end{aligned} \tag{2.9}$$

In the above expression, $\sum_\alpha$ in the zeroth order terms, $\sum_{(\alpha\beta)}$ in the second order terms, and $\sum_{(\alpha\beta\gamma)}$ in the third order terms mean the summations over all the constituent bonds, over all the pairs of the bonds, and over all the sets of three bonds, respectively, and

$$I_{\alpha\beta}=(\tau_\alpha|h|\tau_\beta)\ , \qquad C_{\alpha\beta}=(\tau_\alpha\tau_\alpha;\tau_\beta\tau_\beta)\ ,$$
$$K_{\alpha\beta}=(\tau_\alpha\tau_\beta;\tau_\alpha\tau_\beta)\ , \qquad D_{\alpha,\beta\gamma}=(\tau_\alpha\tau_\alpha;\tau_\beta\tau_\gamma)\ ,$$
$$L_{\alpha,\beta\gamma}=(\tau_\alpha\tau_\beta;\tau_\alpha\tau_\gamma)\ .$$

The discussion on the zeroth order and the second order terms in the preceding articles can of course be applied in the present case. In fact, it is easy to show the equivalence between H_0/Δ_0 in I and Eq. (2.7) and that between $H_2/\Delta_0-H_0\Delta_2/\Delta_0^2$ in I and Eq. (2.8).

§ 3. The Contribution of the Third Order Terms

We compute the magnitude of the contribution of the third order terms Eq. (2.9) to the binding energy of the C–C bond in the diamond crystal. In this case, we can put $\lambda=\mu=1$ from the symmetry consideration of the bond. The structure diagram of the diamond crystal is shown schematically in Fig. 1. Eq. (2.9) consists of the summation over the sets of three bonds. We classify the various sets of three bonds in the diamond crystal into the following groups:

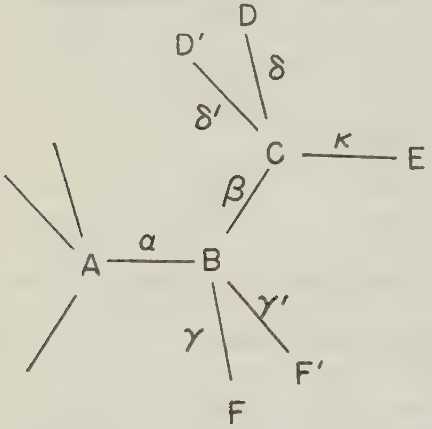

Fig. 1. Schematical Diagram of the Diamond Crystal. Capital letters show the constituent atoms and Greek small letters denote the constituent bonds.

1. (α, β, γ), where α, β and γ are the adjacent bonds with each other.

2. (α, β, δ), where β is adjacent to both of α and δ, but δ is the second nearest neighbouring bond to α and locates at the gauche position for α.

3. (α, β, κ), where α and β, β and κ are the adjacent bonds as in the preceding case, but κ, the second nearest neighbour bond of α, locates at the trans position for α.

4. (α, γ, κ), where α and γ are the adjacent bonds, and κ is the second nearest neighbouring bond for both of α and γ and locates at the trans position for α and at the gauche position for γ.

5. $(\alpha, \gamma, \delta')$, where α and γ are the adjacent bonds, and δ' is the second nearest neighbouring bond for both of α and γ and locates at the gauche position for both of α and γ.

6. (α, δ, η), where α, δ and η are the second nearest neighbouring bonds with each other.

7. Other sets of three bonds.

The sets of three bonds having the same geometrical structure give the same contribution to the binding energy of a bond. The total contribution of the third order terms to the binding energy of a bond is expressed as

$$2E_3(\alpha\beta\gamma)+6E_3(\alpha\beta\delta)+3E_3(\alpha\beta\kappa)$$
$$+12E_3(\alpha\gamma\kappa)+6E_3(\alpha\gamma\delta')+2E_3(\alpha\delta\eta)\ , \qquad (3.1)$$

where we neglect the contribution from the 7th group. In the calculation of each term in Eq. (3.1), the values of the molecular integrals appearing in Eq. (2.9) are readily evaluated, as they are expressed as the linear combinations of the molecular integrals involving the atomic orbitals used already in the previous paper of this series. The values of many center energy integrals are estimated by an approximation like Mulliken's one. In the evaluation of the value of $E_3(\alpha\beta\gamma)$ of the first group, we take into account only the potential of the atoms A, B, C and F in Fig. 1. This corresponds to the assumption that the molecular integrals are approximated by the following formulae:

$$C_{\alpha\xi}\simeq\frac{1}{2}(C_{\alpha x}+C_{\alpha y}),\quad D_{\xi,\alpha\beta}\simeq\frac{1}{2}(D_{x,\alpha\beta}+D_{y,\alpha\beta})\ ,$$

where ξ shows a bond other than α, β, and γ, and $\tau_\xi=(\phi_x+\phi_y)/\sqrt{2(1+S_{xy})}$. This may not introduce any significant error in the calculation of the value of $E_3(\alpha\beta\gamma)$ because of the same reason as we have already given for the approximate validity of Mulliken's approximation. The similar treatments have been applied to compute the values of the other terms in Eq. (3.1), that is, only the effect from the atoms in the set of the three bonds is considered explicitly and other atoms are assumed to be completely shielded by their valence electrons. The result of the computation is given in Table I.

Table I. The Contribution from Each Group (in eV).

$2E_3(\alpha\beta\gamma)$	$6E_3(\alpha\beta\delta)$	$3E_3(\alpha\beta\kappa)$	$12E_3(\alpha\gamma\kappa)$	$6E_3(\alpha\gamma\delta')$	Total
−0.83	−0.59	+0.44	+0.73	−0.42	−0.67

We neglect the contribution from the term $2E_3(\alpha\delta\eta)$ of the sixth group, the magnitude of which is estimated roughly as about 0.1 eV, namely about 1/8 of the first term. As the values of the overlap integrals between the bonds are: $T_{\alpha\beta}\simeq 0.1$, $T_{\alpha\delta}\simeq 0.05$ and $T_{\alpha\kappa}\simeq -0.05$, the order of magnitude of the contribution from each term is found roughly proportional to the product of the corresponding overlap integrals and the total number of the terms belonging to the same group, that is, $2E_3(\alpha\beta\gamma)\simeq 2CT_{\alpha\beta}T_{\beta\gamma}T_{\gamma\alpha}$, where C is a constant. It may, then, be resonable that the contribution from the second to fifth groups almost cancels out each other and the total contribution of the third order terms is roughly equal to the value of the term of the first group, as seen from Table I. The total contribution of the third order terms seems to be by no means negligibly small in the quantitative discussion of the binding energy of the C–C bond in the diamond crystal, but it is smaller than the total contribution of the second order terms, $3E_2(\alpha\beta)+6E_2(\alpha\delta)+3E_2(\alpha\kappa)$, the value of which is about 1.5 eV, though there is an ambiguity in the treatment of the intra-atomic exchange integrals. If we assume that the atomic valence orbital ϕ_i is the eigenfunction of the Hartree-Fock type equation (5.8) of I, we obtain −0.47 eV as the value of $2E_3(\alpha\beta\gamma)$. Furthermore it seems that Mulliken's type approximation used for the calculation of the values of the many center energy integrals is rather crude for the case of the exchange type molecular integrals and gives comparatively small values for these integrals, as seen from the application of this approximation to the two center energy integrals. The last three terms in Eq. (2.9) are almost determined by the three center energy integrals. According to the above consideration it might be possible to obtain a smaller value as the total contribution of the third order terms than that given in Table I. Then it seems that the contribution of the third order terms does not play any essential role in the binding energy of the σ bond. It may also be plausible to assume that the contribution of the fourth order terms is smaller than that of the third order terms and can be neglected.

§ 4. Consideration on the Additivity Rule

In the preceding section we have found that the contribution of the third order terms to the binding energy of the C–C bond is rather small and the fourth order terms may be completely neglected. We shall show that the additivity rule in the binding energies of the saturated hydrocarbons is valid under some assumptions even if the third order terms cannot be neglected. Usually we define the bond energy of a C–H bond as one fourth of the total energy of methane. In terms of Eq. (2.7)–(2.9), it can be expressed as

$$D(CH)=E_0(\alpha)+\frac{3}{2}E_2(\alpha\beta)+E_3(\alpha\beta\gamma)+\frac{1}{4}(E_\sigma^*-E_\sigma)\,, \qquad (4.1)$$

where α, β and γ are the nearest neighbouring C–H bond with each other and $E_\sigma^*-E_\sigma$ is the promotional energy in the free carbon atom. It is not necessary to consider the promotional energy for the hydrogen atoms. If we cannot neglect the second and third order terms in Eq. (4.1), the bond energy of a C–H bond is not determined soley by the quantities of the bond itself but involves the interaction energies between the bonds. The values of the second and third order terms are, however, rather small and approximately determined by the values of the overlap integrals between the bond orbitals. The overlap integral $T_{\alpha\beta}$ has an almost equal value in either case where the nearest neighbouring bonds are C–H or C–C. Then we shall assume that the values of $E_2(\alpha\beta)$ and $E_3(\alpha\beta\gamma)$ in the methane are equal to those of $E_2(\alpha'\beta')$ and $E_3(\alpha'\beta'\gamma')$ in the diamond if $(\alpha\beta)$ and $(\alpha'\beta')$, and $(\alpha\beta\gamma)$ and $(\alpha'\beta'\gamma')$ belong to the same geometrical group, in the sense explained above, respectively. Furthermore, each term in Eq. (4.1) contains the contribution from the potential of the whole molecule, but the potential of the remote atoms is not so important as the C–H bond is expected to be approximately homopolar. If we can ignore in Eq. (4.1) the difference between the corresponding quantities in the second and third order terms of the C–H and C–C bonds, the bond energy of a C–C bond can be calculated using the quantities defined for the ethane as

$$D(CC)=E_0(\beta)+3E_2(\alpha\beta)+6E_2(\alpha\delta)+3E_2(\alpha\kappa)$$
$$+2E_3(\alpha\beta\gamma)+6E_3(\alpha\beta\delta)+3E_3(\alpha\beta\kappa)$$
$$+12E_3(\alpha\gamma\kappa)+6E_3(\alpha\gamma\delta')+\frac{1}{2}(E_C^*-E_C)\,, \tag{4.2}$$

where β denotes the C–C bond and the others represent the C–H bonds. The notation of the bond $\alpha, \beta, \gamma\cdots$ is the same as that explained in the preceding section, and so the geometrical relation among the bonds in the individual terms of Eq. (4.2) can be understood easily. There are two kinds of overlap integrals between the orbitals involved in the second nearest neighbouring bonds. The value of the overlap integral between the orbitals of the bonds locating at the gauche position with each other is almost equal in magnitude to that between the orbitals of the bonds locating at the trans position with each other, but they have the opposite sign, so that the total effect of the second neighbouring bonds to the third order term may be small enough to be neglected. This has been shown for the C–C bond of the diamond crystal in the preceding section. This may be the case even if we take into account the third nearest or more remote neighbouring bonds in the third order terms. Furthermore, the overlap integrals between the orbitals of the third nearest or more remote neighbouring bonds are exceedingly small. Then we may be allowed to neglect their effect. Though each term of Eq. (4.2) involves the potential of the whole molecule, it depends mainly, as discussed in § 3 of II, on the potential of the atoms which are connected by the bond orbitals involved in the term under consideration. The values of the second and third order terms seem to be roughly determined by the product of the overlap integrals considered in the term, for example, we may put approximately $E_3(\alpha\beta\gamma)=CT_{\alpha\beta}T_{\beta\gamma}T_{\gamma\alpha}$, as shown in the preceding section. The value of the overlap integral $T_{\alpha\beta}$ between the bond orbitals τ_α and τ_β is almost equal in any case where the bond orbitals are responsible for the C–H or the C–C bonds. If we assume that the value of each term in Eq. (4.2) is equal to that in the diamond crystal, we can calculate the binding energy of a C–C bond in the diamond from the total binding energies of propane, butane and so on.

Although the above discussion involves a serious assumption, it can be expected that the additivity rule in the binding energies of the saturated hydrocarbons is valid, even if we take the non-orthognality between the bond orbitals into account. Even if we recognize the difference between the C–H and C–C bonds in the second and third order terms, we can show that the additivity rule is asymptotically valid in the long chain molecule of saturated hydrocarbon, if we use the appropriate definitions of the C–H and C–C bond energies which are expressed as

$$\left.\begin{aligned} D(CH)&=D_0(CH)+\frac{1}{2}E_2(\bar{\alpha}\bar{\beta})+2E_2(\bar{\alpha}\beta)+E_3(\bar{\alpha}\bar{\beta}\gamma)\,,\\ D(CC)&=D_0(CC)+2E_2(\bar{\alpha}\beta)+E_2(\alpha\beta)+2E_2(\bar{\alpha}\bar{\delta})+4E_2(\bar{\alpha}\delta)\\ &\quad+2E_2(\bar{\alpha}\bar{\kappa})+E_2(\alpha\kappa)+2E_3(\bar{\alpha}\beta\gamma)+2E_3(\bar{\alpha}\beta\bar{\delta})+4E_3(\bar{\alpha}\beta\delta)+2E_3(\bar{\alpha}\beta\bar{\kappa})\\ &\quad+E_3(\alpha\beta\kappa)+4E_3(\bar{\alpha}\bar{\gamma}\bar{\kappa})+4E_3(\bar{\alpha}\gamma\bar{\kappa})+4E_3(\bar{\alpha}\gamma\kappa)+2\overline{E_3}(\alpha\bar{\gamma}\delta')+4E_3(\bar{\alpha}\gamma\bar{\delta}')\,,\end{aligned}\right\} \tag{4.3}$$

where $D_0(CH)$ and $D_0(CC)$ are the zeroth order bond energies of the C–H and C–C bonds, respectively, the superscript bar means the C–H bond orbitals and the others represent the C–C bond orbitals.

§ 5. Discussion

In this article, we used the bond orbital method to describe the electronic state of the saturated molecule and made the bond orbitals to be orthogonal with each other by Loewdin's method. In this method the operator $(\mathbf{1}+\boldsymbol{T})^{-1/2}$ is defined by a power series of the overlap integrals and the condition for the convergence of the series is

$$|\sum_{\xi}{}' T_{\alpha\xi}|<1\,. \tag{5.1}$$

In our case, as it is found that

$$|\sum_{\xi}{}' T_{\alpha\xi}| \simeq 1\ , \tag{5.2}$$

we cannot expect the rapid convergence of the power series. Schmid[3] also calculated the cohesive energy of the diamond crystal by the use of the orthogonalized atomic orbitals obtained by Loewdin's method, but in this case Loewdins method may be unable to be applied because the condition (5.1) does not hold at all. Under the assumption that the exchange integral $K_{\alpha\beta}$ between the bond orbitals τ_α and τ_β is a quantity of the order of $T^2_{\alpha\beta}$, we rearranged the terms in the expanded series, taking account of the order of magnitude of the overlap integral between the bond orbitals, and obtained the result that the contribution of the third order terms is smaller than that of the second order terms and may not play any essential role in the discussion of the binding energy of the σ bond, though it may be by no means negligible quantitatively. Niira[4] reported that if the total energy of the methane is expanded in the same way as that in this article, the convergence of series is not so simply discussed. However, his calculation showed that the total energy is given in good approximation by the terms up to the second order of the overlap integrals. The same was reported by Lundqvist,[5] who calculated the cohesive energy of LiH by the use of Loewdin's method, though the expanded power series for $(\mathbf{1}+\boldsymbol{T})^{-1/2}$ diverges. We should like to receall here Nukasawa's discussion[6] on the higher order terms, which was already cited in § 6 of I. The fundamental formula in his discussion is written in the previous notation as

$$E_3(\alpha\beta\gamma) = -T_{\alpha\beta}T_{\beta\gamma}T_{\gamma\alpha}\sum_{(\lambda\mu)}\frac{E_2(\lambda\mu)}{T^2_{\lambda\mu}}\ , \tag{5.3}$$

where the summation $\sum\limits_{(\lambda\mu)}$ extends over the pairs of bonds $(\alpha\beta)$, $(\beta\gamma)$ and $(\gamma\alpha)$. He showed that it may be sufficient to consider the terms up to the second order in the calculation of the total energy, if the relations analogous to Eq. (5.3) still hold for the terms higher than the third order and the overlap integrals under consideration are sufficiently small. It is easily shown from Eqs. (2.8) and (2.9) that the condition for the validity of Eq. (5.3) is

$$\begin{aligned} &T_{\alpha\beta}T_{\beta\gamma}T_{\gamma\alpha}(C_{\alpha\beta}+C_{\beta\gamma}+C_{\gamma\alpha})-2(T_{\beta\gamma}T_{\gamma\alpha}D_{\gamma,\alpha\beta}+T_{\gamma\alpha}T_{\alpha\beta}D_{\alpha,\beta\gamma}+T_{\alpha\beta}T_{\beta\gamma}D_{\beta,\gamma\alpha}) \\ &\quad -\left(\frac{T_{\beta\gamma}T_{\gamma\alpha}}{T_{\alpha\beta}}K_{\alpha\beta}+\frac{T_{\gamma\alpha}T_{\alpha\beta}}{T_{\beta\gamma}}K_{\beta\gamma}+\frac{T_{\alpha\beta}T_{\beta\gamma}}{T_{\gamma\alpha}}K_{\gamma\alpha}\right)+2(T_{\alpha\beta}L_{\gamma,\alpha\beta}+T_{\beta\gamma}L_{\alpha,\beta\gamma}+T_{\gamma\alpha}L_{\beta,\gamma\alpha})=0\ , \end{aligned} \tag{5.4}$$

which holds approximately for the actual values of the molecular integrals given in § 3. In our previous calculation of the C–C bond of the diamond crystal it was shown that the effect of the non-orthogonality between the orbitals of the second nearest neighbouring bonds is not significant to the binding energy of the σ bond. Then, the discussion due to Nukasawa is applicable to our system and we may conclude that the approximate value of the binding energy of the σ bond is obtained if we stop at the second order terms with respect to the overlap integrals between the orbitals of the adjacent bonds, in other words, most of the terms higher than the third order is considered to be included effectively in the second order terms by the use of the relations analogous to Eq. (5.3). However, if we consider the approximations assumed in Nukasawa's theory, the error of the value of the binding energy of the σ bond which is calculated in the second order approximation of the overlap integrals between the bond orbitals may be comparable to the contribution of the third order term given in this article.

The author wishes to express his sincere thanks to Professor K. Niira for his incessant encouragement and for his kind reading of the manuscript and to Professor E. Ishiguro for his valuable suggestions. The author is indebted to the Ministry of Education for this research grant.

The Dipole Moment and End-to-end Length of the Isotactic Vinyl Polymer, II.
A Special Simplified Model and Numerical Calculations

By Tsugio MORI

Ôtsu Senior High School, Ôtsu, Shiga-ken, Japan

(Received March 28, 1960)

In the preceding paper[1], fundamental formulas for $\langle\mu^2\rangle_0$, $\langle R^2\rangle_0$, $\langle\mu^2\rangle$ and $\langle R^2\rangle$ are derived. In the present paper, these formulas are brought into the more convenient forms for numerical calculations, and the square well potential of internal rotation of polymer and a linear function $\varphi'(\varphi)$ are introduced. The results of calculations explain that $\langle\mu^2\rangle/n\mu_0^2$ must be 0.3~1.0 when effective bond length is 5~10 Å. These values agree satisfactory with experimental data.

§ 1. Matrix Elements

Principal results of the preceding paper[1] are collected below:—

$$\frac{\langle\mu^2\rangle_0}{n\mu_0^2}=1+2(0\ 0\ 1)\mathbf{Y}^{\mathrm{T}}\mathbf{X}(\mathbf{1}-\mathbf{X})^{-1}\mathbf{Y}\begin{bmatrix}0\\0\\1\end{bmatrix}, \tag{1}$$

$$\frac{\langle R^2\rangle_0}{Nb_0^2}=(0\ 0\ 1)(\mathbf{1}+\mathbf{Z})(\mathbf{1}-\mathbf{X})^{-1}(\mathbf{1}+\mathbf{Z}')\begin{bmatrix}0\\0\\1\end{bmatrix}, \tag{2}$$

$$\frac{\langle\mu^2\rangle}{n\mu_0^2}=1+\frac{\rho^2-P}{1-P}\left(\frac{\langle\mu^2\rangle_0}{n\mu_0^2}-1\right), \tag{3}$$

$$\frac{\langle R^2\rangle}{Nb_0^2}=\rho^2\frac{\langle R^2\rangle_0}{Nb_0^2} \tag{4}$$

and

$$P=(1+\alpha)\frac{Nb_0^2}{\langle R^2\rangle_0}, \tag{5}$$

where we use the notations

$$\mathbf{X}=\langle\mathbf{D}(\varphi')\mathbf{D}(\varphi)\rangle, \tag{6}$$

$$\mathbf{Y}=\left\langle\mathbf{D}\left(\varphi'-\frac{2\pi}{3}\right)\right\rangle, \tag{7}$$

$$\mathbf{Z}=\langle\mathbf{D}(\varphi)\rangle \tag{8}$$

and

$$\mathbf{Z}'=\langle\mathbf{D}(\varphi')\rangle. \tag{9}$$

Therefore we must calculate the elements of these matrices (6)~(9). The (1, 1)-element of **X** is given by

$$\mathrm{X}_{11}=-\alpha\langle\sin\varphi'\sin\varphi\rangle+\alpha^2\langle\cos\varphi'\cos\varphi\rangle+\beta^2\langle\cos\varphi'\rangle.$$

In order to write such formula simply, we introduce the following abbreviations:—

$$\left.\begin{aligned}\langle\mathrm{s's}\rangle&=\langle\sin\varphi'\sin\varphi\rangle,\\ \langle\mathrm{s'c}\rangle&=\langle\sin\varphi'\cos\varphi\rangle,\\ \langle\mathrm{s'}\rangle&=\langle\sin\varphi'\rangle,\\ \langle\mathrm{c's}\rangle&=\langle\cos\varphi'\sin\varphi\rangle,\\ \langle\mathrm{c'c}\rangle&=\langle\cos\varphi'\cos\varphi\rangle,\\ \langle\mathrm{c'}\rangle&=\langle\cos\varphi'\rangle,\\ \langle\mathrm{s}\rangle&=\langle\sin\varphi\rangle,\\ \text{and}\quad \langle\mathrm{c}\rangle&=\langle\cos\varphi\rangle.\end{aligned}\right\} \tag{10}$$

If we put

$$\mathbf{X}=\begin{bmatrix}\mathrm{X}_{11}&\mathrm{X}_{12}&\mathrm{X}_{13}\\ \mathrm{X}_{21}&\mathrm{X}_{22}&\mathrm{X}_{23}\\ \mathrm{X}_{31}&\mathrm{X}_{32}&\mathrm{X}_{33}\end{bmatrix}, \tag{11}$$

we can write down the following formulas:—

$$\left.\begin{aligned}\mathrm{X}_{11}&=-\alpha\langle\mathrm{s's}\rangle+\alpha^2\langle\mathrm{c'c}\rangle+\beta^2\langle\mathrm{c'}\rangle,\\ \mathrm{X}_{12}&=-\langle\mathrm{s'c}\rangle-\alpha\langle\mathrm{c's}\rangle,\\ \mathrm{X}_{13}&=\beta\{\langle\mathrm{s's}\rangle+\alpha(\langle\mathrm{c'}\rangle-\langle\mathrm{c'c}\rangle)\},\\ \mathrm{X}_{21}&=\alpha\langle\mathrm{c's}\rangle+\alpha^2\langle\mathrm{s'c}\rangle+\beta^2\langle\mathrm{s'}\rangle,\\ \mathrm{X}_{22}&=\langle\mathrm{c'c}\rangle-\alpha\langle\mathrm{s's}\rangle,\\ \mathrm{X}_{23}&=-\beta\{\langle\mathrm{c's}\rangle+\alpha'(\langle\mathrm{s'c}\rangle-\langle\mathrm{s'}\rangle)\},\\ \mathrm{X}_{31}&=\alpha\beta(1-\langle\mathrm{c}\rangle),\\ \mathrm{X}_{32}&=\beta\langle\mathrm{s}\rangle,\\ \mathrm{X}_{33}&=\alpha^2+\beta^2\langle\mathrm{c}\rangle.\end{aligned}\right\} \tag{12}$$

We denote the cofactor matrix of $(\mathbf{1}-\mathbf{X})$ by **A**, namely,

$$(\mathbf{1}-\mathbf{X})^{-1}=\frac{\mathbf{A}}{|\mathbf{1}-\mathbf{X}|}=\frac{1}{|\mathbf{1}-\mathbf{X}|}\begin{bmatrix}\mathrm{A}_{11}&\mathrm{A}_{12}&\mathrm{A}_{13}\\ \mathrm{A}_{21}&\mathrm{A}_{22}&\mathrm{A}_{23}\\ \mathrm{A}_{31}&\mathrm{A}_{32}&\mathrm{A}_{33}\end{bmatrix}, \tag{13}$$

where $|\mathbf{1}-\mathbf{X}|$ is the determinant of $(\mathbf{1}-\mathbf{X})$, and

$$|\mathbf{1}-\mathbf{X}|=\begin{vmatrix}1-X_{11} & -X_{12} & -X_{13}\\ -X_{21} & 1-X_{22} & -X_{23}\\ -X_{31} & -X_{32} & 1-X_{33}\end{vmatrix}. \tag{14}$$

Then the relation

$$\mathbf{X}(\mathbf{1}-\mathbf{X})^{-1}=\frac{\mathbf{A}}{|\mathbf{1}-\mathbf{X}|}-\mathbf{1} \tag{15}$$

is easily verified.

Although the matrix **Y** has nine elements, we need to know only its third column elements, which are denoted by B_1, B_2, B_3 respectively, and abbreviated to the one column matrix **B**, namely,

$$\mathbf{Y}\begin{bmatrix}0\\0\\1\end{bmatrix}=\begin{bmatrix}B_1\\B_2\\B_3\end{bmatrix}=\mathbf{B}\,, \tag{16}$$

where

$$\left.\begin{aligned}&B_1=\beta\left\langle \cos\left(\varphi'-\frac{2\pi}{3}\right)\right\rangle,\\ &B_2=\beta\left\langle \sin\left(\varphi'-\frac{2\pi}{3}\right)\right\rangle,\\ &B_3=\alpha\,.\end{aligned}\right\} \tag{17}$$

We also need the third row elements of $(\mathbf{1}+\mathbf{Z})$, and the third column elements of $(\mathbf{1}+\mathbf{Z}')$. They are given by

$$(0\ 0\ 1)(\mathbf{1}+\mathbf{Z})=(\beta,\ 0,\ 1+\alpha) \tag{18}$$

and

$$(\mathbf{1}+\mathbf{Z}')\begin{bmatrix}0\\0\\1\end{bmatrix}=\begin{bmatrix}\beta\langle c'\rangle\\ \beta\langle s'\rangle\\ 1+\alpha\end{bmatrix}. \tag{19}$$

Substitution of (15) and (16) in Eq. (1) yields

$$\frac{\langle \mu^2\rangle_0}{n\mu_0{}^2}=1+\frac{2\mathbf{B}^{\mathrm{T}}\mathbf{A}\mathbf{B}}{|\mathbf{1}-\mathbf{X}|}-2\mathbf{B}^{\mathrm{T}}\mathbf{B}\,, \tag{20}$$

where

$$\mathbf{B}^{\mathrm{T}}\mathbf{A}\mathbf{B}=B_1{}^2A_{11}+B_2{}^2A_{22}+B_3{}^2A_{33}+B_2B_3(A_{23}+A_{32})+B_3B_1(A_{31}+A_{13})+B_1B_2(A_{12}+A_{21}) \tag{21}$$

and

$$\mathbf{B}^{\mathrm{T}}\mathbf{B}=B_1{}^2+B_2{}^2+B_3{}^2\,. \tag{22}$$

While the substitution of (13), (18) and (19) in Eq. (2) yields

$$\begin{aligned}\frac{\langle R^2\rangle_0}{Nb_0{}^2}=\frac{1}{|\mathbf{1}-\mathbf{X}|}&[\beta\langle c'\rangle\{\beta A_{11}+(1+\alpha)A_{31}\}\\ &+\beta\langle s'\rangle\{\beta A_{12}+(1+\alpha)A_{32}\}+(1+\alpha)\{\beta A_{13}+(1+\alpha)A_{33}\}]\,.\end{aligned} \tag{23}$$

Now, the details of the determinant $|\mathbf{1}-\mathbf{X}|$ and elements of the matrix **A** are needed. They are collected below:—

$$\begin{aligned}|\mathbf{1}-\mathbf{X}|=\beta^2[&(1-\langle c'\rangle)(1-\langle c\rangle)(1-\langle c'c\rangle)+(1-\langle c'\rangle)\langle s\rangle\langle c's\rangle+(1-\langle c\rangle)\langle s'\rangle\langle s'c\rangle-\langle s'\rangle\langle s\rangle\langle s's\rangle\\ &+\alpha\{(1-\langle c'\rangle)(1-\langle c\rangle)\langle s's\rangle+(1-\langle c'\rangle)\langle s\rangle\langle s'c\rangle\\ &\quad+(1-\langle c\rangle)\langle s'\rangle\langle c's\rangle-(1-\langle c'c\rangle)\langle s'\rangle\langle s\rangle\}]\,,\end{aligned} \tag{24}$$

$$\left.\begin{aligned}&A_{11}=\beta^2[(1-\langle c\rangle)(1-\langle c'c\rangle)+\langle s\rangle\langle c's\rangle+\alpha\{(1-\langle c\rangle)\langle s's\rangle+(\langle s'c\rangle-\langle s'\rangle)\langle s\rangle\}]\,,\\ &A_{12}=-\beta^2[(1-\langle c\rangle)\langle s'c\rangle-\langle s\rangle\langle s's\rangle+\alpha\{(1-\langle c\rangle)\langle c's\rangle-(\langle c'\rangle-\langle c'c\rangle)\langle s\rangle\}]\,,\\ &A_{13}=\beta[(1-\langle c'c\rangle)\langle s's\rangle+\langle s'c\rangle\langle c's\rangle\\ &\qquad+\alpha\{(1-\langle c'c\rangle)(\langle c'\rangle-\langle c'c\rangle)+\langle s's\rangle^2+\langle c's\rangle^2+(\langle s'c\rangle-\langle s'\rangle)\langle s'c\rangle\}\\ &\qquad\quad+\alpha^2\{(\langle c'\rangle-\langle c'c\rangle)\langle s's\rangle+(\langle s'c\rangle-\langle s'\rangle)\langle c's\rangle\}]\,,\\ &A_{21}=\beta^2(1-\langle c\rangle)\langle s'\rangle\,,\\ &A_{22}=\beta^2(1-\langle c'\rangle)(1-\langle c\rangle)\,,\\ &A_{23}=-\beta[(1-\langle c'\rangle)\langle c's\rangle-\langle s'\rangle\langle s's\rangle+\alpha\{(1-\langle c'\rangle)\langle s'c\rangle-(1-\langle c'c\rangle)\langle s'\rangle\}]\,,\\ &A_{31}=\beta[\langle s'\rangle\langle s\rangle+\alpha\{(1-\langle c\rangle)(1-\langle c'c\rangle)+\langle s\rangle\langle c's\rangle\}\\ &\qquad\qquad\qquad+\alpha^2\{(1-\langle c\rangle)\langle s's\rangle+(\langle s'c\rangle-\langle s'\rangle)\langle s\rangle\}]\,,\\ &A_{32}=\beta[(1-\langle c'\rangle)\langle s\rangle-\alpha\{(1-\langle c\rangle)\langle s'c\rangle-\langle s\rangle\langle s's\rangle\}\\ &\qquad\qquad\qquad-\alpha^2\{(1-\langle c\rangle)\langle c's\rangle-(\langle c'\rangle-\langle c'c\rangle)\langle s\rangle\}]\,,\end{aligned}\right\} \tag{25}$$

and

$$\left.\begin{aligned}A_{33}=&(1-\langle c'\rangle)(1-\langle c'c\rangle)+\langle s'\rangle\langle s'c\rangle\\&+\alpha\{(2-\langle c'\rangle-\langle c'c\rangle)\langle s's\rangle+(\langle s'c\rangle+\langle s'\rangle)\langle c's\rangle\}\\&+\alpha^2\{(1-\langle c'c\rangle)(\langle c'\rangle-\langle c'c\rangle)+\langle s's\rangle^2+\langle c's\rangle^2+(\langle s'c\rangle-\langle s'\rangle)\langle s'c\rangle\}\\&+\alpha^3\{(\langle c'\rangle-\langle c'c\rangle)\langle s's\rangle+(\langle s'c\rangle-\langle s'\rangle)\langle c's\rangle\}\,.\end{aligned}\right|$$

It is remarked that we can easily verify

$$\beta A_{11}+(1+\alpha)A_{31}=\frac{1+\alpha}{\beta}(\beta^2\langle s'\rangle\langle s\rangle+A_{11})\,,$$

and

$$\beta A_{12}+(1+\alpha)A_{32}=\frac{1+\alpha}{\beta}\{\beta^2(1-\langle c'\rangle)\langle s\rangle+A_{12}\}$$

from (25). Then Eq. (23) becomes

$$\frac{\langle R^2\rangle_0}{Nb_0^2}=\frac{1+\alpha}{|\mathbf{1}-\mathbf{X}|}[\beta^2\langle s'\rangle\langle s\rangle+\langle c'\rangle A_{11}+\langle s'\rangle A_{12}+\beta A_{13}+(1+\alpha)A_{33}]\,. \tag{26}$$

If the rotation of each bond were to be independent of the others, we would replace $\langle s's\rangle$, $\langle s'c\rangle$, $\langle c's\rangle$, $\langle c'c\rangle$ by $\langle s'\rangle\langle s\rangle$, $\langle s'\rangle\langle c\rangle$, $\langle c'\rangle\langle s\rangle$, $\langle c'\rangle\langle c\rangle$ respectively, and would reduce (26) to

$$\frac{\langle R^2\rangle_0}{Nb_0^2}=\frac{(1+\alpha)\{1+2(\langle s'\rangle\langle s\rangle-\langle c'\rangle\langle c\rangle)+(\langle s'\rangle^2+\langle c'\rangle^2)(\langle s\rangle^2+\langle c\rangle^2)\}}{(1-\alpha)\{(1-\langle c'\rangle)(1-\langle c\rangle)-(\langle c'\rangle-\langle c'\rangle^2-\langle s'\rangle^2)(\langle c\rangle-\langle c\rangle^2-\langle s\rangle^2)\}}\,. \tag{27}$$

In this paper, however, we have no regard for the independent bond rotation. Eq. (27) has been derived by Nagai[2].

§2. Potential of Internal Rotation

Since the method of numerical calculations in this paper is quite primitive, it is disirable that assumptions concerning with the internal rotation are as simple as possible. In the preceding paper[1], two notations φ and φ' are introduced in order to represent the rotations of adjoining bonds. In the present paper, we put two assumptions for φ and φ'. First a linear function

$$\varphi'=\lambda\varphi+\frac{2\pi}{3} \tag{28}$$

is assumed, where λ is a constant, and the constant term $2\pi/3$ corresponds to $\varphi'(0)=2\pi/3$, which conforms with the assumption in the preceding paper. On the other hand, a square well potential V defined by

$$\left.\begin{aligned}V&=0\quad(\text{when}\quad 0\leqq|\varphi|\leqq\mathcal{E})\\&=\infty\quad(\text{when}\quad|\varphi|>\mathcal{E})\end{aligned}\right\} \tag{29}$$

is assumed for the internal rotation, where $\mathcal{E}$ is a parameter which varies with some conditions, that is, temperature, interaction between polymer and solvent, etc. The first assumption (28) means an imagination that two kinds of potential widths, $2\mathcal{E}$ and $2|\lambda|\mathcal{E}$, may alternate in the polymer chain, since the asymmetric carbon atoms appear every two bonds in the chain. The second assumption (29) defines the mean of any physical quantity ξ, namely,

$$\langle\xi\rangle=\frac{\int_{-\infty}^{\infty}\xi\exp(-V/kT)d\varphi}{\int_{-\infty}^{\infty}\exp(-V/kT)d\varphi}=\frac{1}{2\mathcal{E}}\int_{-\varepsilon}^{\varepsilon}\xi d\varphi\,. \tag{30}$$

For example, we have

$$\langle s's \rangle = \frac{1}{2\varepsilon}\int_{-\varepsilon}^{\varepsilon} \sin\left(\lambda\varphi + \frac{2\pi}{3}\right) \sin\varphi \, d\varphi \, .$$

Some of such means are collected below:—

$$\left.\begin{aligned}
\langle s's \rangle &= \frac{1}{2}\left\{\frac{\sin(1-\lambda)\varepsilon}{(1-\lambda)\varepsilon} - \frac{\sin(1+\lambda)\varepsilon}{(1+\lambda)\varepsilon}\right\}\cos\frac{2\pi}{3}\,, \\
\langle s'c \rangle &= \frac{1}{2}\left\{\frac{\sin(1-\lambda)\varepsilon}{(1-\lambda)\varepsilon} + \frac{\sin(1+\lambda)\varepsilon}{(1+\lambda)\varepsilon}\right\}\sin\frac{2\pi}{3}\,, \\
\langle s' \rangle &= \frac{\sin\lambda\varepsilon}{\lambda\varepsilon}\sin\frac{2\pi}{3}\,, \\
\langle c's \rangle &= -\frac{1}{2}\left\{\frac{\sin(1-\lambda)\varepsilon}{(1-\lambda)\varepsilon} - \frac{\sin(1+\lambda)\varepsilon}{(1+\lambda)\varepsilon}\right\}\sin\frac{2\pi}{3}\,, \\
\langle c'c \rangle &= \frac{1}{2}\left\{\frac{\sin(1-\lambda)\varepsilon}{(1-\lambda)\varepsilon} + \frac{\sin(1+\lambda)\varepsilon}{(1+\lambda)\varepsilon}\right\}\cos\frac{2\pi}{3}\,, \\
\langle c' \rangle &= \frac{\sin\lambda\varepsilon}{\lambda\varepsilon}\cos\frac{2\pi}{3}\,, \\
\langle s \rangle &= 0\,, \\
\langle c \rangle &= \frac{\sin\varepsilon}{\varepsilon}\,, \\
B_1 &= \beta\frac{\sin\lambda\varepsilon}{\lambda\varepsilon}\,, \\
B_2 &= 0 \\
\text{and}\qquad B_3 &= \alpha\,.
\end{aligned}\right\} \qquad (31)$$

Here we consider three typical cases, namely, $\lambda=0, 1, -1$. If $\lambda=0$, two adjoining bonds compose a rigid segment holding asymmetric carbon atom and dipolar substituent between them, and the rotation is possible only at joints of segments. If $0<\lambda<1$, φ' is an increasing function of φ, but the scale of rotation in a segment is smaller than that of a whole segment. The assumption $0<\lambda<1$ is equivalent to the imagination that a relaxation effect may exist between excitation φ and response φ'. If $\lambda=1$, the scale of rotation in a segment is the same order as that of a whole segment. If $\lambda<0$, φ' is a decreasing function of φ, and it may be shown after numerical calculations that the case $\lambda=-1$ cannot explain the experimental data.

We substitute $\lambda=0, 1, -1$ one after another in (31), and put the notations

$$f_1 = \frac{\sin\varepsilon}{\varepsilon}\,, \quad f_2 = \frac{\sin 2\varepsilon}{2\varepsilon}\,. \qquad (32)$$

The results are collected in Table I.

Table I.

	$\lambda=0$	$\lambda=1$	$\lambda=-1$
$\langle s's \rangle$	0	$-\frac{1}{4}(1-f_2)$	$\frac{1}{4}(1-f_2)$
$\langle s'c \rangle$	$\frac{\sqrt{3}}{2}f_1$	$\frac{\sqrt{3}}{4}(1+f_2)$	$\frac{\sqrt{3}}{4}(1+f_2)$

B_1	β	βf_1	βf_1
B_2	0	0	0
B_3	α	α	α

§ 3. Numerical Calculations and Conclusions

The first step of our numerical calculations is to deal with the quantities for the unperturbed configuration, i.e., $\langle\mu^2\rangle_0/n\mu_0^2$ and $\langle R^2\rangle_0/Nb_0^2$. If we substitute the formulas of Table I in (24), (21) and (22) and make use of the values

$$\alpha=\frac{1}{3}\,,\qquad \beta=\frac{\sqrt{8}}{3}\,, \tag{33}$$

then we have the following relations.

$$\left.\begin{aligned}&\lambda=0:\\ &\qquad |\mathbf{1}-\mathbf{X}|=\frac{4}{3}(1-f_1^2)\,,\\ &\qquad \mathbf{B}^{\mathrm{T}}\mathbf{AB}=\frac{1}{3}(3-f_1-f_1^2)\,,\\ &\qquad \mathbf{B}^{\mathrm{T}}\mathbf{B}=1\,.\end{aligned}\right\} \tag{34}$$

$$\left.\begin{aligned}&\lambda=1:\\ &\quad |\mathbf{1}-\mathbf{X}|=\frac{2}{27}(1-f_1)\{9+(1+2f_1)(5+4f_2)\}\,,\\ &\quad \mathbf{B}^{\mathrm{T}}\mathbf{AB}=\frac{1}{972}[81+\{11+16f_1-4(1-f_2)\}(5+4f_2)\\ &\qquad\qquad -32f_1\{(1-f_2)(5+4f_2)-3(1-f_1)(2+f_2)\}\\ &\qquad\qquad +128f_1^2(1-f_1)(7+2f_2)]\,,\\ &\quad \mathbf{B}^{\mathrm{T}}\mathbf{B}=\frac{1}{9}(1+8f_1^2)\,.\end{aligned}\right\} \tag{35}$$

$$\left.\begin{aligned}&\lambda=-1:\\ &\quad |\mathbf{1}-\mathbf{X}|=\frac{2}{27}(1-f_1)\{9+(1+2f_1)(7+2f_2)\}\,,\\ &\quad \mathbf{B}^{\mathrm{T}}\mathbf{AB}=\frac{1}{972}[81+\{11+16f_1+2(1-f_2)\}(7+2f_2)\\ &\qquad\qquad +16f_1\{(1-f_2)(7+2f_2)+3(1-f_1)(5+f_2)\}\\ &\qquad\qquad +128f_1^2(1-f_1)(8+f_2)]\,,\\ &\quad \mathbf{B}^{\mathrm{T}}\mathbf{B}=\frac{1}{9}(1+8f_1^2)\,.\end{aligned}\right\} \tag{36}$$

Then we can calculate the values of $\langle\mu^2\rangle_0/n\mu_0^2$ according to the formula (20) as the function of ε within the interval

$$0\leqq\varepsilon\leqq\pi\,. \tag{37}$$

The results are given in Table II.

On the other hand, we have the following relations by the use of (26) and Table I, and refering (33).

$$\left.\begin{aligned}&\lambda=0:\\ &\qquad \frac{\langle R^2\rangle_0}{Nb_0^2}=\frac{4(1+f_1+f_1^2)}{3(1-f_1^2)}\,.\end{aligned}\right\} \tag{38}$$

$$\left.\begin{aligned}&\lambda=1:\\&\quad\frac{\langle R^2\rangle_0}{Nb_0^2}=\frac{2\{27+(1+4f_1^2+4f_2)(5+4f_2)\}}{3(1-f_1)\{9+(1+2f_1)(5+4f_2)\}}\,.\end{aligned}\right\}\tag{39}$$

$$\left.\begin{aligned}&\lambda=-1:\\&\quad\frac{\langle R^2\rangle_0}{Nb_0^2}=\frac{2\{27+(7+4f_1^2-2f_2)(7+2f_2)\}}{3(1-f_1)\{9+(1+2f_1)(7+2f_2)\}}\,.\end{aligned}\right\}\tag{40}$$

Table II. $\langle\mu^2\rangle_0/n\mu_0^2$.

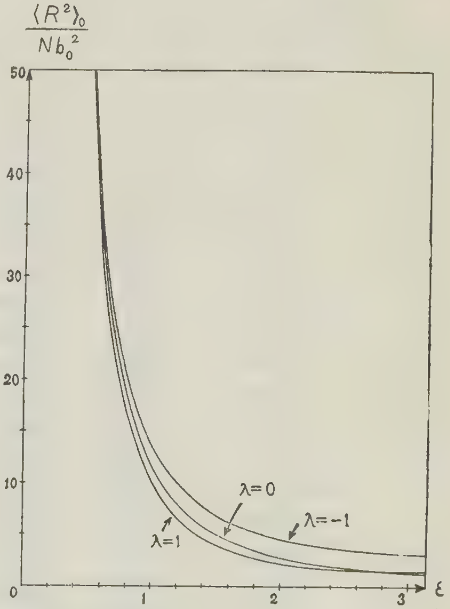

Fig. 2. Plots of $\langle R^2\rangle_0/Nb_0^2$ against ε.

Then we can calculate the values of these quantities within the interval (37), and have Table III.

According to these Tables, $\langle\mu^2\rangle_0/n\mu_0^2$ and $\langle R^2\rangle_0/Nb_0^2$ are plotted against ε in Figs. 1 and 2, respectively.

Here we define the effective bond length b' by

$$b'=(\langle R^2\rangle/N)^{1/2}\,, \tag{41}$$

and that corresponding to the unperturbed configuration b_0' by

$$b_0'=(\langle R^2\rangle_0/N)^{1/2}\,. \tag{42}$$

It is reported experimentally that

$$\langle\mu^2\rangle/n\mu_0^2=0.3\sim0.8 \qquad (43)$$[3),4)]

and

$$b'=5\sim11\,[\text{Å}]\,. \qquad (44)$$[5),6)]

The unperturbed configuration cannot explain these experimental values according to the reason described below. If we put $b_0'=9\,[\text{Å}]$ and $b_0=1.54\,[\text{Å}]$, we have $\langle R^2\rangle_0/Nb_0^2=34$ which corresponds to $\varepsilon\simeq0.6$ in Table III. While, in Table II, the same ε-value corresponds to $\langle\mu^2\rangle_0/n\mu_0^2\simeq4$ which confricts the experimental value (43). This disagreement is common to each case $\lambda=0,\ 1,\ -1$. However, the above disagreement is rather natural in the case in which the parameter ρ concerning with the excluded volume effect is not considered.

Now we take the second step of numerical calculations. The preceding step is equivalent to set the value $\rho=1$, but we consider $\rho>1$ in the present step. Let us put $\rho^2=2$ as a test case and calculate the values of $\langle R^2\rangle/Nb_0^2$ and $\langle\mu^2\rangle/n\mu_0^2$ from (3), (4) and (5). We neglect the insertion of the former values, because they are easily got by doubling each value of Table III. The latter values are shown in Table IV, and plotted against ε in Fig. 3.

Table IV. $\langle\mu^2\rangle/n\mu_0^2$ for $\rho^2=2$.

ε	$\lambda=0$	$\lambda=1$	$\lambda=-1$
0	∞	∞	∞
0.2	73.3	72.1	75.1

π	−∞	1.071	1.208

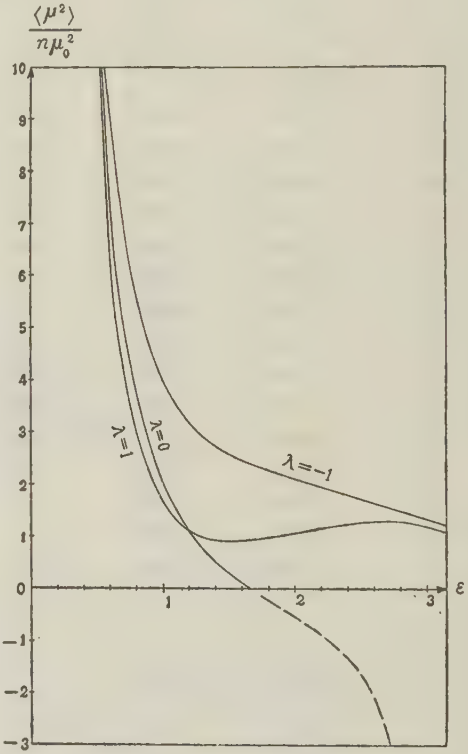

Fig. 3. Plots of $\langle\mu^2\rangle/n\mu_0^2$ against ε for $\rho^2=2$.

From this result, we have two suggestions. In the first place, the internal rotation corresponding to $\lambda=-1$ may be neglected, because $\langle\mu^2\rangle/n\mu_0^2$ is in this case always larger than 1 contrary to the experimental value (43). The second suggestion originates from the fact that $\langle\mu^2\rangle/n\mu_0^2$ in the case $\lambda=0$ is negative within the interval $1.7<\varepsilon<\pi$, and $-\infty$ at $\varepsilon=\pi$. Of course, the negative value of $\langle\mu^2\rangle$ is impossible, then the internal rotation of the rigid segment is limited within the interval $0<\varepsilon<1.7$. In general, it is conceived that the free rotation of the rigid segment may bring a confrict saying that a kind of mean square quantity becomes negative as $\langle\mu^2\rangle$ in this paper.

Table V. Calculated values at $\varepsilon=1.3$ (74°29′)

ρ^2	b'[Å]		$\langle\mu^2\rangle/n\mu_0^2$	
	$\lambda=0$	$\lambda=1$	$\lambda=0$	$\lambda=1$
1	4.01	3.62	0.897	0.993
2	5.67	5.11	0.769	0.984
4	8.02	7.24	0.512	0.966
6	9.83	8.86	0.256	0.948

Therefore we conclude that we should adopt $\lambda\geqq 0$ and $1.2<\mathcal{E}<1.4$ in order to explain the experimental value (43).

We have discussed above the test case of $\rho^2=2$, which brings to us some suggestions. Then we put on the next trial

$$\lambda=0,\ 1;\quad \mathcal{E}=1.3;\quad \rho^2=1,\ 2,\ 4,\ 6$$

and calculate $\langle\mu^2\rangle/n\mu_0^2$ and effective bond length b'. The results are shown in Table V, where $b_0=1.54$ [Å] is used. In this Table, values of the row of $\rho^2=1$ are calculated from Tables II and III by the interporation at $\mathcal{E}=1.3$, and values of other rows are calculated from the row of $\rho^2=1$ and the formulas (4), (5) and (3).

Now, Table V indicates to us that the experimental values (43) and (44) may be simultaneously interpreted by making choice of $\lambda=0\sim1$, $\rho^2=2\sim6$ and $\mathcal{E}\simeq1.3$.

On the other hand, it is also remarked that the $\mathcal{E}$-value 1.3 is nearly the minimum point of $\langle\mu^2\rangle/n\mu_0^2$ in the case of $\lambda\simeq1$.

The author wishes to express his thanks to Mr. K. Shindô of Shiga University for his kind discussions and constant encouragement.

The Superexchange Interaction between Cr^{+3} pair in Chromium Bi-nuclear Complex Ions.

By Hanako KOBAYASHI, Taiichiro HASEDA and Eizo KANDA

Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai, Japan

and Masayasu MORI

Institute of Polytechnics, Osaka City University, Osaka, Japan

(Received May 6, 1960)

The investigation of the magnetic properties of chromium bi-nuclear complex compounds was made. The results of the magnetic susceptibility measurements were analyzed on the assumption that their magnetic behaviours are determined mainly by the superexchange interaction between two Cr^{+3} ions in the same complex unit. The coefficient of the superexchange interaction J was estimated to be about $-30\,k$ in the cases of $[(NH_3)_5Cr\text{-}OH\text{-}Cr(NH_3)_5]^{+5}$ and $[(NH_3)_5Cr\text{-}OH\text{-}Cr(NH_3)_4OH]^{+4}$ complex ions. In the case of $[(NH_3)_5Cr\text{-}O\text{-}Cr(NH_3)_5]^{+4}$, the susceptibility is very small below room temperature, hence a large absolute value of J is required to account for the experimental result. The susceptibility of $[Cr(NH_3)_5Cl]Cl_2$ which is a usual mononuclear complex salt, was measured for the sake of comparison with the above mentioned bi-nuclear complex salts. The susceptibility obeys in this case the Curie-Weiss law in the range between 2.5°K and room temperature. The Weiss constant Θ is $-0.8°K \pm 0.1°K$ and the Curie constant C is 1.82. The X-ray powder patterns of these complexes were taken and examined in comparison with the magnetic properties.

§1. Introduction

The structures and the magnetic and optical properties of the bi-nuclear complex compounds of chromium were investigated by Wilmarth, Graff and Gustin(1) and by Mori, Ueshiba and Yamatera(2). In these compounds, two chromium ions in a complex unit have the oxygen or hydroxyl bridge between them. The spins of the two Cr^{+3} ions will interact through the brige. This may be regarded as a type of the superexchange interaction. On the other hand, the interaction between the spins of Cr^{+3} ions belonging to the different complex units, will be much weaker than the interaction between those in the same complex unit. Thus, the magnetic properties of these compounds are considered to be predominantly determined by the interaction between a couple of ions through the bridge in each complex unit. The situation resembles in some respects the case of copper acetate(3) which is a sort of bi-nucler complex compound of Cu^{+2} ions. In the latter case the magnetic properties are considered to be determined by the direct mutual interaction of two Cu^{+2} ions in a complex unit. Welo(4) in 1928 and Gijsman, Karantassis and Wucher(5) in 1954 measured the magnetic susceptibilities of some tri-nuclear complex compounds of Cr^{+3} and Fe^{+3}. Kambe(6) estimated the magnitude of the mutual interaction between Cr^{+3} and Fe^{+3} ions by analysing the Welo's results. The Hamiltonian used was, $\mathscr{H}=-2J[(\boldsymbol{S}_1\boldsymbol{S}_2)+(\boldsymbol{S}_2\boldsymbol{S}_3)+\alpha(\boldsymbol{S}_3\boldsymbol{S}_1)]$ in which $\boldsymbol{S}_1$, $\boldsymbol{S}_2$ and $\boldsymbol{S}_3$ were the spins of the three magnetic ions in one complex unit. The values of J consistent with the experimental results were $-14k \langle J \langle -18k$ assuming $\alpha=1$.

Bi-nuclear complex ions of chromium investigated in the present work are as follows:

$$[(NH_3)_5Cr\text{-}OH\text{-}Cr(NH_3)_5]^{+5} \cdots\cdots\cdots (A)$$

$$[(NH_3)_5Cr\text{-}OH\text{-}Cr(NH_3)_4OH]^{+4} \cdots\cdots (B)$$

and $$[(NH_3)_5Cr\text{-}O\text{-}Cr(NH_3)_5]^{+4} \cdots\cdots\cdots (C).$$

The bridges in the complex units are expected to be almost linear in the former two complexes and definitely linear in the last one. The purpose of the present investigation is to obtain information about the superexchange interaction through these bridges.

§2. Experiments

The measurements of the magnetic susceptibility were carried out by the Hartshorn bridge method. The a.c. frequency used was 90 cycles per sec. and the strength of the magnetic field in the measuring coil was 20~100 Oe. The measurements were made in the temperature range down to 1.5°K. As the samples are unstable in light and moisture, special care was taken to avoid them. The measuring apparatus used is capable to detect the susceptibility of a sample of 1 g which has the gram susceptibility of 1×10^{-5} (c.g.s.e.m.u.) in the accuracy of ±1%. However the accuracies on the whole in the present experiments were about ±3% below 20.4°K and about ±10% above 20.4°K.

Samples

$[(NH_3)_5Cr\text{-}OH\text{-}Cr(NH_3)_5]_2Cl_3(ClO_4)_7H_2O$ (Decammine-μ-ol-dichromium (III) chloride perchlorate) (A)

This salt was prepared by precipitation with perchloric acid from aqueous solution of decammine-μ-ol-dichromium (III) chloride which was prepared using Jφrgensen's procedure. The salt precipitates in the form of needle crystal of rose colour. The colour changes into pale purple light and moisture.

$[(NH_3)_5Cr\text{-}OH\text{-}Cr(NH_3)_4OH]Cl_4H_2O$ (Hydroxononammine-μ-ol-dichromium (III) chloride 1-hydrate) (B)

This salt was prepared according to the direction of Jφrgensen for the preparation of erythrochromium (III) chloride. The dark red complex salt thus prepared contained nine moles of ammonia per each pair of two chromium atoms, in accordance with the observation of Wilmarth et al.⁽¹⁾. This salt also turns violet in light and moisture.

$[(NH_3)_5Cr\text{-}O\text{-}Cr(NH_3)_5](ClO_4)_4$ (Decammine-μ-oxo-dichromium (III) perchlorate) (C)

This salt was prepared by the reaction of (A) with ammonia sodium perchlorate solution. The colour of this sample is deep blue, but it becomes blue if it is dried after washing with ether. The colour changes into red purple in light and moisture.

$[Cr(NH_3)_5Cl]Cl_2$ (Chloropentamminechromium (III) chloride)

This salt was prepared by boiling a mixture of hexamminechromium (III) chloride and hydrochloric acid for 30 min.. The crude chloride thus obtained was dissolved in water and recrystallized by adding hydrochloric acide. The bright red chloride was washed with ethanol and dried in air.

Magnetic Susceptibility

Complex compounds A and B. The magnetic susceptibilities of these complex compounds χ_{2M}* are shown in Fig. 1. The values are corrected for small amount of impurity and diamagnetism⁽⁹⁾**. The susceptibilities in the room temperature range obey the Curie-Weiss law with $\Theta\cong-30$°K and the Curie constant C is consistent with the spin value $S=3/2$ of a Cr^{+3} ion. The susceptibilities of these two salts have their maximum values at about 50°K and have very small values at liquid helium temperatures.

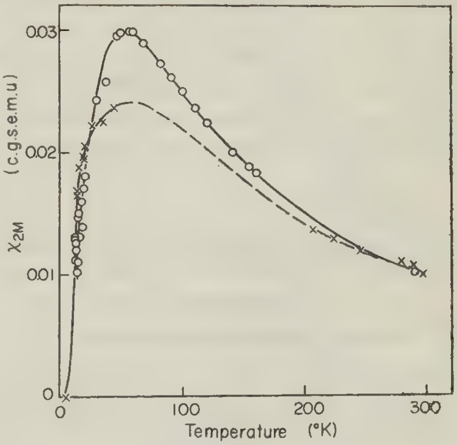

Fig. 1. Magnetic susceptibilities.
O: $\{[(NH_3)_5CrOHCr(NH_3)_5]Cl_{1.5}(ClO_4)_{3.5}\cdot\frac{1}{2}H_2O\}$,
×: $[(NH_3)_5CrOHCr(NH_3)_4OH]Cl_4\cdot H_2O$.

Complex compound C. The magnetic susceptibilities of this salt, χ_{2M} were 0.0010 (±0.0001) (c.g.s.e.m.u.) between 14.5°K and 20.4°K, 0.0010 (±0.0001) (c.g.s.e.m.u.) at 80°K, 0.0010 (±0.0001) (c.g.s.e.m.u.) at 105°K and 0.0020 (±0.0002) (c.g.s.e.m.u.) at 290°K. Any remarkable hump of susceptibility could not be detected between 105°K and 290°K. This complex compound is decomposed above the room temperature by warming up even in the dark place and the decomposed sample shows a normal paramagnetic susceptibility.

---

* The symbol χ_{2M} used here for bi-nuclear complex compounds stands for the value for one mole of complex compound, which contains two gram ions of Cr^{+3}.

** The following values multiplied by -1×10^{-6} were used for the calculstion of the diamagnetic molar susceptibilities. Cl^-:25, ClO_4^-:33, Cr^{+3}:15, H_2O:13, NH_3:1.1, -O-:5, and OH^-, -OH-:9.

$[Cr(NH_3)_5Cl]Cl_2$. The molar magnetic susceptibility of this salt χ_M is shown in Fig. 2 and Table I, in which the diamagnetic correction has not been made. The paramagnetic susceptibility follows the Curie-Weiss law between 2.5°K and room temperature. The values of C and Θ are 1.82 and −0.8°K respectively.

§ 3. Discussion.

Complex compounds A and B. Though the single crystals of the two complex compounds have not been obtained, their X-ray patterns of powder samples were taken. They resemble very much each other as are shown later and their magnetic behaviours are also alike as indicated in Fig. 1. The analysis of the data on one of them may be applied to the other. The bond angle of the bridge in these complex compound is not exactly 180°, because there is a H-atom attached to the oxygen of the bridge. In the following, it is assumed that the orbital anguler momentum of each Cr^{+3} ion is quenched and only the spin angular momentum remains free, and so the Cr^{+3} ion is effectively in the $S=3/2$ state. If the electron spins of two Cr^{+3} ions are denoted by S_1 and S_2 and the coefficient of the mutual exchange interaction between S_1 and S_2 by J, the Hamiltonian of this bi-nuclear complex ions under the external magnetic field H will be given as follows.

$$\mathscr{H}=J\cdot \boldsymbol{S}_1\cdot \boldsymbol{S}_2+g\beta \boldsymbol{H}(\boldsymbol{S}_1+\boldsymbol{S}_2)$$

Energy levels are obtained as shown in Fig. 3. Then, the magnetic susceptibility of a complex unit is calculated by means of the partition function obtained from these energy levels, as follows:

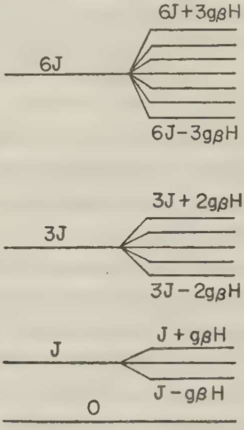

Fig. 3. Energy levels of bi-nuclear complex ion of Cr^{+3}.

$$\chi_{2M}=\frac{Ng^2\beta^2}{kT}\;\frac{2e^{5J/kT}+10e^{3J/kT}+28}{e^{6J/kT}+3e^{5J/kT}+5e^{3J/kT}+7},$$

where β is the Bohr magneton, k Boltzman's constant, T absolute temperature, g spectroscopic splitting factor, (2.00 was adopted.) and N Avogadro's number.

The calculated χ_{2M} are shown in Fig. 4. as function of absolute temperature in which J

is used as a parameter. The best fit was obtained by assuming $J=-28\,k$ in the complex A and $J=-36\,k$ in the complex B. The agreement between the experimental values and the calculated ones is sufficient in the temperature range above 50°K in the former complex compound. The deviation from the calculated values at lower temperatures may be attributed to some slight deformation in crystal structure in the complex. In the latter complex, $|J|$ is somewhat larger than in the former. The detailed structure determination of these complex compounds by X-ray analysis has not been made, as mentioned above, because of the difficulty in getting a perfect single crystal. It is probable, however, from the chemical and optical investigations⁽¹⁾⁽²⁾ that the bridge between two Cr^{+3} ions in these complex units, is

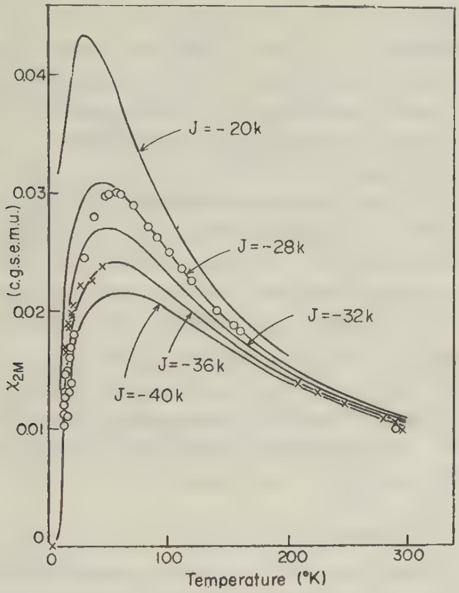

Fig. 4. Magnetic susceptibilities.
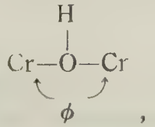
O: $\{[(NH_3)_5CrOHCr(NH_3)_5]Cl_{1\cdot5}(ClO_4)_{3\cdot5}\cdot\frac{1}{2}H_2O\}$,
×: $[(NH_3)_5CrOHCr(NH_3)_4OH]Cl_4\cdot H_2O$.



$$\overset{\displaystyle H}{\overset{|}{Cr-O-Cr}}\ ,\quad \phi$$

in which the angle ϕ is almost 180°. The mutual interaction between two Cr^{+3} ions is thought of as the superexchange interaction of the 3d electrons of Cr^{+3} through O^{-2} in -OH- bridge. The superexchange interaction of Cr^{+3} $(3d^3)$ through 180° bridge is thought to be antiferromagnetic ($J<0$) in nature⁽¹⁰⁾. The obtained value of J ($-28\,k\sim-36\,k$) may be compared with J in the bulk crystals such as Cr_2O_3. The value of about $-30\,k$ is not unreasonable considering the number of the nearest neighbours and the Weiss constant ($\Theta=500$°K) in Cr_2O_3⁽¹¹⁾. Recently, some attempts have been made to decide the value of J by the paramagnetic resonance method in highly diluted crystals such as Mn^{+2} in MgO (1:100)⁽¹²⁾ or Cr^{+3} in ruby (1:100)⁽¹³⁾ In the Mn–O–Mn case, $J=28k\pm4\,k$ was found out and in the case of Cr^{+3} pair in ruby, the estimated value of J was about $-359\,k$. The present value of $J=-30\,k$ for Cr^{+3} pair is considerably different from the above value though the bridge between Cr^{+3} pair is not -O- (as in the ruby case) but -OH- in the present case.

Complex compound C. The salt C was expected to show the most typical superexchange interaction in the case of 180° bridge. The observed susceptibility of a complex unit is about 0.001 (c.g.s.e.m.u.) in the wide temperature range. It has a little temperature dependence increasing with increasing temperature, but it could not definitely be determined whether there is any hump of susceptibility between 80°K and 300°K or not according to our apparatus. In the case of complex A, the model of two localized spins of $S=3/2$ interacting with each other via the -OH- bridge was taken. If the same model is assumed in this case, it is required that the coefficient of the exchange interaction J is negative and its absolute value should be larger than $200\,k$ to account for the experimental results. This absolute value of J is extremely large, in contrast to the values of J which was found in the range between $28\,k$ and $36\,k$ by Kambe⁽⁶⁾ and others⁽⁷⁾ and in almost the same range in the case of complexes A and B in our experiments.

The compound $K_4Ru_2Cl_{10}O\cdot H_2O$ which has a complex anion $[Cl_5Ru\text{-}O\text{-}RuCl_5]^{-4}$ shows diamagnetic susceptibility at room temperature. Dunitz and Orgel⁽¹⁴⁾ explained this diamagnetisum by applying the molecular orbital theory. Structure of the complex C is thought similar to this anion and the application of the molecular orbital theory may also be not unreasonable in this case. But, the straight-forward application of the molecular orbital theory analogous to the treatment by Dunitz and Orgel gives rise to the paramagnetic state of S=1 which comes from the two unpaired electrons remaining in the doubly degenerated non-bonding orbital. And this is not consistent with our experimental result if any mechanism which brings the two spins into an interaction is not considered.

$[Cr(NH_3)_5Cl]^{+2}$. As is expected, this complex ion is found to be a normal paramagnetics and the susceptibility follows the Curie-Weiss law. The obtained Curie constant C=1.82 is in reasonable agreement with Cr^{+3} ($3d^3$), S=3/2. The Weiss constant $\Theta=-0.8°K$ is somewhat larger than is usually expected. The crystal structure of this salt has not been determined, but it is sure that each Cr^{+3} ion is surrounded octahedrally by five NH_3's and one Cl^- ion. If the passages or paths of the superexchange interaction are considered to lie between Cr^{+3} ions, they will be such as follows:

$$Cr^{+3}\text{-}NH_3\text{—}Cl^-\text{-}Cr^{+3} \qquad \text{(I)}$$

$$Cr^{+3}\text{-}NH_3\text{—}NH_3\text{-}Cr^{+3} \qquad \text{(II)}$$

$$Cr^{+3}\text{-}NH_3\text{—}Cl^-\text{—}NH_3\text{-}Cr^{+3} \qquad \text{(III)}$$

$$Cr^{+3}\text{-}NH_3\text{—}Cl^-\text{—}Cr^{+3} \qquad \text{(IV)}$$

etc..
One of the present authors (T.H.) has pointed out the importance of hydrogen bond in the superexchange interaction, discussing the antiferromagnetic nature in $CoCl_2\cdot 6H_2O$⁽¹⁵⁾. Although the conclusion has not definitly been obtained in the $[Cr(NH_3)_5Cl]Cl_2$ case, it is noteworthy to refer that the large Weiss constant Θ may have some connection with the possible existence of hydrogen bond such as N-H—Cl on the path I or III etc.,.

X-ray powder patterns.

The X-ray powder patterns of the bi-nuclear complex salts investigated were obtained by Norelco camera. They are shown in Fig. 5. The results obtained are very well consistent with the data by Wilmarth, Graff and Gustin⁽¹⁾. As is apparent from Fig. 5, the complexes A and B resemble each other, but are quite different from the complex C. These facts are consistent with the magnetic behaviours mentioned above.

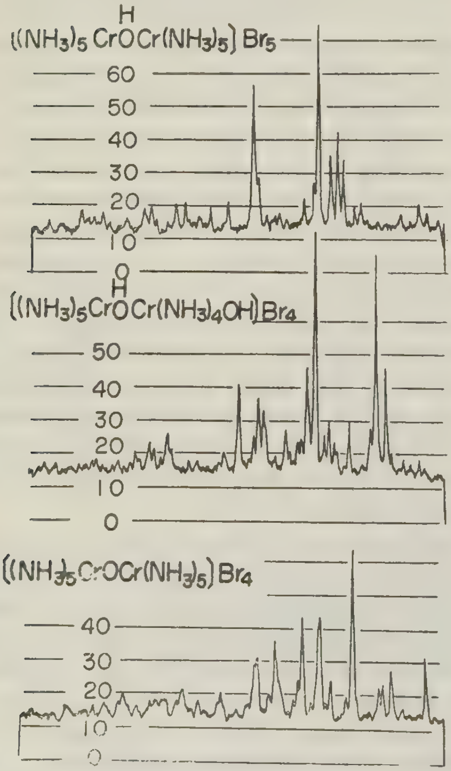


Fig. 5. X-ray powder patterns.

§ 4. Summary.

It was intended to obtain experimentally the magnitude and the sense of the superexchange interaction of Cr^{+3} pair through the investigation on the bi-nuclear complex compounds of chromium. Because, the magnetic properties of the bi-nuclear complex are thought to be determined for the most part by the superexchange interaction between the pair of the two magnetic ions through an intervening diamagnetic oxygen ion. The coefficient of the superexchange interaction in the pair of Cr^{+3} ions coupled by the almost linear $\overset{\mathrm{H}}{\overset{|}{-\mathrm{O}-}}$ bridge was found out in the range of $-28k\sim-36k$. In the case of -O- bridge, the extremely large absolute value of J, which amounted to $200k\sim400k$, was required to explain the experimental results, if the same model is used as in the case of the $\overset{\mathrm{H}}{\overset{|}{-\mathrm{O}-}}$ bridge.

The susceptibility of $[Cr(NH_3)_5Cl]Cl_2$ which is a usual mono-nuclear complex, obeys the Curie-Weiss law from 2.5°K to room temperature. The Weiss constant Θ obtained is $-0.8°K$. A comparatively large value such as this may be understood in connection with the possibility of existance of hydrogen bond on the interaction paths which are considered between two Cr^{+3} ions.

We are now intending to investigate the other bi-nuclear complex compounds of Cr^{+3} in which the bond angle of the bridge is almost 90°. From the preliminally experiments, rather small $|J|$ value is expected in such salts.

The authors wish to express their sincere thanks to Dr. H. Yamatera in St. Pauls Univ. Tokyo, for his valuable discussion especially on the chemical properties of the salts investigated. Their thanks are also due to Messers. I. Tsubokawa and T. Watanabe for the measurements of the susceptibility at higher temperatures.

A Study of Sorbed Water on Cellulose by Pulsed NMR Technique

By Masahumi SASAKI,* Takao KAWAI**, Akira HIRAI*,
Tsuneo HASHI* and Akira ODAJIMA***.

* *Department of Physics, Faculty of Science, Kyoto University.*

(Received May 6, 1960)

The state of sorbed water on cellulose has been studied by pulsed NMR technique. From the experimental results of spin-lattice relaxation time (T_1) and spin-spin relaxation time (T_2), observed as a spin echo decay time, following conclusions have been derived. (1) Two phases of the sorbed water are classified; the localized and the mobile. (2) The correlation time (τ_N) derived from T_1 using BPP theory, is consistent with that (τ_D) derived from dielectric measurements. (3) T_1 is by one or two order longer than T_2 in contradiction to BPP theory for extremely narrowing case. As an explanation for this fact, we propose that, when we consider about T_2, the effects of magnetic nuclei contained in the absorbent must be taken into account, though no theory is given. (4) The average life-time of water molecule sorbed on cellulose in the localized state is estimated to be several hundredths of a second and to decrease with temperature.

§ 1. Introduction

The spin-lattice relaxation time (T_1) and the spin-spin relaxation time (T_2) are very useful quantities for studying the state of sorbed water, as well as the dielectric relaxation time and other thermodynamical quantities.

One of the authors (A.O.) has measured the line-width of proton of water molecule sorbed on cellulose by using a high resolution NMR spectrometer[1] and compared the apparent correlation time (τ_N) derived from his data by BPP theory[2] with that (τ_D) from dielectric measurements[3,4,5]. The result is that τ_N is by about one order longer than τ_D.

If both τ_N and τ_D are the correlation times of rotational Brownian motion of water molecule in the sorbed state, they should be connected by the relation $\tau_N=\frac{1}{3}\tau_D$. So our initial purpose of this study is to clarify whether τ_N is consistent with τ_D or not, by means of T_1 measurement. As a result, we have found that τ_N derived from T_1 is consistent with τ_D from dielectric data.

Furthermore, it was found that there coexist two T_1's, but not two T_2's. It is very interesting that Zimmerman *et al.*[6,7,8] have found a similar result for T_1 and T_2 of sorbed water on silica gel by using the pulsed NMR technique. In their case, two T_2's coexisted, but two T_1's only in a limited range of water content. In a recent journal, we noticed that Winkler[9] studied sorbed water on allumina by using the pulsed NMR technique, observing the same kind of phenomena as Zimmerman's and ours.

The experimental data obtained and their interpretations and discussions will be given in detail below.

§ 2. Experimental Results

We have measured T_1 of proton of sorbed water on cellulose as a function of water content (x) and of temperature (T), by using 90°–90° pulse method[10] at 25 Mc/sec. The water content is defined as the ratio of weight of the sorbed water to the weight of the cellulose. The samples used were of the water contents of 12.5%, 16.5%, 20.3%, 36%, 44%, 55%, and 148%. The apparatus used has been described in detail elsewhere[11].

One example of our measurements is shown in Fig 1, where the difference between the nuclear signal just after the first pulse (y_1) and that after the second (y_2) is shown as a function of the pulse interval (τ) in a semi-logarithmic scale. In many cases, the curve of ln (y_1-y_2) *versus* τ is a straight line, whose slope gives T_1. But in our case, y_1-y_2 is given by the following expression:

$$y_1-y_2=y_{11}\exp\left(-\frac{\tau}{T_{11}}\right)+y_{12}\exp\left(-\frac{\tau}{T_{12}}\right).$$

From this figure, we can obtain three quantities: T_{11}, T_{12} and $y_{11}/(y_{11}+y_{12})$.

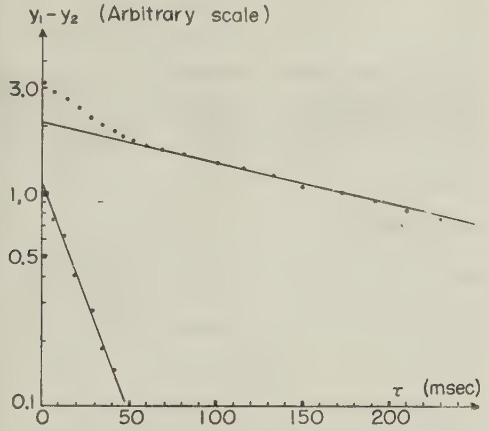

Fig. 1. Semi-logarithmic plots of the differences between the nuclear signal amplitude after the first pulse (y_1) and that after the second (y_2) *versus* the pulse interval (τ). Experimental plots are represented as

$$y_1-y_2=y_{11}\exp\left(-\frac{\tau}{T_{11}}\right)+y_{12}\exp.\left(-\frac{\tau}{T_{12}}\right),$$

giving three quantities; $T_{11}=20$ msec, $T_{12}=165$ msec, and $y_{11}/(y_{11}+y_{12})=0.35$.

Sample: Proton of sorbed water molecule on cellulose.

Water content (Weight of sorbed water/Weight of cellulose): 16.5%.

Temperature: 13°C.

Then the question arises whether these two T_1's are entirely due to the sorbed water, since cellulose molecule $(C_6H_{10}O_5)_n$ also contains protons. In order to check this point, we have measured the signal amplitude just after the first pulse, $(y_1=y_{11}+y_{12})$ as a function of the water content. The data obtained are shown in Fig. 2. The experimental points are on a straight line, which passes through the origin. If some protons in the cellulose contribute to nuclear signals, this straight line would displace to intersect the ordinate axis, and, if some protons in the sorbed water do not contribute to nuclear signals, this straight line would displace to intersect the abscissa axis. From this fact, we can conclude that the nuclear signal is wholly due to the sorbed water, and that all protons in the sorbed water contribute to the nuclear signal. That the protons in the cellulose do not contribute to the nuclear signal is consistent with the circumstances that our apparatus cannot detect the signal produced by protons in a rigid state, as alreary stressed in our previous article concerning the apparatus[11] and protons in the cellulose are considered to be in a rigid state. The half line-width of proton in the cellulose was measured by Varian spectrometer and found to be broader than 10 gauss.

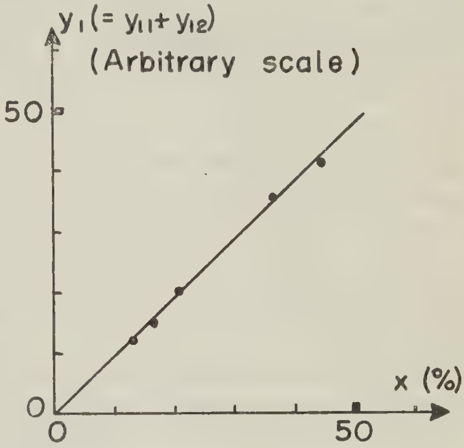

Fig. 2. Water content dependence of y_1 $(=y_{11}+y_{12})$ at room temperature, showing that three quantities (T_{11}, T_{12}, and $y_{11}/(y_{11}+y_{12})$) are all concerned with sorbed water. (See § 2).

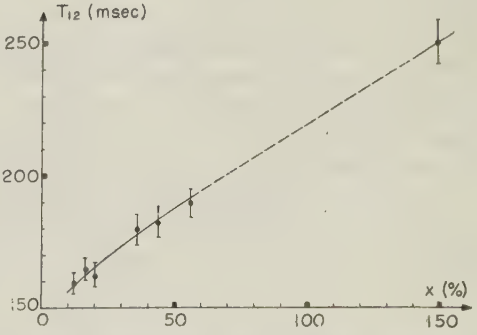

Fig. 3 (a). Water content dependence of T_{12} (longer T_1) at room temperature.

The values of T_{11}, T_{12} and $y_{11}/(y_{11}+y_{12})$ as functions of water content (x) and of temperature (T) are shown in Figs. 3~6. Rough measurements of spin echo decay time (T_2) have also been made only at room temperature as a function of water content, and shown in

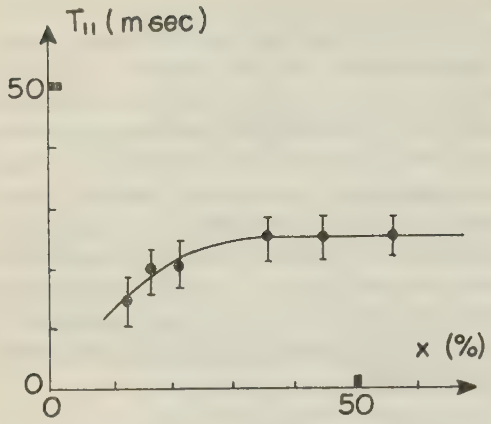

Fig. 3 (b). Water content dependence of T_{11} (shorter T_1) at room temperature.

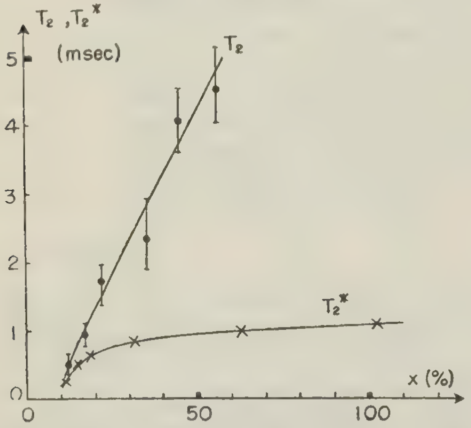

Fig. 3 (c). Water content dependence of T_2 (spin echo decay time) and $T_2{}^*=(\pi\Delta H_{1/2})^{-1}$ at room temperature. $\Delta H_{1/2}$ (half line-width) is obtained from the steady state measurement (reference 1).

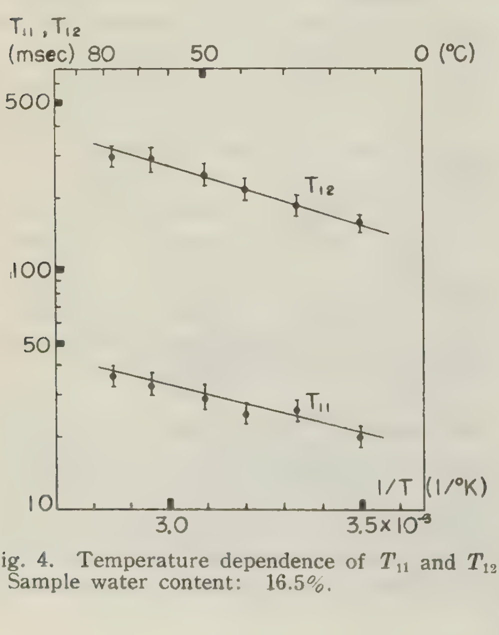

Fig. 4. Temperature dependence of T_{11} and T_{12}. Sample water content: 16.5%.

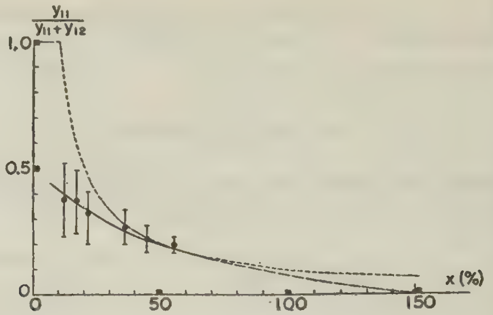

Fig. 5. Water content dependence of $y_{11}/(y_{11}+y_{12})$ at room temperature. Dotted curve is obtained from the simplified model of sorption (cf. § 3 (d).)

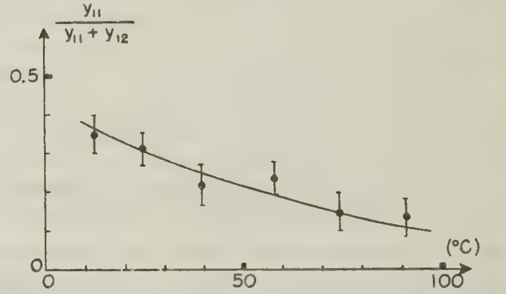

Fig. 6. Temperature dependence of $y_{11}/(y_{11}+y_{12})$. Sample water content: 16.5%.

Fig. 3 (c). In Fig. 3 (c), $T_2{}^*=(\pi\Delta \mathrm{H}_{1/2})^{-1}$ obtained from line-width measurement[1] is also shown for reference. Using these data, we shall discuss the sorbed state of water molecule in the next section.

§ 3. Discussions

a) Coexistence of two T_1's

As already mentioned, we have obtained two T_1's of proton of sorbed water on cellulose. From this fact, we can conclude that there are two different phases of the sorbed water. This is consistent with Zimmerman's data[6,7,8], Winkler's data[9], and dielectric data[12,13]. Now we propose that the shorter T_1 (T_{11}) is due to protons of the localized water, perhaps hydrogen-bonding with OH groups of cellulose, and the longer T_1 (T_{12}) to protons of the mobile water, not directly adhering to cellulose, but perhaps hydrogen-bonding with other water molecules.

The nuclear magnetic resonance of multiphase system has been studied by many workers[7,8,14,15]. Among them, Zimmerman-Brittin's analysis[7] based on the stochastic theory, seems to be very suitable for the analysis of our data. Now, we analyse our data by their theory.

At this point, there is something to note, from the experimental point of view, about the possibility of the observation of two or more T_1's, which is particularly interesting in high polymer NMR researches[16]. We draw the curves, as in Fig. 1,

$$y_1-y_2=Ae^{-a\tau}+Be^{-b\tau},$$

for various values of a, b and $A/(A+B)$ ($A+B$ being normalized to unity). Then we find that the condition that two T_1's can be measured separately is that $b/a>5$ or $b/a<1/5$, and $10>\frac{B}{A}>\frac{1}{10}$. These conditions are rather strict limitations. We have measured, indeed, T_1's of various high polymers, but we could not have so far measured two T_1's separately.

b) Values of T_{11} and T_{12}.

T_{11} is of the order of 20 msec and T_{12} of the order of 200 msec. Both increase slightly when the water content is increased (Fig. 3 (a), (b)). For simplicity, we assume that the exchange rate between the localized state and the mobile state is so low that the average life-time of a water molecule in the localized state (τ_{ex}) is very much longer compared with T_1. In this case, T_{11} gives the exact spin-lattice relaxation time for protons of the localized water and T_{12} that for protons of the mobile water.

As far as T_1 is concerned, we take the simplest model that the energy of spin system relaxes to the rotational Brownian motion of water molecules by the magnetic dipole-dipole interaction. Then, following BPP theory[2] revised by Kubo and Tomita[17], T_1 is given by

$$\frac{1}{T_1}=\frac{3}{10}\gamma^4h^2b^{-6}\left(\frac{\tau_N}{1+\omega^2\tau_N^2}+\frac{4\tau_N}{1+4\omega^2\tau_N^2}\right),$$

where b is the inter-proton distance in a water molecule, which is taken to be 1.5 A, and ω, is 2π times the resonance frequency, 25 Mc/sec in our case. Now, from the data of temperature dependence of both T_{11} and T_{12} (Fig. 4), it is obvious that we are dealing with extremely narrowing case in BPP theory, where $\omega\tau_N\ll1$. Then we can derive the correlation times τ_{N1} and τ_{N2} to be of the order of 10^{-10} sec and 10^{-11} sec corresponding to T_{11} and T_{12} respectively. Based on our model already mentioned, τ_N and τ_D should be connected by the following relation:

$$\tau_N=\frac{1}{3}\tau_D=\frac{4\pi\eta a^3}{3kT},$$

where η is the viscosity coefficient, and a the radius of water molecule. Our value of τ_{N2} of the mobile water is favorably compared with τ_D derived from dielectric measurements[3,4,5], which is of the order of 10^{-10} sec.

If the exchange between two states cannot be neglected, which would be the actual situation (see § 3 (d)), the apparent values of T_1's are shorter than the actual T_1's[7,8]. This effect is serious at high temperature. Even if we take this effect into account, it is obvious that we are dealing with the extremely narrowing case, and the orders of magnitude of τ_N's would not be altered.

We have assumed that the relaxation mechanisms for both of water molecules, the localized and the mobile, are the same, and have attributed the difference between T_{11} and T_{12} to the difference between their τ_N's. But, in the actual situation, the relaxation mechanisms for both may be different. For instance, the relaxation mechanisms for the localized water may be via non-spherical Brownian motion such as considered by one of the authors (A.O.)[18], or via paramagnetic impurities contained in cellulose. These points are not clear at the present stage of our investigation.

Finally, our data must be compared with T_1's of protons of sorbed water on silica gel obtained by Zimmerman and Lasater[8]. Their values of T_1 corresponding to our data are of the order of 20 msec, only single T_1 existing except for 10.6, 12.6, and 13.6% samples. The reason for the difference between their data and ours is not clear, and perhaps the difference of the adsorbent is its origin, and it is a further task to clarify this difference.

c) Values of T_2

Since our apparatus is not suitable for accurate measurement of T_2, we made only rough measurements of T_2, where we could not separate two T_2's so far. We think it is a great task left for us to solve the question whether we can separate two T_2's in our sample. We are now proceeding to modify our apparatus to measure the spin echo decay time accurately.

T_2 varies from 0.5 msec to 4.5 msec, with the water content increasing (Fig. 3 (c)) and T_2 is by about one order of magnitude shorter than T_{11}. In general, if the mechanisms for T_1 and T_2 are of the same origin, BPP theory gives the relation $T_1=T_2$ in the extremely narrowing case with which we are dealing. Now we explain this disagreement by considering that the main mechanisms responsible for T_1 and T_2 are different. For T_1 we have considered that the main mechanism is due to the rotational Brownian motion of water molecule. For T_2 we propose that the protons contained in the cellulose, which themselves are not detected in the signal, make some local field at the positions of sorbed water molecules, varying from position to position, and shorten T_2. The formulation of the spin echo decay time in this situation is another task left for us and we shall discuss this point after we shall have completed the accurate measurement of T_2.

d) Values of $y_{11}/(y_{11}+y_{12})$

First we consider the dependence of $y_{11}/(y_{11}+y_{12})$ on water content. $y_{11}/(y_{11}+y_{12})$ decreases with the water content. Eor 148% sample at room temperature, we could not separate two T_1's i.e. $y_{11}/(y_{11}+y_{12})\simeq 0$ (Fig. 5).

The quantity $y_{11}/(y_{11}+y_{12})$ represents the ratio of the number of water molecules in the localized state to the total number of water molecules, if the exchange between the localized and the mobile states is neglected.

Then we consider a simplified model of sorption, such that, with the water content increasing, water molecules make hydrogen bonds with OH groups of cellulose until there are no OH groups left for hydrogen bonding, and only after that the mobile water appears. The degree of crystallinity of our cellulose sample is about 70% and the OH groups inside the crystalline part do not take part in the sorption. According to this model, a simpe calculation shows that the dependence of $y_{11}/(y_{11}+y_{12})$ on water concent is represented by the dotted curve in Fig. 5. In the general tendency, this dotted curve is like the experimental curve. In order to make more precise comparison, however, the following facts must be taken into account. First, when the water content is increasing, the mobile water would appear before the monolayer is fully completed. Second, there may be some swelling effects. Finally, the exchange between the localized and the mobile states cannot be neglected, and then $y_{11}/(y_{11}+y_{12})$ is smaller than the actual population ratio[7,8].

Next, we consider the temperature dependence of the value of $y_{11}/(y_{11}+y_{12})$, which decreases with the temperature increasing (Fig. 6). We explain this phenomenon in the following way. The average life-time of a water molecule in the localized state (τ_{ex}) would not be so much longer than T_{11} and it would vary with the temperature as τ_{exo} exp $\Delta H/RT$, where ΔH is the activation energy for the hydrogen bond between water molecule and OH group of cellulose. When the temperature is increased, the actual relaxation time T_{11} increases and τ_{ex} decreases, and gradually T_{11} becomes comparable with τ_{ex}. So, $y_{11}/(y_{11}+y_{12})$ decreases with the temperature. Of course, the above explanation is one of the possible explanations for the data of Fig. 6. Following the above explanation, we estimate τ_{ex} to be of the order of several tens of msec at room temperature. Since we can separately measure T_{11}'s of the order of 20 msec, the average life-time in the localized state of the sorbed water on cellulose is not shorter than 20 msec at room temperature. On the other hand, for the sorbed water on silica gel, Zimmerman *et al.* obtained the value of 3 msec for the average life-time in the localized state, which is again by one order of magnitude shorter than ours. This difference is also a task for further investigation, as the difference in the values of T_1.

§ 4. Conclusions

We have measured the spin-lattice relaxation time of proton of sorbed water on cellulose. There are two different phases of water molecule. the localized and the mobile. The data of T_1 was analysed by BPP theory. The correlation time derived from T_1 is consistent with the value from dielectric measurements. The value of T_2 is by about one or two order of magnitude shorter than T_1, contradicting with the theoretical prediction $T_1=T_2$ for extremely narrowing case, we are dealing with. We have qualitatively explained this discrepancy by considering the effects of protons contained in cellulose. But a more quantitative treatment, that is, the theory of T_2 of the heterogeneous system, which is constituted by two sets of spins in different environments, one being in the fluctuating lattice (protons of sorbed water) and the other in the rigid lattice (protons in cellulose), must be developed. The average life-time in the localized state of sorbed water molecule on cellulose would be of the order of several tens of msec.

By this study, many points left for questions in the previous study by one of the authors (A.O.) have become clear. Further points left for us are to measure accurately the spin echo decay time, to develop the theory of the T_2 of the heterogeneous system, and to clarify the difference between the sorption mechanisms on cellulose and on silica gel.

The authors would like to express their sincere thanks to Professor I. Takahashi for his continual interest and discussions. It is also our pleasure to acknowledge the assistance of Mr. S. Inoue of Hokkaido University.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 15, No. 9, SEPTEMBER, 1960

Study of Aqueous Solution of Strong Electrolyte—Reexamination of Molecular Refraction*

By Takeshi SATOH and Koreaki HAYASHI

Department of Physics, Defense Academy, Obaradai, Yokosuka, Japan

(Received, May 11, 1960)

Molecular refraction of 1–1 electrolyte aqueous solution was reexamined in the light of a proposed model. So-called Lorentz-Lorenz function was plotted against molar fraction of electrolyte. Linear relationships and critical phenomenon dividing the whole range into two were found. By applying our theory we obtain total number of hydration, $n_I^{(+)}+n_I^{(-)}+n_{II}^{(+)}+n_{II}^{(-)}$, where the hydration numbers around each cation and anion are defined as $n_I^{(+)}$, $n_I^{(-)}$ referred to the primary region and $n_{II}^{(+)}$, $n_{II}^{(-)}$ referred to the secondary region respectively. We could also estimate the polarizability α_* of water molecule which are considered as 'solvent in concentrated range' and subjected to the sufficient effect of polarization from surrounding ions.

§1. Introduction

Recently one of the authors (T.S.) has offered a model (1) of aqueous solution of strong electrolyte, which is to be applied throughout the whole range of concentration. In short the kernel of our model consists in two points: one is an extension of definition of so-called hydration layer and the other is perception that there exists critical range of concentration and consequently we can divide the whole into two, distinctly different ranges from structural viewpoint. Then we use primary hydration numbers $n_I^{(+)}$, $n_I^{(-)}$ and secondary hydration numbers $n_{II}^{(+)}$, $n_{II}^{(-)}$. The superscript (+) or (−) refers that a layer concerned is one located arond a cation or an anion respectively.

Now we are going to reexamine molecular refraction from an above-mentioned standpoint. Of course this problem had been studied three decades ago and a trial, theoretical explanation has been given by Böttcher(2). As well-known, 'law of additivity of molecular refraction' is valid in multi-component systems. The application of this law is unexpectedly capable in wider field. Let the molecular refraction of a solution considered be denoted by R, that of each component by R_i and molar fraction of each component by f_i, the law is formulated in the equation,

$$R=\sum_i R_i f_i. \tag{1}$$

On the other hand molecular refraction R is defined as $(\mu/\rho)\,(n^2-1)/(n^2+2)$, where the notations are used as following:

n = refractive index of solution,

ρ = density of solution,

μ = average molecular weight of solution,

$= \sum_i \mu_i f_i$.

In this paper we restrict our consideration in two-component systems. Then it is easily seen that if we plot so-called Lorentz-Lorenz function $\rho^{-1}(n^2-1)/(n^2+2)$ against molar fraction of solute f, we will obtain such a curve as shown in Fig. 1. Fig. 1. shows an example of water-methylalcohol solution at 22°C, where

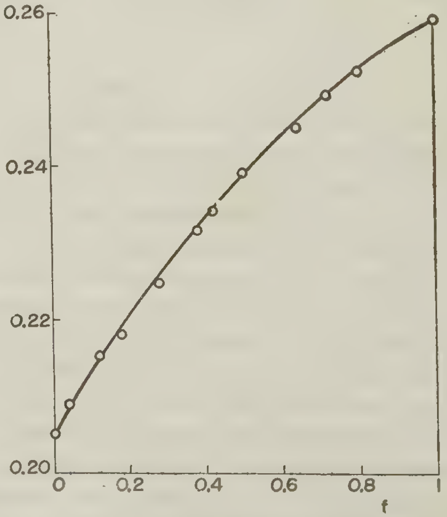

Fig. 1. Methylalcohol (22°C)

---

* Read at the annual meeting of the Physical Society of Japan held at University of Tokyo on April 6, 1960.

methylalcohol is taken as solute.

§ 2. Experimental Data

Let us back and consider our systems. Since dissociation can be assumed perfect because of 1–1 electrolytes, it turns out that variable f representing molar fraction of cation and anion simultaneously is the same to that of electrolyte solute. And then f is limited to the order of only several percent. Consequently we notice that Lorentz-Lorenz function is expected to be approximately linear to f.

In the literatures we find available data for analysis which were done by Fayans' collaborators, H. Kohner(3), W. Geffcken(4), and P. Hölemann and H. Kohner(5). The Plots of $\rho^{-1}(n^2-1)/(n^2+2)$ versus f are shown in Fig. 2 to Fig. 6. In these figures we find distinctive features that relation can be approximately indicated by two straight lines having different slopes. But we must recognize that there is only small number of points, particularly in dilute range. For this reason we tried reobservations for supplemental data by preparing more detailed points of concentration.

Here we describe the outline of the experimental. Sodium chloride, sodium bromide, potassium chloride, potassium bromide and potassium iodide have been studied as electrolyte solutes. All samples were special-class

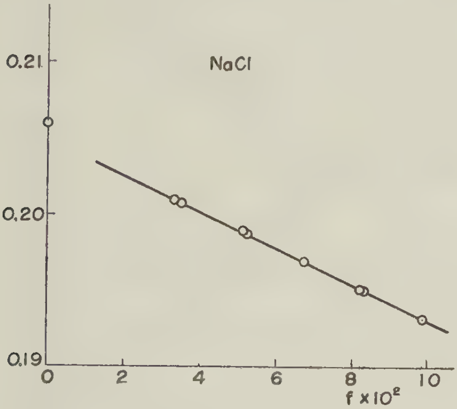

Fig. 2. Sodium chrolide (25°C)

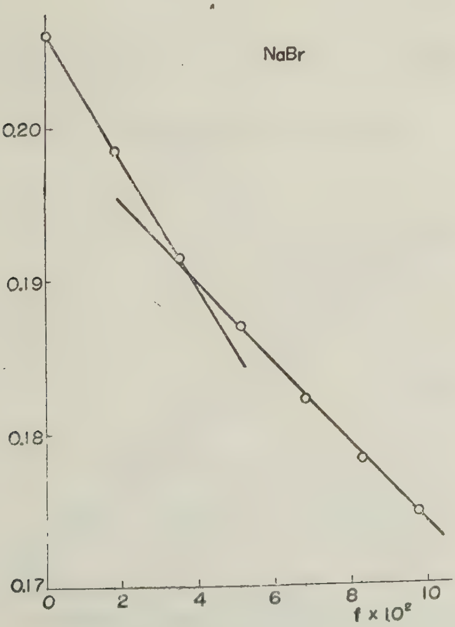

Fig. 3. Sodium bromide (27°C)

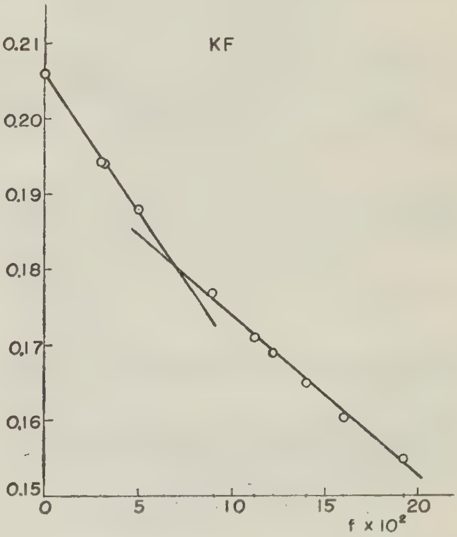

Fig. 4 Potassium fluoride (25°C)

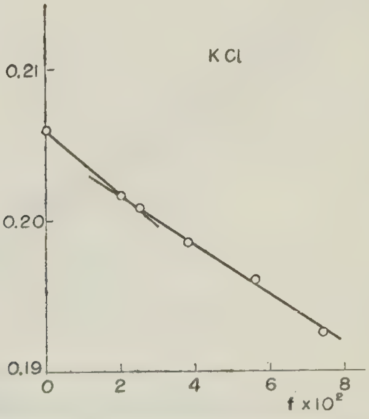

Fig. 5. Potassium chrolide (55°C)

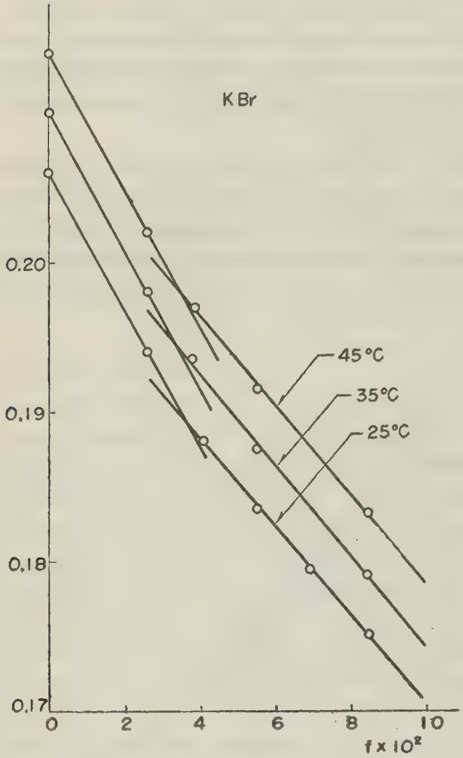
commercial products, which were dried in a thermostat for several hours before making solutions. Refractive indices of solutions have been measured by Abbe refractometer using light source of a sodium discharge tube.

Temperature of specimen was kept constant by passing water through jacket from water works. Error of refractive index was limited within ±2 at the fourth decimal, while that of temperature of specimen cell ± (0.1 or 0.2)°C. The density of solution has beed measured by a picnometer. The results are shown in Fig. 7 to Fig. 11. From these figures we can probably draw our conclusion upon experimental facts.

§ 3. Theoretical Interpretation

We take cation, anion and water as the



[Measuring points corresponding to 35° and 45°C are plotted in a way of translation by constant.]

Fig. 6. Potassium bromide (25 C)

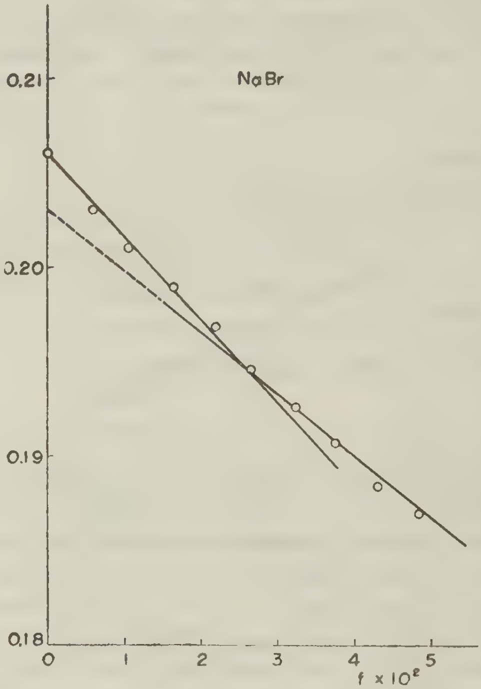


Fig. 8. Sodium bromide (20°C)

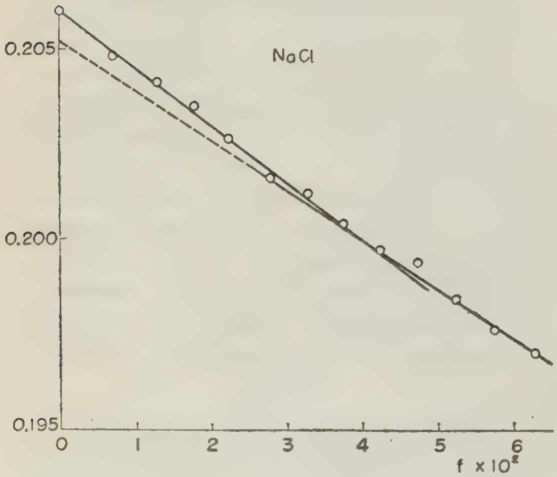

Fig. 7. Sodium chrolide (19°C)

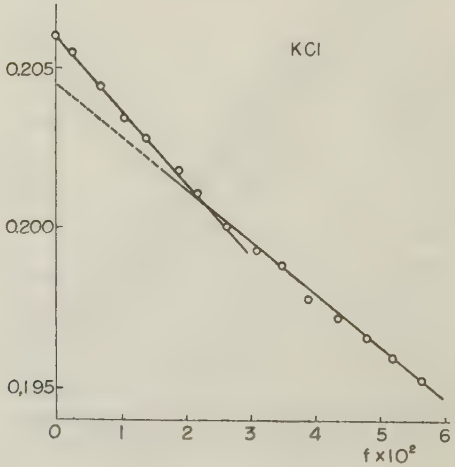

Fig. 9. Potassium chrolide (19°C)

components. However, from above situation based upon our model simple treatment of water might not be permitted. That is, we should consider molecular refraction of water molecular which corresponds to different state; $R_{\mathrm{I}}^{(+)}$, $R_{\mathrm{I}}^{(-)}$ referred to waters in primary hydration region, $R_{\mathrm{II}}^{(+)}$, $R_{\mathrm{II}}^{(-)}$ referred to those in secondary hydration region and R_0 referred to the normal, free water molecules. R_+ and R_- denote those of cation and anion.

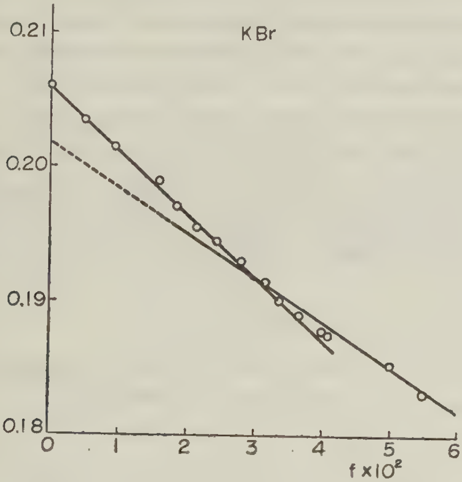

Fig. 10. Potassium bromide (19°C)

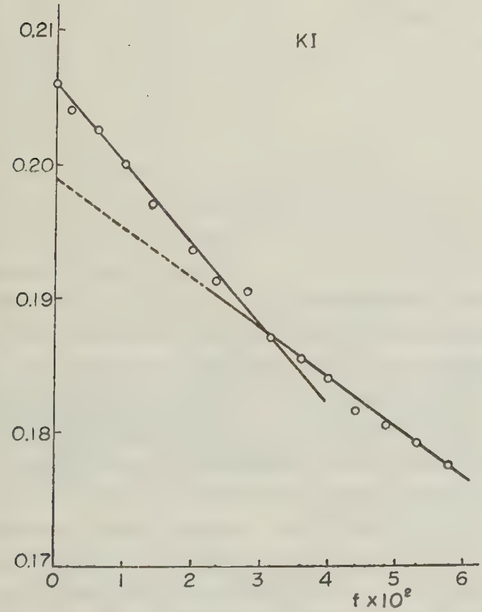

Fig. 11. Potassium iodide (19°C)

(i) *dilute range*

Since molar fraction of the cation and the anion is f, that of water is $1\text{-}2f$. Molar fractions of different types of water are, therefore, given in the following from.

types of water molecule	molar fraction
primary layer of cation	$n_{\mathrm{I}}^{(+)}f$
primary layer of anion	$n_{\mathrm{I}}^{(-)}f$
secondary layer of cation	$n_{\mathrm{II}}^{(+)}f$
secondary layer of anion	$n_{\mathrm{II}}^{(-)}f$
normal	$1-(n_{\mathrm{I}}^{(+)}+n_{\mathrm{I}}^{(-)}+n_{\mathrm{II}}^{(+)}+n_{\mathrm{II}}^{(-)}+2)f$

Consequently, $\sum\limits_j R_j f_j$ can be written:

$$\begin{aligned}\sum R_j f_j &= (R_+ + R_-)f \\ &+ (R_{\mathrm{I}}^{(+)} n_{\mathrm{I}}^{(+)} + R_{\mathrm{I}}^{(-)} n_{\mathrm{I}}^{(-)} \\ &+ R_{\mathrm{II}}^{(+)} n_{\mathrm{II}}^{(+)} + R_{\mathrm{II}}^{(-)} n_{\mathrm{II}}^{(-)})f + R_0\{1-(n_{\mathrm{I}}^{(+)} \\ &+ n_{\mathrm{I}}^{(-)} + n_{\mathrm{II}}^{(+)} + n_{\mathrm{II}}^{(-)} + 2)f\} \\ &= R_0(1+Af),\end{aligned} \tag{2}$$

where coefficient A is written by an equation,

$$\begin{aligned}A = \{&(R_+ + R_-) + (R_{\mathrm{I}}^{(+)} n_{\mathrm{I}}^{(+)} + R_{\mathrm{I}}^{(-)} n_{\mathrm{I}}^{(-)} \\ &+ R_{\mathrm{II}}^{(+)} n_{\mathrm{II}}^{(+)} + R_{\mathrm{II}}^{(-)} n_{\mathrm{II}}^{(-)}) - R_0(n_{\mathrm{I}}^{(+)} \\ &+ n_{\mathrm{I}}^{(-)} + n_{\mathrm{II}}^{(+)} + n_{\mathrm{II}}^{(-)} + 2)\}/R_0.\end{aligned} \tag{3}$$

While $\bar{\mu}(=\sum\limits_j \mu_j f_j)$ is $\mu_0(1+Bf)$, where μ_0 is denoted as molecular weight of water and coefficient $(\mu_+ + \mu_- - 2\mu_0)/\mu_0$ is abbreviated by B.

Of course $\mu_+ + \mu_-$ equals to molecular weight of solute. Hence Lorentz-Lorenz equation can be written in the following from:

$$\begin{aligned}\rho^{-1}(n^2-2)/(n^2+2) &= (R_0/\mu_0)(1+Af)(1+Bf)^{-1} \\ &\approx (R_0/\mu_0)\{1-(B-A)f\}.\end{aligned} \tag{4}$$

Here we neglect higher order terms more than square of f. Eq. (4) shows that $\rho^{-1}(n^2-1)/(n^2+2)$ is approximately linear to f and so our theoretical derivation agrees satisfactorily with experimental result.

(ii) *concentrated range*

When concentration reaches to a critical point, almost no free water molecule exists in solution. We must, therefore, consider different members of component, namely water molecules can be now classified into three. Hence molar fractions of these three types of water are given in the same manner.

types of water molecule	molar fraction
primary layer of cation	$n_{\mathrm{I}}^{(+)}f$
primary layer of anion	$n_{\mathrm{I}}^{(-)}f$
over-all secondary layer	$1-(n_{\mathrm{I}}^{(+)}+n_{\mathrm{I}}^{(-)}+2)f$

If R corresponding to secondary-region water molecule is designated as R_*, $\sum\limits_j R_j f_j$ can be written:

$$\sum R_j f_j = (R_+ + R_-)f + (R_{\mathrm{I}}^{(+)} n_{\mathrm{I}}^{(+)} + R_{\mathrm{I}}^{(-)} n_{\mathrm{I}}^{(-)})f + R_*\{1-(n_{\mathrm{I}}^{(+)} + n_{\mathrm{I}}^{(-)} + 2)f\} = R_*(1+A_*f), \tag{5}$$

where coefficient A_* is written as follows:

$$A_*=\{(R_+ + R_-)+(R_{\mathrm{I}}^{(+)}n_{\mathrm{I}}^{(+)}+R_{\mathrm{I}}^{(-)}n_{\mathrm{I}}^{(-)} - R_*(n_{\mathrm{I}}^{(+)}+n_{\mathrm{I}}^{(-)}+2)\}/R_*. \tag{6}$$

Hence,

$$\rho^{-1}(n^2+1)/(n^2+2)=(R_*/\mu_0)(1+A_*f)(1+Bf)^{-1}\approx(R_*/\mu_0)\{1-(B-A_*)f\}, \tag{7}$$

where higher order terms more than square of f are neglected as in Eq. (4). Eq. (7) is also seen to be able to explain experimental fact. By using available graphs we are now going to determine hydration number. In Eq. (4) and Eq. (7) we can obtain absolute value of gradient, say g and g_*, and constant factor term, R_0/μ_0 and R_*/μ_0 (consequently R_0 and R_*) respectively. Hence we have,

$$(R_0/\mu_0)(B-A)=g \tag{8}$$

and

$$(R_*/\mu_0)(B-A_*)=g_*. \tag{9}$$

Substituting Eq. (3) and Eq. (6) into these equations,

$$(R_+ + R_-)+(R_{\mathrm{I}}^{(+)}n_{\mathrm{I}}^{(+)}+R_{\mathrm{I}}^{(-)}u_{\mathrm{I}}^{(-)}+R_{\mathrm{II}}^{(+)}n_{\mathrm{II}}^{(+)}+R_{\mathrm{II}}^{(-)}n_{\mathrm{II}}^{(-)})-R_0(n_{\mathrm{I}}^{(+)}+n_{\mathrm{I}}^{(-)}+n_{\mathrm{II}}^{(+)}+n_{\mathrm{II}}^{(-)}+2)=B-g(\mu_0/R_0), \tag{10}$$

$$(R_+ + R_-)+(R_{\mathrm{I}}^{(+)}n_{\mathrm{I}}^{(+)}+R_{\mathrm{I}}^{(-)}n_{\mathrm{I}}^{(-)})-R_*(n_{\mathrm{I}}^{(+)}+n_{\mathrm{I}}^{(-)}+2)=B-g_*(\mu_0/R_*). \tag{11}$$

When Eq. (10) is subtracted from Eq. (11), the following equation is obtained,

$$(R_0-R_*)(n_{\mathrm{I}}^{(+)}+n_{\mathrm{I}}^{(-)}+n_{\mathrm{II}}^{(+)}+n_{\mathrm{II}}^{(-)}+2)=\mu_0\{(g/R_0)-(g_*/R_*)\}.$$

The over-all hydration number is, therefore, determined by:

$$n_{\mathrm{I}}^{(+)}+n_{\mathrm{I}}^{(-)}+n_{\mathrm{II}}^{(+)}+n_{\mathrm{II}}^{(-)}=\{\mu_0/(R_0-R_*)\}\times\{(g/R_0)-(g_*/R_*)\}-2. \tag{12}$$

Values of $n_{\mathrm{I}}^{(+)}+n_{\mathrm{I}}^{(-)}+n_{\mathrm{II}}^{(+)}+n_{\mathrm{II}}^{(-)}$ for several 1-1 electrolyte species calculated from Eq. (12) are tabulated in Tab. 1.

§ 4. Discussion

Böttcher has thought that the experimental fact that apparent dependency of molecular refraction of component upon the concentration is caused by a limited validity of the Lorentz-Lorenz formula and all the deviations can be explained by his corrected Lorentz-Lorenz formula⁽²⁾. While our treatment is based upon the assumption that the additivity law of molecular refraction holds widely. We consider that the knick phenomena are to be attributed rather to structural change in the solution. Then, if we adopt a conventional relationship that polarizability α of a particle is proportional to molecular refraction R, we obtain the values of α_* corresponding to R_*, which are listed in Tab. 1. Clearly α_* is smaller than α_0, although the difference is not so remarkable. (The value of polarizability α_0 at 25°C is 1.470 A^3, which should be distinguished from Böttcher's value 1.303 A^3 because of different definition.) This is easily understandable since in the region in which α_* is defined water molecule undergoes sufficiently the polarization effect from ion. Moreover, it seems interesting and meaningful that α_* has a general tendency of decrease against the increasing of ionic radius.

We can quote glass as an appropriate example in concentrated range. Although glass is super-cooled liquid, it is just like our systems in extremely concentrated ionic solution. A similar treatment to this paper are found to be applied successfully in the structural study of glass(6).

The neglect of higher order terms more than f^2 in Eq. (4) and Eq. (7), particularly in the latter, must be examined in such a case as KBr or KI, which has large value of B. Because, in these samples f^2-term may become to be somewhat comparable to f^1-term around larger value of concentration near saturation. But we cannot detect these trend in our experimental ranges as seen in Fig. 10 and Fig. 11. Bjerrum has pointed out that we must consider an influence of ion association, which may occur mainly in high concentrations. Since ion association increases proportional to the square of concentration, its contribution to Eq. (7) is of the order of f^3. We might, therefore, neglect this effect.

Table 2. Estimation of secondary hydration number $n_{II}^{(+)}+n_{II}^{(-)}$

	$n_I^{(+)}+n_I^{(-)}$	$n_{II}^{(+)}+n_{II}^{(-)}$
NaCl	6	28
NaBr	6	26
KCl	5	34
KBr	5	22
KI	5	19

It should be remembered that the value of $n_I^{(+)}+n_I^{(-)}+n_{II}^{(+)}+n_{II}^{(-)}$ calculated by Eq. (12) might not be regarded to be very accurate, because that values of g and g_* obtained graphically can only be determined fairly rough. After allowing this circumstance, we try to estimate total number of secondary hydration. If we use total number of primary hydration that has been simply called hydration number, we can obtain total number of secondary hydration to each electrolyte. Mean values of $n_I^{(+)}+n_I^{(-)}$(7) used for estimation and those of $n_{II}^{(+)}+n_{II}^{(-)}$ determined thus are listed in Tab. 2. Hydration number is supposed almost independent on temperature. This is verified by a fact that all the slopes of straight lines corresponding to various temperatures are determined nearly the same whithin experimental error as seen in Fig. 6.

The values of critical concentration $C_{crit.}$ may be compared with ones determined with other hydration-dependent quantities. At present we have only few examples available for this comparison. Here we will refer a result of viscosity. With NaCl we can find good agreement between present work and recent report by Suryanarayana and Venkatesan(8).

The authors takes this opportunity to thank Prof. J. Itoh for his suggestion concerning the subject of hydration. Special thanks are due to Dr. I. Oshida and Prof. K. Ishiguro for their deep interests and invaluable discussions. Finally, we would like to thank Mrs. M. Hakuya for her assistance of measurement and calculation during this work.

On the Magnetic Properties of a $CrBr_3$ Single Crystal

By Ichiro TSUBOKAWA

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai, Japan.

(Received May , 1960)

Magnetic properties of single crystals of $CrBr_3$ have been measured with a magnetic balance and also with a torque magnetometer. The ferromagnetic Curie point has been found to be 37°K from the temperature dependences of magnetization and of torque. Based on the data of the magnetic susceptibility above the Curie point, the paramagnetic Curie point θ_p, Curie constant C_M and the effective Bohr magneton number have been determined to be 47°K, 1.84 and 3.85 μ_B respectively. From the saturation magnetization at 4 2°K, the moment of chromium ion is estimated to be 3 μ_B, coinciding with the spin moment obtained from the susceptibility measurement above the Curie temperature. Direction of easy magnetization lies along the c-axis of the hexagonal lattice, and the second order and the fourth order anisotropy constants are estimated to be $K_1=-5.08\times10^5$ and $K_2=0.65\times10^5$ erg/cc respectively. In the present results, there is found a small deviation in the torque curves from simple sinusoidal form, $L=K \sin 2\theta$, which is discussed on the basis of the higher order term of magnetic anisotropy in the high field strength range and also of the domain-theoretical consideration in the low field strength range.

§ 1. Introduction

Several anhydrous di- or trihalides of the elements of the iron group shown an interesting magnetic property which is known to be metamagnetism. For these compounds, the paramagnetic Curie temperatures θ_p have a positive sign, and in the temperature range below these points the magnetic susceptibilities depend on the magnetic field strength. In spite of $\theta_p > 0$, it was discovered by neutron diffraction experiments that the magnetic spin ordering in the crystal lattice of these compounds is antiferromagnetic. On the other hand, the chromium trihalides, $CrCl_3$⁽¹⁾ and $CrBr_3$⁽²⁾⁽³⁾, are considered to have different magnetic properties in comparision with those mentioned above, but any detailed study was not yet undertaken. On this point of view, the magnetic properties of a single crystal of $CrBr_3$ were investigated by the present author.

§ 2. Experimental Results

A single crystal of $CrBr_3$ was prepared by heating the powdered chromium (99.3%) in the vapour of bromine (99.9%) up to about 750°C. A schematic diagram of the apparatus for growing $CrBr_3$ crystals is shown in Fig. 1. The crystals were grown up to about $4\times7\times7$ mm³ in dimension and were cooled in the furnace F_1. The $CrBr_3$ crystals appeared in the form of hexagonal plates with a cleavage plane of (0001), dark green in color.

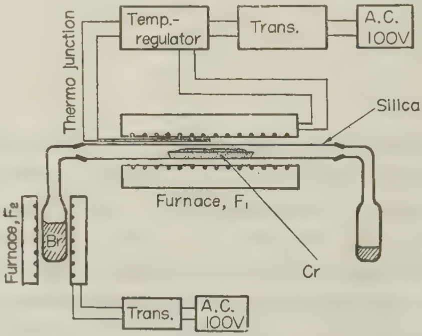

Fig. 1 A schematic diagram of the apparatus for growing the $CrBr_3$ crystals: Powdered chromium was placed in furnace F_1 and heated to 750°C. Bromine vapor was prepared by heating bromine in a glass container to 50°C by furnace F_2.

Chemical analysis showed that the $CrBr_3$ crystals thus obtained contained only trivalent chromium ions. It was also confirmed by a Debye-Scherrer X-ray pattern that the crystal was hexagonal in structure with the lattice constants $a=3.66$ Å and $c=18.30$ Å, which agreed closely with the results of the previous work(4).

Temperature dependence of specific magnetization σ and of susceptibility χ above the Curie point were also measured and the results are shown in Figs. 2 and 3. The ferromagnetic Curie temperature was estimated to be about 37°K by plotting the σ^2–T curve. In Fig. 3, the inverse susceptibility is also plotted against the temperature, which shows that the paramagnetic susceptibility above the Curie temperature obeys the epuation

$$\chi=\frac{0.0063}{T-47},$$

whence the paramagnetic Curie point was determined to be $\theta_p=47$°K and the Curie constant, C_M, and the effective Bohr magneton number, p_{eff}, are 1.84 and 3.84 μ_B respectively.

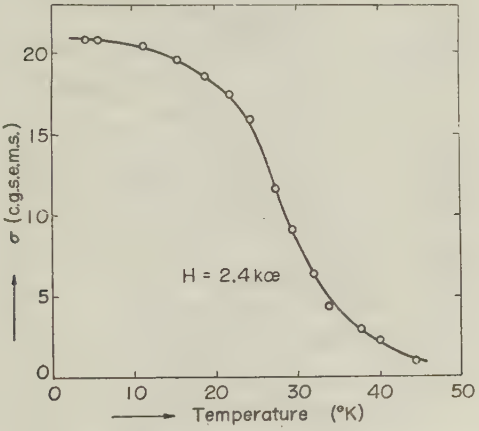

Fig. 2. Temperature dependence of magnetization.

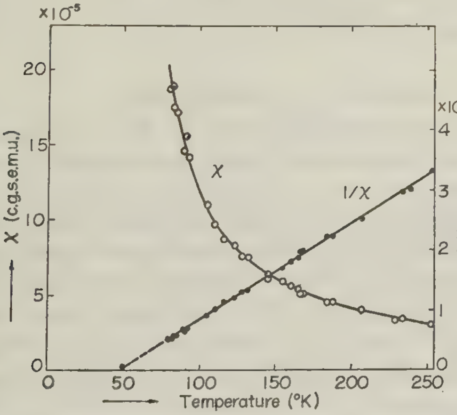

Fig. 3. Temperature dependence of the susceptibility above the Curie point. (Inverse susceptibility is also plotted).

Torque measurement was performed by means of a torque magnetometer. A single crystal specimen used in the present experiment was spherical in shape, 2 mm in diameter. Some typical torque curves at 4.2°K in the a–c placn are shown in Fig. 4. The stable position for the specimen could not be found when the magnetic field was oriented near a-direction of the crystal. When the applied field was 2.4 koe, the torque maximum appeared at $\theta=48°$, θ representing the poler angle of the field direction from c-axis, but it displaced towards the a-axis with increasing field strength. The deflection θ reached its maximum value 62° at about 7 koe and then decreased with the further increase of magnetic field strength. The maximum

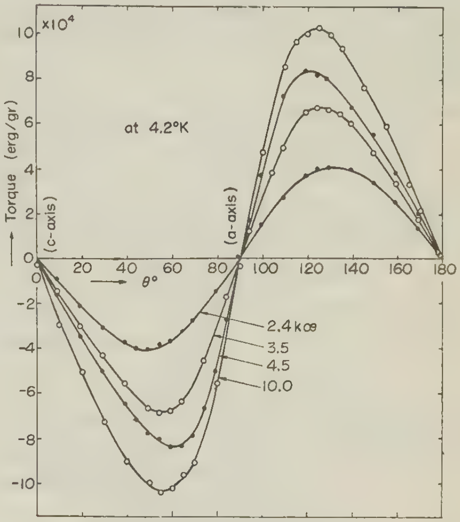

Fig. 4. Torque curves at 4.2°K.

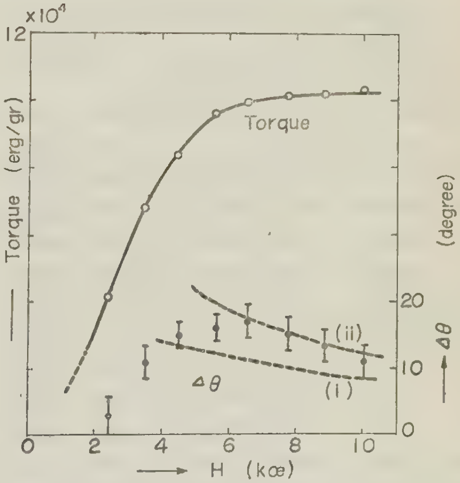

Fig. 5. Field dependences of the value of the torque maximum and of $\Delta\theta$.

torques and deviations $\Delta\theta$ of the torque maximum position from 45° for each curve are plotted against the applied field strength in Fig. 5. A temperature dependence of the value of the torque maximum measured in the field strength of 10 koe is shown in Fig. 6. Further torque measurements were performed above the Curie temperature, and $(\chi_c-\chi_a)$ calculated by using the value of torque is shown in Table 1.

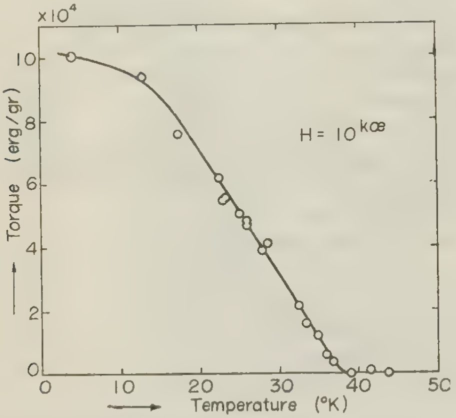

Fig. 6. Temperature dependence of torque.

Table I. The values of $\chi_c-\chi_a$.

Temp.	$\chi_c-\chi_a$	Temp.	$\chi_c-\chi_a$	Temp.	$\chi_c-\chi_a$
43.0°K	116×10^{-6}	64.3°K	4.6×10^{-6}	101°K	0.80×10^{-6}
43.5	106	66.0	3.7	106	0.75
43.8	96	70.0	2.5	109	0.71
43.9	84	73.0	2.1	124	0.57
44.0	67	74.7	1.85	141	0.45
45.0	52	76.3	1.68	154	0.38
45.5	47	77.5	1.59	159	0.37
50.0	26	78.0	1.36	166	0.35
51.2	20	80.0	1.31	178	0.32
53.2	17.0	81.0	1.25	190	0.30
54.0	14.6	86.0	1.14	203	0.27
56.5	11.9	91.0	1.00	223	0.26
56.7	11.6	94.0	0.91	239	0.24
58.0	10.6	97.0	0.86	269	0.23
60.5	8.3	99.0	0.84	293	0.21

The magnetization curves at 4.2°K for the direction of c–axis and that perpendicular to it were taken by means of a magnetic balance, and the results are shown in Fig. 7. As it shows, c–axis is the direction of easy magnetization and the technical saturation is reached by the field strength of 4 koe. The saturation value at 4.2°K is estimated to be 58 gauss/gr, which corresponds to 270 gauss/cc. The dotted curve in Fig. 7 shows the average value of magnetizations for the directions of easy and difficult magnetization, which agrees very well with that of the powder specimen reported by Hansen(3).

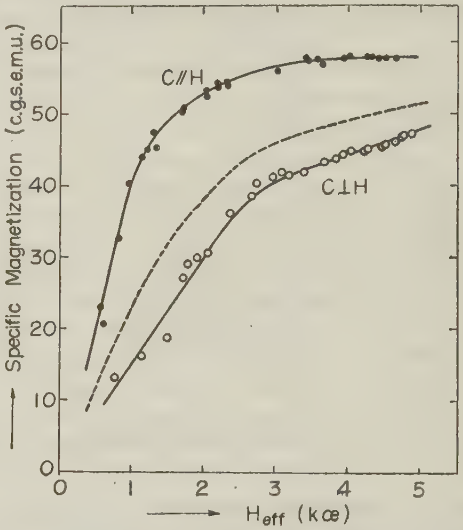

Fig. 7. Magnetization curves parallel to a–axis and c–axis.

§ 3. Discussions of the Results

A lot of hexagonal halides of the elements of the iron group show metamagnetic properties, whereas, the present compound is considered to be ferromagnetic since this compound does not show any antiferromagnetic behaviors for low magnetic field strength. Also the Curie-Weiss law holds above the critical point and the paramagnetic Curie temperature is higher than the ferromagnetic Curie point.

From the results of the magnetization curves of single crystals and of the torque measurement, it is concluded that the direction of easy magnetization lies along c–axis of the crystal. The saturation moment in c–direction at 4.2°K would be supposed to be about 3 μ_B from the results obtained. On the other hand, from the susceptibility measurement above the Curie temperature, we determined that the spin quantum number is 3/2. These values agree well with the spin magnetic moment of Cr^{3+} ion.

Paths of superexchange interaction in the present compound may be classified into those in the c-plane as well as along the c-direction. The crystal structure of $CrBr_3$ is shown in Fig. 8, and the path of the interaction in the c-plane is A—O—B which passes through one intermediate anion, while the other along the c-direction is C—O′—O″—D which passes through two intermediate anions. All other kinds of paths are considered to have a negligible contribution to the net interaction since overlapping of the charge clouds of ions in these paths is not expectable to be large from the view point of the ionic radii of Cr^{3+} and Br^-. The angle of A—O—B linkage is calculated to be about 89°. Kanamori(5) suggested that if the cations are Cr^{3+} and the angle of the linkage, 90°, the sign of superexchange interaction is ferromagnetic. Hence, the interaction along the c-directions is considered to be also ferromagnetic.

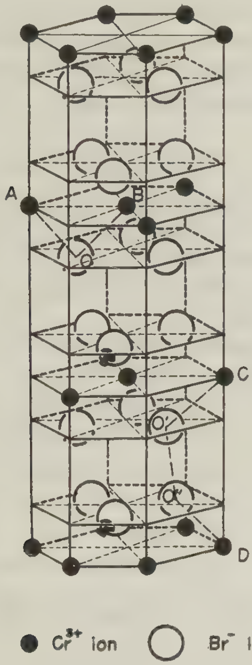

Fig. 8. Crystal sturcture of $CrBr_3$.

Next the behavior of the torque curve is discussed. In the strong field range, the maximum of the torque curve shown in Fig. 4 reaches a saturation value; Based on the uniaxial anisotropy energy,

$$U=K\cos^2\theta,$$

(K represents the anisotropy constant) and from the saturation value of torque maximum, K is estimated to be -4.8×10^5 erg/cc. In this case the dependence of the position of torque maximum, $\theta_m=\pi/4+\varDelta$, on the magnetic field strength is given by

$$\sin(2\varDelta)=\left[\sqrt{1+32\,(K/HI_s)^2}-1\right]\Big/(8K/HI_s)$$

neglecting the higher order terms in K/HI_s[*], where H is the magnetic field strength and I_s, the value of the saturation magnetization. Putting the obtained values of K and I_s mentioned above into the equation, the value of $\varDelta$ is obtained as shown by the dotted curve (i) in Fig. 5. As it shows, discrepancy of the order of a few degrees exists between theoretical and experimental results. Such a difference may be due to the higher order term of the anisotropy energy. Introducing a higher order term of the anisotropy energy

$$U=K_1\cos^2\theta+K_2\cos^4\theta,$$

the saturation value of maximum torque is expressed by

$$L_{max}=-(K_1+K_2),$$

at sufficiently strong field strengths. On the other hand, the position θ_m of maximum torque is given by

$$\theta_m=\pi/4+\varDelta+\varDelta',$$

$$\varDelta=K_2/(K_1+K_2),$$

$$\varDelta'=\frac{(A\cos 2\varDelta-4B\sin 4\varDelta)(A\cos 2\varDelta-\mathrm{B}\sin 4\varDelta)}{A\cos 2\varDelta-}$$

$$\frac{-(A\sin 2\varDelta+2B\cos 4\varDelta)^2}{4B\sin 4\varDelta}\cdot\frac{1}{HI_s}$$

with $A=-(K_1+K_2)$ and $B=-\frac{K_2}{2}$. The fittest curve (ii) shown in Fig. 5 has been obtained by choosing the values

$$K_1=-5.08\times10^5 \text{ and } K_2=0.65\times10^5 \text{ erg/cc.}$$

On the other hand, as the field strength decreases, the torque curve takes again a sinusoidal form as expressed by

$$L=A\sin 2\theta,$$

where A is a canstant. Such a fact is qualitatively explained by the fact that the magnetic moment of the specimen I lies along easy direction of magnetization by the application of very weak fields and is also proportional to the effective field strength in the direction: The magnetization in c-direction is expressed to be

$$I(H)\backsim H\cos\theta.$$

---

[*] The value of K/HI_s takes a value 0.18 at $H=10$ koe.

The torque value is expressed by

$$L = IH \sin\theta .$$

Eliminating I, from the above equations the following expression for L is obtained

$$L \backsim H^2 \sin 2\theta .$$

Hence in this case the torque curve approaches to a sinudoidal form, as is observed by the field strength of 2.4 koe.

The anisotropy constant is also calculable from the area between the magnetization curves along the direction of easy and difficult magnetization. Extrapolating the magnetization curves of the a-direction, we can evaluate the anisotropy constant to be about -5×10^5 erg/cc which agrees closely with the value K_1 estimated from the torque curve.

The anisotropy constant calculated basing on the dipole-dipole interaction is 3.66×10^5 erg/cc, which has the opposite sign as compared with the experimental value. Such discrepancy will be solved by considering the interaction energy between the spin and the orbital moment of chromium ion under the influence of bromine ions, especially that of the polarized bromine ions in the crystal lattice of this compound. A detailed calculation by Dr. Yamada of this Institute is now in progress.

Acknowledgements

The author wishes to express his cordial thanks to Professors T. Hirone and H. Watanabe for their encouragement and useful discussions. Also he wishes to express his hearty thanks to Drs. S. Maeda and N. Tsuya for their valuable discussions.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 15, No. 9, SEPTEMBER, 1960

The Three-Level Gas Maser as a Microwave Spectrometer

By Tatsuo YAJIMA and Koichi SHIMODA

Department of Physics, Faculty of Science,
University of Tokyo, Tokyo

(Received June 4, 1960)

A method of microwave spectroscopy using three-level maser action is described, and some preliminary experiment on HDCO is given. A b-type transition, $3_{03}\leftarrow2_{12}$, which is connected with a a-type transition $2_{11}\leftarrow2_{12}$, has been definitely assigned by the observation of three-level maser action. Moreover, the weak transition, $3_{03}\leftarrow2_{12}$, was observed with very good signal to noise ratio by using the strong transition, $2_{11}\leftarrow2_{12}$, as a detecting transition. Theories of the three-level maser action in gases are also compared with experiment and shown to be in good agreement. Further applications of the three-level gas maser as a spectrometer as well as an amplifier are discussed.

§ 1. Introduction

The principle of the three-level maser was first proposed for a gas system by Bassov and Prokhorov in 1955¹⁾. The successful operation of the three-level maser was performed using paramagnetic crystals²⁾ at liquid helium temperature following the proposal by Bloembergen³⁾. One of the authors employed a three-level gas maser as a spectrometer to observe a direct l-type doubling transition of OCS at 12.78 Mc[4].

The three-level gas maser amplifier has the following advantages over the solid state maser. The gas maser is operated at room temperature or at dry-ice temperature rather than at liquid helium temperature. The maser material of gas may be filled in a sealed-off waveguide cell, without using a vacuum pump or a liquid nitrogen trap as in beam-type masers. The band-width of a gas maser is variable in a wide range from some ten kilocycles to more than 10 Mc simply by changing the pressure of the working gas, although larger pumping power is required as the band-width increases. Another feature of the gas maser is its feasibility for shorter waves than conventional microwaves, while the paramagnetic solid state maser will find it difficult to apply to higher frequencies, (say above 100 Gc). Because the traveling wave type gas maser employs a simple waveguide structure, it is more favorable for millimeter waves than the solid state traveling wave maser which employs an intricated structure. The noise temperature of the gas maser should generally be larger than that of the solid state maser but considerably lower than the room temperature, even though the temperature of the gas is high.

On the other hand, operation of the three-level maser as an amplifier or an oscillator becomes difficult at lower frequencies, because the absorption coefficient of spectral lines decreases in proportion to the square of the transition frequency. At higher frequencies, however, sufficient pumping power is not easily available. Therefore, the three-level gas maser has not yet been tested as an amplifier at the present stage.

However, besides the use as an amplifier or an oscillator, the three-level gas maser has some spectroscopic applications as mentioned before. As a microwave spectrometer, it has following advantages. First, the three-level gas maser can be used in obtaining concrete assignment of transitions in a complicated microwave spectrum. Secondly, a weak transition can be detected with much improved sensitivity by using the three-level maser action, if another strong transition which involves one common energy level with the former one is used as a detecting transition.

This paper describes a microwave double resonance experiment on HDCO molecule to demonstrate the behavior described above, including a study on the three-level maser action itself inherent in the gas system.

§ 2. Sensitivity of the Three-level Microwave Spectrometer

Suppose that a molecule has three energy levels as shown in Fig. 1. Two transitions, (1↔3) and (2↔3), are allowed and their frequencies are written as ν_p and ν_s, respectively. The three-level maser action may be considered as the change in intensity of one transition (2↔3) due to a relatively strong radiation corresponding to the other transition (1↔3). The transitions (1↔3) and (2↔3) are called the pumping transition and the signal transition respectively.

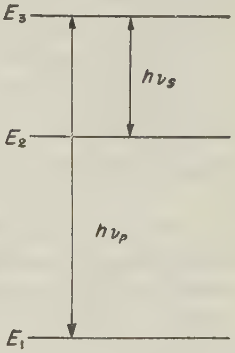

Fig. 1. A three-level system.

A semi-classical explanation of the three-level maser action based on a change in population difference alone is well known. The relaxation times between various levels may be asumed to be equal in a gaseous state, and $h\nu_p$, $h\nu_s \ll kT$ where T is the temperature of the gas. Then, the relative change of absorption coefficient at the center of the transition (2↔3) due to the pumping radiation of frequency ν_p can be derived from Eq. (6) in reference (5). The absorption coefficient α_s* of the transition (2↔3) under pumping radiation is expressed in the form

$$\frac{\alpha_s}{\alpha_{s0}}=\frac{1+2w(2-r)}{1+4w} \tag{1}$$

$$r=\nu_p/\nu_s$$

$$w=\frac{2\pi|\mu_p|^2P_0}{3v_gh^2(\Delta\nu)^2S}$$

---

* For the net induced emission of power, α_s is negative.

where α_{s0} is the absorption coefficient without pumping, w the usual saturation parameter for the plane polarized wave, P_0 the pumping power, μ_p the dipole matrix element for the transition $(1\leftrightarrow 3)$, $\Delta\nu$ the half half-width of the line, v_g the group velocity of the pumping radiation in the waveguide, and S the cross-sectional area of the waveguide.

The semi-classical theory gives a good approximation for most solid state masers, unless pumping power is not very large, because $T_1 \gg T_2$ holds usually, where T_1 and T_2 are the longitudinal and transverse relaxation times respectively. However, in the case of a gas system where the relaxation occurs through molecular collisions $(T_1 \approx T_2)$, the semi-classical treatment may not be correct. The quantum mechanical treatment of the three-level maser has already been given by A. Javan[5] and A. M. Clogston[6]. The ratio of the gas absorption coefficient with and without pumping can also be derived from Eq. (21) in reference (5).

$$\frac{\alpha_s}{\alpha_{s0}}=\frac{1+w(4-3r)}{(1+4w)\,(1+w)} \tag{2}$$

Eqs. (1) and (2) will be compared with experimental results in the next section. Notice that in some cases Eq. (1) gives larger values than Eq. (2), and vice versa in other cases.

Now, let us consider the sensitivity of a three-level gas maser for spectroscopic purposes. When $\nu_p \gg \nu_s$, saturation between states 1 and 3 by a strong radiation results in an enormous increase in the population difference between states 2 and 3, and hence the absolute value of absorption coefficient at the signal frequency increases in a large amount. A semi-classical treatment of the sensitivity of this type of three-level spectrometer and an experimental study on OCS has already been reported[4]. A quantum-mechanical evaluation for the case when $\nu_p=24{,}355.50$ Mc and $\nu_s=12.78$ Mc, at the pumping power level of $w=\frac{1}{2}$* gives

$$|\alpha_s|/\alpha_{s0}=630$$

An increase of sensitivity by such a large factor enables one to observe low frequency transition of the molecule.

Next, let us consider a case when both ν_p and ν_s are in the microwave frequency range. Then the ratio ν_p/ν_s is not very large so that the method described above is not effective. For example, taking values of $\nu_p/\nu_s=10$ and $w=\frac{1}{2}$, we have only

$$|\alpha_s|/\alpha_{s0}=2.7$$

However, there is another method of using the three-level maser as a sensitive spectrometer. Consider a case when the transition probability between states 1 and 3 is much smaller than that between states 2 and 3. Accordingly the absorption coefficient of the gas in its thermal equilibrium at the frequency ν_p is much smaller than that at the signal frequency ν_s. A change in absorption coefficient of the strong transition $(2\leftrightarrow 3)$ caused by the weak pumping transition $(1\leftrightarrow 3)$ may be observed in order to detect the weak transition $(1\leftrightarrow 3)$. The increase of sensitivity which is obtained by this method is calculated as follows.

The change in absorption coefficient, $|\Delta\alpha_s| = |\alpha_s-\alpha_{s0}|$, is assumed to be observed by a usual waveguide-type spectrometer. The signal to noise ratio of a spectral line with the absorption coefficient α is proportional to $\alpha\sqrt{P}$, were P is the microwave power. The signal to noise ratio increases with the input power P, but the saturation effect and the increase of detector noise put a limit for input power. Then the maximum available signal to noise ratio of the line turns out to be proportional to approximately $\alpha^{1\cdot 0\sim 0\cdot 5}$.

Therefore, a direct observation of the transition $(1\leftrightarrow 3)$ may be assumed to exhibit the signal to noise ratio proportional to the absorption coefficient in thermal equilibrium, α_{p0}, while the change of absorption at the frequency ν_s can be observed with the signal to noise ratio proportional to $|\Delta\alpha_s|$, if the sensitivity of the spectrometer is the same at the frequencies ν_p and ν_s. For the case of interest when $\alpha_{p0} \ll \alpha_{s0}$, the increase of the signal to noise ratio is quite large since $|\Delta\alpha_s|/\alpha_{p0} \gg 1$, so long as the sufficient power at the frequency ν_p is used. A measure of the increase of sensitivity is obtained from Eq. (2) as

$$\frac{|\Delta\alpha_s|}{\alpha_{p0}}=\frac{w(3r+1+4w)}{(1+4w)(1+w)}\,\frac{\alpha_{s0}}{\alpha_{p0}} \tag{3}$$

---

* This corresponds to $|y|^2\tau^2=\frac{1}{2}$ in ref. (5), and is an approximate condition for maximum power of net induced emission, when $\nu_p \gg \nu_s$

For example, when $w=\frac{1}{2}$, one obtains

$$\frac{|\Delta\alpha_s|}{\alpha_{p0}}=\frac{1+r}{3}\frac{\alpha_{s0}}{\alpha_{p0}}\gg 1$$

Because the microwave spectrometer is generally more sensitive at lower frequencies, the actual increase of sensitivity will be somewhat larger than the value given by Eq. (3).

It seems worth noticing that the sensitive detection of weak lines by such a method can also be applied for a case when $\nu_p < \nu_s$ or $r < 1$. Now the lower frequency transition is detected by the change in absorption of the higher frequency transition. It is quite obvious that the method described above is not restricted for the level system with $E_3 > E_2 > E_1$, but can be applied generally for any three-level systems if one weak transition is connected to another strong transition through a common level. Three-level systems, where the levels are $E_2 > E_3 > E_1$, $E_1 > E_2 > E_3$ and in other cases, are essentially the same as that described above.

The three-level maser detector for ultra-microwaves proposed by one of the authors[7] is also closely related to the present case. However, the three-level maser spectrometer of this type differs from the three-level maser detector, since the former is intended to detect weak absorption using a large power at the frequency ν_p, while the latter is to detect a small power using the strong absorption at the pumping frequency.

§ 3. Experimental Results on HDCO

A number of three-level systems can be found in the energy levels of molecules. A three-level gas maser of formaldehyde-d_1, HDCO, was experimentally investigated for spectroscopic purposes. The microwave spectrum of HDCO has been studied in our laboratory[8),9)] and a fairly complete report by T. Oka will be published in near future. Since the molecular axis of HDCO differs from the inertia axis by some angle, the component of electric dipole moment along the b-axis enables one to observe b-type transition which are absent in H_2CO and D_2CO. In order to use the b-type transition for the study of molecular structure a search for a b-type transition, $3_{03} \leftarrow 2_{12}$, was carried out, but resulted in a doubtful assignment because the molecular constants determined from a-type transitions were not accurate enough to discriminate spectral lines of other rotational states or those due to impurities. This R^b-type transition, $3_{03} \leftarrow 2_{12}$, constitute a three-level system with a strong Q^a-type transition, $2_{11} \leftarrow 2_{12}$, as shown in Fig. 3. Therefore a definitive assigning of the R^b-type transition was intended by the effect of its pumping action on the Q^a-type transition, $2_{11} \leftarrow 2_{12}$. Another purpose of the experiment on this level system was to investigate the sensitivity consideration of the three-level spectrometer as described in § 2. There is a large difference of absorption coefficient between two allowed transitions, since the component of dipole moment on the b-axis is much smaller than that on the a-axis. Namely, by using the strong transition, $2_{11} \leftarrow 2_{12}$, as a detecting transition, the weak transition, $3_{03} \leftarrow 2_{12}$, was expected to be observed with better signal to noise ratio.

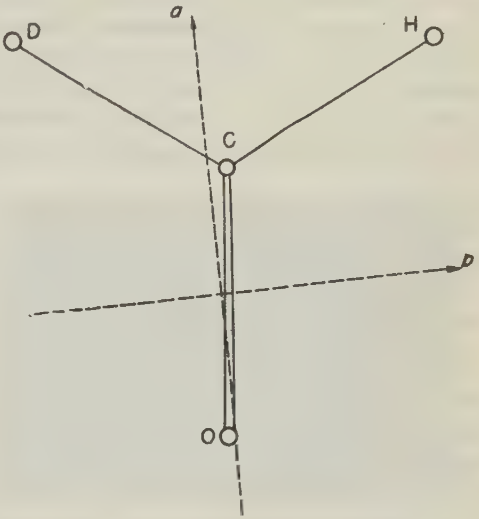

Fig. 2. Molecular structure of HDCO. a and b represent the principal axes of inertia.

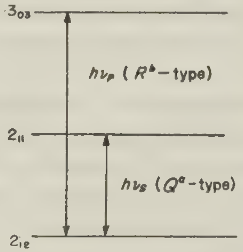

Fig. 3. A three-level energy diagram of HDCO

The frequencies, the components of electric dipole moment, the squares of the dipole matrix elements, and the calculated absorption coefficients in thermal equilibrium at room temperature of the two transitions, $3_{03}\leftarrow 2_{12}$ and $2_{11}\leftarrow 2_{12}$, are listed in Table I.

Table I. A set of three-level transitions in HDCO

	pumping	signal
transition	$3_{03}\leftarrow 2_{12}$	$2_{11}\leftarrow 2_{12}$
frequency (Mc)	34916.4	16038.06
component of the dipole moment (Debye)	$\mu_b=0.21$	$\mu_a=2.30$
square of the dipole matrix element (Debye²)	0.0095	0.88
absorption coefficient* (cm⁻¹)	1.9×10^{-6}	3.7×10^{-5}

* calculated under the assumptions of $\Delta\nu=10$ Mc/mmHg and 100% purity.

From the values in Table I the expected increase of sensitivity, $|\Delta\alpha_s|/\alpha_{p0}$, in observing the transition, $3_{03}\leftarrow 2_{12}$, was calculated as a function of P_0 and $\Delta\nu$ as shown in Fig. 4. It may be seen from the figure that one can easily obtain a large increase of sensitivity by the use of the pumping power of the order of several ten milliwatts which is easily attainable by a commercially available klystron.

Fig. 5 shows a block diagram of the experimental setup of a three-level spectrometer. The absorption cell is made of a K-band waveguide of 1 meter length, with the cross section of 10.7 mm×4.3 mm I.D., in which the usual Stark electrode is inserted. In order to increase the pumping effect, it is preferable to use the waveguide of smaller cross-sectional area, as long as the signal frequency is above the cut-off frequency of the waveguide.

Gaseous sample was obtained by heating powdered paraformaldehyde-d_1 of about 90% purity. The gas pressure must be low to reduce the line-width so as to increase the pumping effect. But the line-width is limited by the broadening due to the wall collision

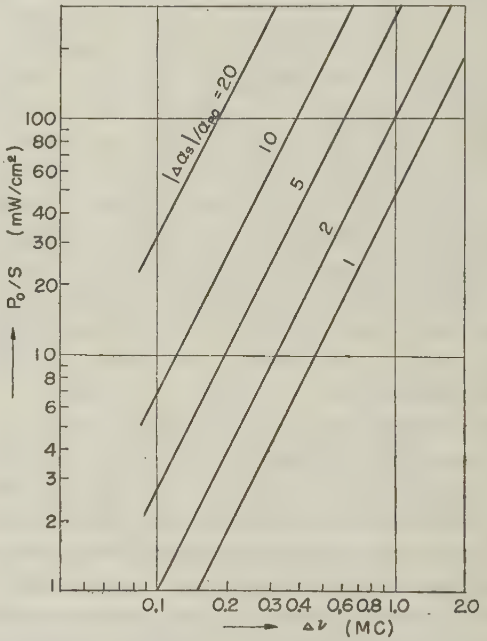

Fig. 4. Calculated increase of sensitivity, $|\Delta\alpha_s|/\alpha_{p0}$, as a function of line-width, $\Delta\nu$, and pumping power, P_0/S, in observing the transition $3_{03}\leftarrow 2_{12}$ of HDCO by the three-level maser technique.

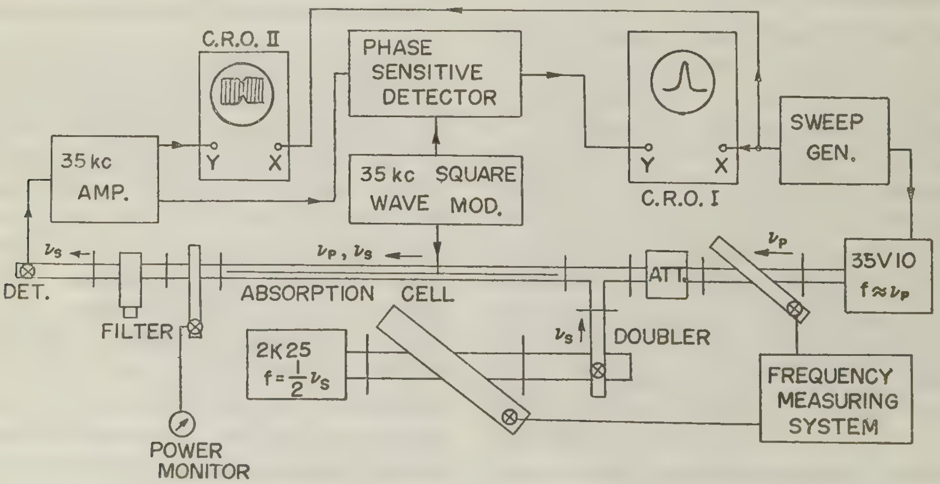

Fig. 5. Block diagram of the three-level microwave spectrometer.

and the Doppler effect which are calculated as 19 kc for the cell used and 39 kc for the frequency, 35 Gc, respectively.

The signal power was supplied by a crystal doubler driven by a 2K25 klystron, and the strong pumping power was delivered by a 35V10 milimeter-wave klystron. In order to prevent the pumping power from entering the detector, a filter made of a rectangular cavity with $Q \approx 800$ is placed between the cell and the detector. The pumping power is monitored by a crystal detector in an auxiliary waveguide.

The three-level maser action can be observed by two methods. For one case, the signal frequency is fixed and the pumping frequency is swept; and for the other case, the signal frequency is swept. For the spectroscopic purpose to detect the pumping transition, the former method is appropriate. The experimental study was carried out in this case. A square-wave Stark modulation at a frequency of 35 kc was employed to observe the change of absorption at the signal frequency due to pumping. The signal frequency was fixed at the center of the line, ν_s, by monitoring a maximum amplitude of the 35 kc amplifier output on the screen of C.R.O.–II. An automatic frequency control of the signal frequency might be desirable, but it was not necessary for a short time observation.

Now, the three-level maser action was observed, when the pumping frequency was swept in a certain range including the correct frequency of the transition, $3_{03} \leftarrow 2_{12}$. This was explicitly displayed on the screen of C.R.O.–II as shown in Fig. 6, where the horizontal axis represents the change of pumping frequency. The dip in the figure which indicates the decrease of absorption coefficient at the center of the signal transition, $2_{11} \leftarrow 2_{12}$, occurs at the expected frequency of 34916.4 Mc. Thus the *b*-type transition, $3_{03} \leftarrow 2_{12}$, has been definitely assigned. The dip increased, of course, with decreasing linewidth and with increasing pumping power. About 80% decrease of the absorption coefficient could be obserbed with the pumping power of 60 milliwatts. With more power, one might observe the induced emission.

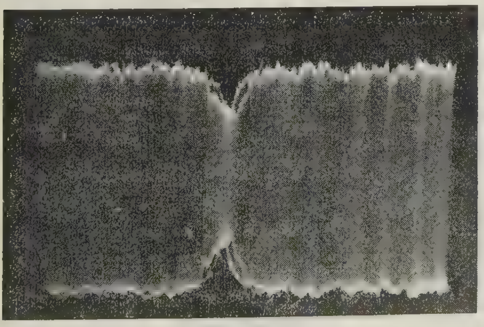

Fig. 6. Three-level maser action in HDCO displayed on an oscilloscope screen. The ordinate shows absorption intensity at the center of the transtion $2_{11} \leftarrow 2_{12}$, and the abscissa represents the change of pumping frequency including the transition frequency of $3_{03} \leftarrow 2_{12}$.

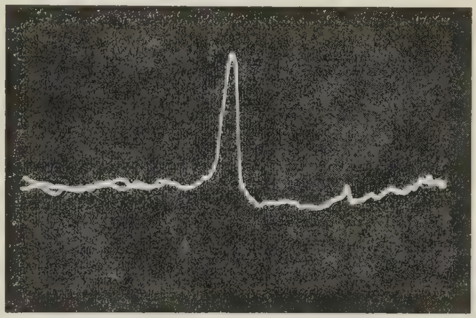

Fig. 7. Spectral line of the pumping transition, $3_{03} \leftarrow 2_{12}$, of HDCO detected by the change of the signal transition, $2_{11} \leftarrow 2_{12}$.

After a phase sensitive detector with a low pass filter, a spectral line was obtained with a very good signal to noise ratio on the screen of C.R.O.–I as shown in Fig. 7. This is the pumping transition, $3_{03} \leftarrow 2_{12}$, detected by the absorption change of the signal transition, $2_{11} \leftarrow 2_{12}$. The signal to noise ratio of the $3_{03} \leftarrow 2_{12}$ line obtained by this method was found to be better by about 10 times than that observed directly in the same absorption cell with a conventional method. This is considered as a verification of the sensitivity of the three-level spectrometer.

The three-level maser action was also observed by the other method with the fixed pumping frequency and the swept signal frequency. However, the stable measurement was difficult because of the frequency instability of the klystron at the pumping frequency.

Now, the theoretical formulae (1) and (2) can be compared with experimental results by plotting α_s/α_{s0} versus P_0 or $\Delta\nu$. The experimental values α_s/α_{s0} can be obtained immediately from Fig. 6, and shown in Fig. 8. The line-width, $\Delta\nu$, was varied by changing the gas pressure and the pumping power, P_0, was constant to nearly 60 milliwatts. Theoretical curves were calculated for the power and $v_g = 0.84\,c$. The agreement between the quantum mechanical theory and the experiment seems to be good within the experimental accuracy. It is noted that the curve of the semi-classical theory deviates considerably from the observed values.

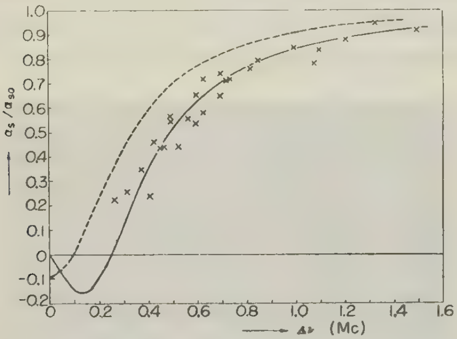

Fig. 8. Relative change of absorption coefficient at the center of transition $2_{11} \leftarrow {}_{12}$ by the pumping of transition $3_{03} \leftarrow 2_{12}$ in HDCO.

× observed point for $P_0 = 60$ mW

§ 4. Concluding Remarks

The application of three-level maser technique to microwave spectroscopy was discussed and a successful experiment on HDCO molecule was described. There are many three-level systems of molecules for which the present technique can be applied, because for spectroscopic purposes the method is not restricted to the level scheme of Fig. 1 as mentioned before. For the cases of more complicated spectra where the hyperfine structure and the effect of internal motions are present, or the isotopically substituted molecules and some unknown impurities are present among the molecules under study, the method described here may also be applied effectively in identifying some paticular lines.

To use the three-level system of gas as an amplifier, the required conditions are, of course, much more severe. A K-type doubling transition of an asymmetric top molecule may be used at the signal and a transition of $\Delta J = \pm 1$ as pumping for that purpose. Several examples which are estimated to exhibit a relatively intense induced emission power with the pumping frequency of below 100 Gc are listed in Table II.

Further investigation on the quantum mechanical behavior of the three-level maser needs stronger pumping. Experimental studies on three-level systems of other molecules are in progress.

Table II. Three-level systems in which appreciable net induced emission is expected.

	(1)	(2)	(3)	(4)	(5)
molecule	HDS	HDO	HDCO	HDCO	HDCO
pumping	$2_{2,0} \leftarrow 3_{0,3}$	$4_{3,1} \leftarrow 5_{2,4}$	$3_{0,3} \leftarrow 2_{1,2}$	$7_{1,6} \leftarrow 6_{2,5}$	$12_{2,10} \leftarrow 11_{3,9}$
signal	$2_{2,0} \rightarrow 2_{2,1}$	$4_{3,1} \rightarrow 4_{3,2}$	$2_{1,1} \rightarrow 2_{1,2}$	$6_{2,4} \rightarrow 6_{2,5}$	$11_{3,8} \rightarrow 11_{3,9}$
ν_p* (Mc)	28.8×10^3	62.4×10^3	34916.4	25.6×10^3	27.1×10^3
ν_S (Mc)	11283.83	5702.78	16038.06	8922.6	5702.6
$-\alpha_{s,\max.}$ (mW/cm^2)	4.6×10^{-6}	1.4×10^{-5}	6.0×10^{-6}	4.5×10^{-6}	3.5×10^{-6}
$P_{0,\mathrm{opt.}}$ (mW/cm^2)	980	4.6	87	140	120

* The values of ν_p have not been measured excepting the case of (3).

$-\alpha_{s,\max}$ is the maximum intensity of net induced emission expressed as negative absorption coefficient at room temperature; and $P_{O,\mathrm{opt}}$ is the optimum pumping power of the plane wave per unit area giving maximum net induced emission when the line-width $\Delta\nu$ is 100 kc.

The authors are indebted to Mr. T. Oka for his helpful discussions and informations on the microwave spectrum of HDCO.

Monte Carlo Calculations of Motion of Electrons in Helium

By Tomizo ITOH and Toshimitsu MUSHA
Electrical Communication Laboratory, Musashino-shi, Tokyo

Monte Carlo calculations are performed with an electronic computor to investigate the behavior of electrons in helium gas in a uniform electric field. The ionization and excitation coefficients and the drift velocities of electrons in helium for $E/p_0=40$, 80 and 160 v/cm/mmHg are obtained. The velocity distributions of electrons are also calculated.

§ 1. Introduction

For an investigation of an electrical discharge in a gas, it is important to know the behavior of electrons in an electric field. The fundamental quantities such as ionization and excitation coefficients and the velocity distribution of electrons were calculated approximately by other workers only when an electric field is uniform and/or weak[1)2)3)]. The present work is performed in the hope to offer a new method of calculation applicable to the case of strong and/or non-uniform electric fields which often appear in actual discharges in gases.

The essential feature of the gas discharge phenomena consists in the motion of charged particles and the mutual interaction among the particles, i.e., electrons, ions, and neutral molecules. When the charged-particle density is very low compared with that of the gas molecules, only two-body collisions between an electron and a neutral molecule become important. In such a case, if we take one electron in the gas and trace its orbit with an electronic computing machine considering the influence of an electric field and electron-molecule collisions, information on the fundamental quantities of the discharges may be obtained.

In this paper a Monte Carlo method is presented for calculating the motion of electrons in a static uniform electric field; and its application to helium is described.

§ 2. Method of the Calculation

In a uniform electric field E an electron moves on a parabolic orbit until it collides with a gas molecule. The kinetic energy which the electron gains in the electric field is lost in collisions. In the case of large E/p_0 (p_0 is the gas pressure at 0°C), the rate of energy lost in elastic collisions is negligible compared with that in inelastic ones[4)]. We assume, therefore, that in an elastic collision an electron is scattered by a gas molecule with its kinetic energy unchanged. On the other hand, when it excites or ionizes a gas molecule in a collision it loses a certain amount of energy corresponding to the excitation or the ionization potential of the gas molecule respectively, changing its direction of motion. In the latter case another electron is deprived of the gas molecule and a part of the energy of the primary electron is shared with the secondary one. After the ionizing collision either of two electrons may be trace thereafter. Consequently we select one arbitrarily here.

As to the angle of scattering, it is assumed to distribute isotropically in any kind of collision. This assumption has to be introduced from the memory capacity of our computing machine.

2.1 *Decision of the Collision Occurrence*

In a Monte Carlo calculation dealing with a problem of neutron passage in a medium, a free path length of a neutron is determined by a simple exponential law with a random number since the particle does not change its kinetic energy in the flight. Regarding an electron accelerated in an electric field, however, another method must be employed to decide a collision occurrence because the collision cross section of a gas molecule for an electron varies with the electron energy. The method adopted here is as follows:

The probability P that an electron collides with gas molecule in the small distance dx along its path is expressed as

$$P=dx/\lambda, \tag{1}$$

where λ is the mean free path of the electron dependent on the electron energy. Suppose that the orbit of an electron in an electric field is divided into small sections, then the probability that the electron collides with gas molecules in each section can be calculated from λ. On the contrary when the probability has been given previously the length of each section l is computed from Eq. (1) provided $p \ll 1$. The smaller l is, the longer the calculation time becomes while we have better approximation. Hence we give the probability 0.1 to each section so that $l=0.1\lambda$ in approximation. The mean free path λ of an electron in helium at 0°C and 1 mmHg is calculated for any electron energy from the formula which is a good approximation to the observed values[5]. In every section, whether the electron collides or not is decided by a pseudo-random number q provided by a subroutine (taking the middle part of the square of the preceding random number) stored in our computing machine. Since q takes a value between 0 and 1 arbitrarily the probability that q falls on the interval from 0 to 0.1 is equal to the collision probability of the electron in each section. Consequently when q falls between 0 and 0.1 the electron is judged to collide with a gas molecule in the section. If a collision does not occur after such a decision, the length of the next section is calculated, and a decision of collision occurrence will be given again. The procedure described above is repeated unitil a collision occurs.

2.2 *Calculation of Particle Parameters*

The coordinate axis z being set antiparallel to the electric field, the state of the motion of an electron is specified by its speed V, the direction cosine $\cos\theta$, where θ is the angle made by the line of flight with the z axis, and the time t. If an electron is in a state (V, $\cos\theta$, z, t) it will take, after a flight along the orbit by a length l, a new state (V', $\cos\theta'$, $z+\Delta z$, $t+\Delta t$). These parameters are connected by the following relations:

$$V'\sin\theta'=V\sin\theta \tag{2}$$

$$mV'\cos\theta'=mV\cos\theta+eE\Delta t \tag{3}$$

$$\frac{1}{2}mV'^2=\frac{1}{2}mV^2+eE\Delta z \tag{4}$$

where m and $-e$ are the mass and the electric charge of the electron, respectively; Δz is the projection of l on the z axis. The exact expression of Δz as a function of l is complicated containing terms of a logarithm and square roots. The calculation of such terms with the computing machine requires relatively long time and, moreover, Δz must be calculated in each small section, so that it is suitable to be expressed approximately as (see Fig. 1)

$$\Delta z=l\cos\theta. \tag{5}$$

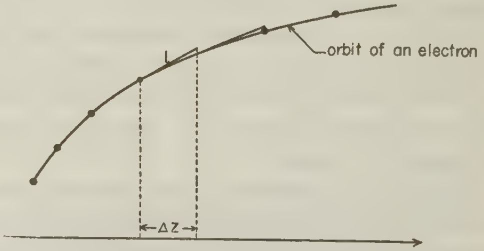

Fig. 1. Illustration of the tangential approximation. The length l of the electron flight is measured on a tangent at each dividing point of the orbit of an electron.

2.3 *Decision of the Kind of Collisions*

Whenever a collision occurs the kind of collision has to be decided. In the present work for helium the electron-atom collisions are classified in four kinds, i.e., that of electric, ionizing, exciting to the metastable state 2^3S_1, and exciting to the other levels. The three kinds of inelastic-collision probabilities P per 1 cm of the electron flight are calculated for

Table I. Values of the constants in eq. (5) for three kinds of inelastic collisions.

Kind of collisions	A (ev^2)	B (eV·cm)$^{-1}$	C (cm^{-1})	ε_0 (ev)
Excit. to the 2^3S_1 level	2.50×10^{-1}	1.09×10^{-1}	3.11×10^{-2}	19.8
Excit. to the other levels	1.85×10^{3}	6.88×10^{1}	0	19.0
Ionization	4.90×10^{3}	1.72×10^{2}	0	24.46

any electron energy ε according to the formulas which approximate the experimental results[6] up to the electron energy of 100 eV. These formulas are expressed in the form

$$P=\frac{B(\varepsilon-\varepsilon_0)}{A+(\varepsilon-\varepsilon_0)^2}+C \tag{6}$$

where A, B, C and ε_0 are constants dependent on the kind of collision. Table I lists these constants for helium. In Fig. 2 the experimental data and the values calculated from Eq. (6) for the ionizing collision are shown.

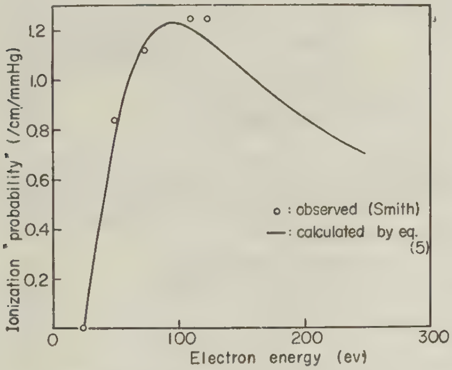

Fig. 2. Ionization "probability" of electrons in helium.

Table II. Excited levels of the helium atom with relatively large excitation cross sections.

State	Excitation energy (ev)
2^1S_0	20.6
2^3P_1	20.9
2^1P_1	21.2
3^1P_1	23.1
Average	21.45

The values of energy loss of an electron in an exciting collision in helium are 19.8 ev to the metastable 2^3S_1 level and 21.4 ev to the other excitation levels; the latter is the average value over four levels which have relatively large cross sections (Table II). In an ionizing collision the energy loss is not definite since a part of the energy of the primary electron is shared with the secondary one. The energy distribution of electrons produced in ionizing collisions of 100 ev incident electrons with helium were measured by Goodrich[7] (Fig. 3). Such a distribution is assumed to hold in the other incident electron energy. Immediately after an ionizing collision the energy of an electron is determined by a random number submitting to such a distribution.

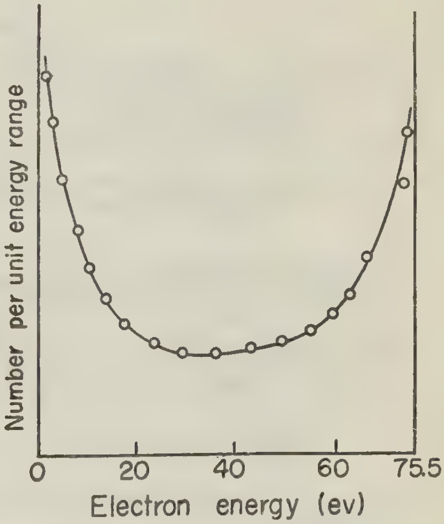

Fig. 3. Energy distribution of electrons produced in ionizing collisions of 100 volt electrons with helium as observed by Goodrich.

As previously stated when a random number q takes any value between 0 and 0.1 we consider that an electron collides with a gas molecule. If the electron energy is less than the lowest excitation energy (19.8 ev of the 2^3S_1 level) it must be an elastic collision. When the electron has enough energy to excite this level the excitation-collision probability P_{met} to this level in this small section l is calculated from Eq. (6) and compared with q. In case $q\leq P_{\text{met}}$ occurs an excitation to this level.

When $q>P_{\rm met}$ the excitation-collision probability $P_{\rm exc}$ to the other levels is to be calculated provided that the electron energy is more than 21.45 ev, and this kind of excitation is considered to occur for $q \leq P_{\rm net}+P_{\rm exc}$. Contrarily when the electron energy is less than 21.45 ev it must be an elastic collision. The similar process for ionization collision is repeated $q>P_{\rm met}+P_{\rm exc}$. If we have $q>P_{\rm met}+P_{\rm exc}+P_{\rm ion}$, where $P_{\rm ion}$ is the probability of ionizing collision in the section, this means an elastic collision (see Fig. 4).

Thus decided the kind of collision, the speed V'' and the direction cosine $\cos\theta''$ after the collision are computed from the angle of scattering and the loss of the electron energy. The scattering angle (and also the electron energy in case of an ionizing collision) is determined using another random number.

2.4 *Velocity Distribution of Electrons*

As mentioned above, the motion of an electron is traced throughout the calculations. This electron can be taken arbitrarily among the ensemble of electrons under the same physical conditions. The values of the velocity of one electron are sampled in every constant time interval τ in the process of calculation. As the whole system may be considered in stationary state, this sequence of samples would be taken as an ensemble and, the ergodicity of the random process in the system being assumed, this new ensemble is statistically equivalent to the original one. Based on such considerations the velocity distributions of electrons are obtained. Fig. 4 shows the flow chart of the calculations.

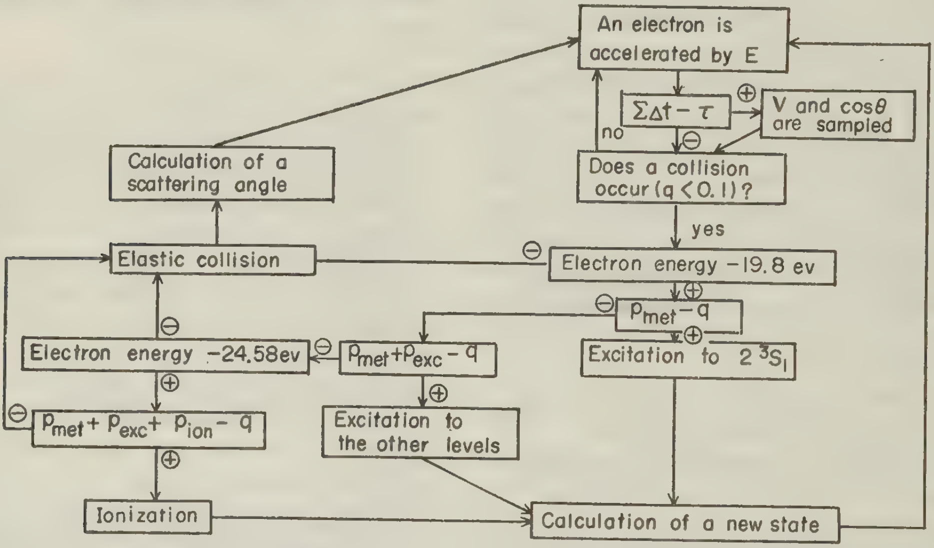

Fig. 4. Flow chart of the Monte Carlo calculation of the motion of an electron in an electric field.

§ 3. Results

As the calculation proceeds, the following data are punched out as the outputs of the computing machine.

(a) V and $\cos\theta$ sampled in the constant time interval τ.

(b) z and t at which an inelastic collision occurs with suitable marks to distinguish the kind of them.

Appropriate statistical treatments of data (a) yield the velocity distributions of electrons. The drift velocities, and the ionization and the excitation coefficients of electrons are derived from the data (b) in the following manner.

The plots of z versus t are on a nearly straight line whose slope z/t gives the drift velocity of an electron. The ionization coefficient α is defined as

$$\alpha = \lim_{z\to\infty} N_i(z)/z \tag{7}$$

where $N_i(z)$ is the number of ionization collisions that occur during the electron flight from $z=0$ to $z=z$. Calculated values of $N_i(z)/z$ versus z in the case of $E/p_0=80$ v/cm/mmHg are shown in Fig. 5. As seen in this figure values of $N_i(z)/z$ scatter widely for small z's, tending to converge to a certain value as z increases. In the present work we take as α a value of $N_i(z)/z$ at the largest z, whose deviation from the limiting value would be within few percents. The excitation coefficients are treated in the same way.

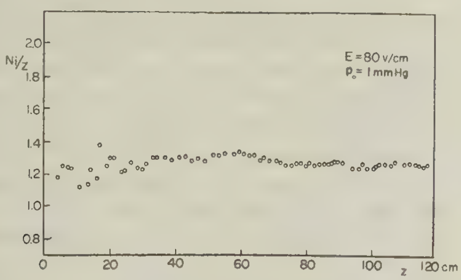

Fig. 5. The number of ionizations per *cm* averaged over the distance z of the electron drift.

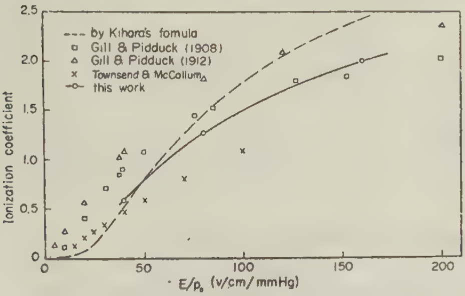

Fig. 6. Ionization coefficients of electrons in helium *vs*. E/p_0 with the observed and calculated values by other workers.

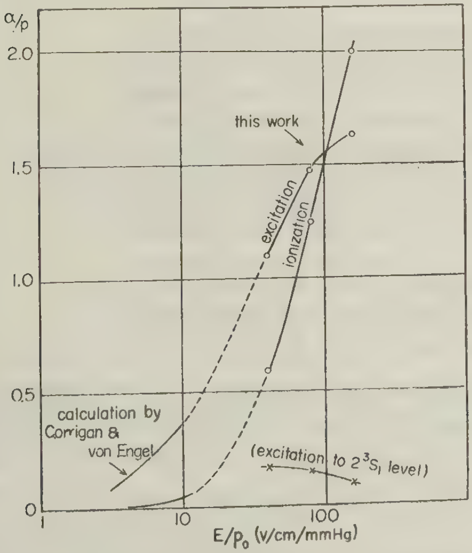

Fig. 7. Coefficients of ionization and excitation. The excitation coefficient to the 2^3S_1 metastable level is plotted separately, and the results calculated by Corrigan & von Engel for 10 of E/p_0 are also plotted which are connected with the results of this work by broken lines.

The ratios of α to the gas pressure p_0 are plotted against E/p_0 in Fig. 6. In this figure the experimental values by other workers[8] and calculated values from Kihara's[3] formula (9.5) are shown. In Fig 7 the coefficients of ionization and excitation to the metastable level 2^3S_1 and to the other levels are shown.

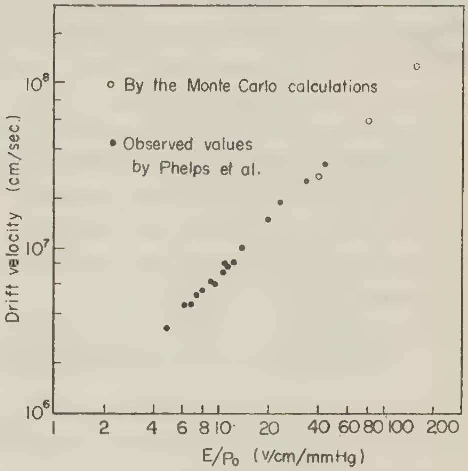

Fig. 8. Drift velocity of electrons in helium.

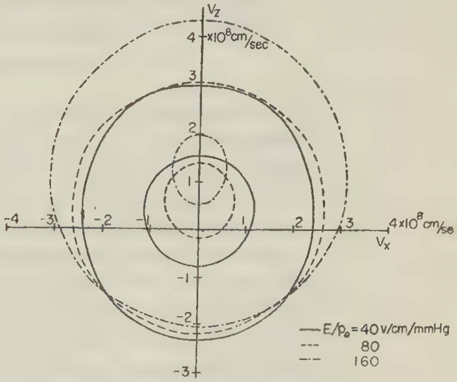

Fig. 9. Velocity distributions of electrons in helium. The inner contour denotes the density three times as much as that of the outer one.

For comparison the calculated values by Corrigan and von Engel[2] in the low E/p_0 region making use of the energy distributions of electrons calculated theoretically by Smit[9] are also illustrated in this figure. The excitation coefficient of helium in high E/p_0 has not yet been calculated or measured by other workers. The drift velocity of an electron in helium is plotted in Fig. 8 against E/p_0 together with the observed values by Phelps et al[10]. The drift velocity increases nearly proportionally to E/p_0. Fig. 9 is the velocity distributians of electrons each of which is compiled from about 15000 data.

We are deeply indebted to Dr. K. Takatsu for his kind advices and encouragements throughout this investigation. We also wish to thank Dr. Z. Kiyasu and Dr. T. Shindo for many fruitful discussions and suggestions, and to members of the electronic computor group in our laboratory for their technical assistances.

Ion Optics in Long, Multistage Accelerator Tubes

By Masateru SONODA, Akira KATASE, Masao SEKI and Yoshihisa WAKUTA

Department of Nuclear Engineering, Faculty of Engineering,
Kyushu University, Fukuoka

(Received May 23, 1960)

The recurrence formulae for the cardinal elements of a multistage accelerator tube are derived. The calculated results for an equidiameter cylinder lens obtained by the consecutive applications of the formulae are not so different from those obtained by assuming a uniform acceleration and still show the appreciable deviations from the experimental data. The errors would, therefore, become large, unless the experimental values are used for the cardinal elements of an individual accelerating lens on which the calculation for multistage accelerator tube is based. As an example, the cardinal elements for a 12-stage accelerator tube is shown The comparison with those obtained by the assumption of a uniform acceleration shows that the latter results are not satisfactorily accurate for such a multistage accelerator.

§ 1. Introduction

The rectilinear multistage accelerator made up of many cylindrical accelerating electrodes has been used frequently because of its simplicity of mechanical construction. The ion optics for this case has, however, been investigated, by assuming that the electric field in the accelerator is uniform,[1)2)] or by the consecutive multiplications of lens matrices.[3)] In the former method, the results deviate considerably from practice, if the appreciable lengths of field free spaces exist between the accelerating gaps, whereas the latter method is much cumbrous. To solve these difficulties, we have found the recurrence formulae for the cardinal elements of the accelerating system and have succeeded in obtaining the ion optical characteristics accurately and comparatively simply.

§ 2. Method of Calculation

It is assumed that the electric potential distribution in the accelerating system can be represented schematically as shown in Fig. 1. The potential in this case is taken relative to zero potential at zero ion kinetic energy (negative for positive ions).

We denote here as follows (see Fig. 2).

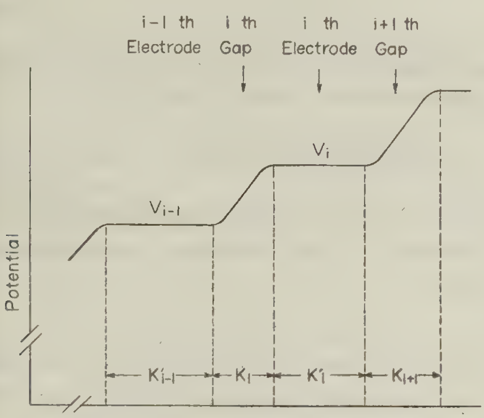

Fig. 1. Potential distribution in an accelerating system.

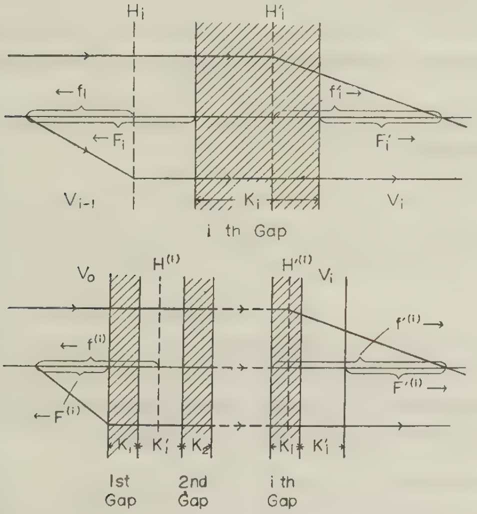

Fig. 2. Cardinal elements. H and H' are the principal plane in the source space side and image space side respectively. The shaded portions show the space where an electric field is applied.

K_i: the length of the i-th space where an electric field is applied,

K'_i: the length of the field free space between the i-th and $(i+1)$-th gaps,

V_i: the potential of the i-th electrode,

$N_i = V_i/V_{i-1}$: the ratio of potential of the i-th and $(i-1)$-th electrodes,

F_i, F'_i: the distance of the focal point of the i-th gap lens from the i-th gap field boundary in the source space side and image space side respectively,

f_i, f'_i: the focal length of the i-th gap lens in the source space side and image space side respectively,

$F^{(i)}$, $F'^{(i)}$: the distance of the focal point of the system composed of the first i gap lenses and i field free spaces, from the lens boundary in the source space side and image space side respectively,

$f^{(i)}$, $f'^{(i)}$: the focal length of the system composed of the first i gap lenses and i field free spaces, in the source space side and image space side respectively,

$\boldsymbol{A}_i$: the lens matrix of the system composed of the i-th gap and the i-th field free space,

$\boldsymbol{A}^{(i)}$: the lens matrix of the system composed of the first i gap lenses and i field free spaces,

D_i: the determinant of $\boldsymbol{A}_i$,

and

$D^{(i)}$: the determinant of $\boldsymbol{A}^{(i)}$.

(a) *Recurrence formulae for $f^{(i)}$ and $f'^{(i)}$*

According to U. Timm,[3] the lens matrix of the i-th gap is

$$\begin{bmatrix} \dfrac{F'_i}{f'_i} & \dfrac{f_i f'_i - F_i F'_i}{f'_i} \\ -\dfrac{1}{f'_i} & \dfrac{F_i}{f'_i} \end{bmatrix},$$

where

$$\left.\begin{aligned} \frac{F'_i}{K_i} &= -\frac{4}{3}\,\frac{N_i(N_i^{1/2}-3)}{(N_i-1)(N_i^{1/2}-1)}, \\ \frac{F_i}{K_i} &= \frac{4}{3}\,\frac{3\,N_i^{1/2}-1}{(N_i-1)(N_i^{1/2}-1)}, \\ \frac{f'_i}{K_i} &= \frac{8}{3}\,\frac{N_i}{(N_i-1)(N_i^{1/2}-1)}, \\ \frac{f_i}{K_i} &= \frac{8}{3}\,\frac{N_i^{1/2}}{(N_i-1)(N_i^{1/2}-1)}. \end{aligned}\right\} \qquad (1)$$

in the case of a uniform field.

Whereas, the matrix for the field free space is

$$\begin{bmatrix} 1 & K'_i \\ 0 & 1 \end{bmatrix}.$$

Hence, the matrix $\boldsymbol{A}_i$ becomes

$$A_i=\begin{bmatrix}1 & K'_i\\ 0 & 1\end{bmatrix}\times\begin{bmatrix}\frac{F'_i}{f'_i} & \frac{f_if'_i-F_iF'_i}{f'_i}\\ -\frac{1}{f'_i} & \frac{F_i}{f'_i}\end{bmatrix}$$

$$=\begin{bmatrix}\frac{F'_i-K'_i}{f'_i} & \frac{f_if'_i-F_iF'_i+K'_iF_i}{f'_i}\\ -\frac{1}{f'_i} & \frac{F_i}{f'_i}\end{bmatrix}. \qquad (2)$$

And the determinant of lens matrix is

$$D_i=|A_i|=f_i/f'_i\ . \qquad (3)$$

Furthermore,

$$A^{(i)}=A_i\cdot A_{i-1}\cdot\cdots\cdots A_1\ . \qquad (4)$$

Then, $D^{(i)}$ is given as

$$D^{(i)}=f^{(i)}/f'^{(i)}=D_i\cdot D_{i-1}\cdot\cdots\cdots D_1$$

$$=\frac{f_i\cdot f_{i-1}\cdots\cdots f_1}{f'_i\cdot f'_{i-1}\cdots\cdots f'_1}\ . \qquad (5)$$

Next, we consider $f^{(i)}$ and $f'^{(i)}$. From Eq. (4),

$$A^{(i)}=\begin{bmatrix}a_{11}^{(i)} & a_{12}^{(i)}\\ a_{21}^{(i)} & a_{22}^{(i)}\end{bmatrix}=A_i\cdot A^{(i-1)}$$

$$=\begin{bmatrix}\frac{F'_i-K'_i}{f'_i} & \frac{f_if'_i-F_iF'_i+K'_iF_i}{f'_i}\\ -\frac{1}{f'_i} & \frac{F_i}{f'_i}\end{bmatrix}$$

$$\times\begin{bmatrix}a_{11}^{(i-1)} & a_{12}^{(i-1)}\\ a_{21}^{(i-1)} & a_{22}^{(i-1)}\end{bmatrix}, \qquad (6)$$

and

$$a_{11}^{(i)}=F'^{(i)}/f'^{(i)}\ , \qquad (7)$$

$$a_{21}^{(i)}=-1/f'^{(i)}\ , \qquad (8)$$

$$a_{22}^{(i)}=F^{(i)}/f'^{(i)}\ . \qquad (9)$$

Therefore,

$$a_{11}^{(i)}=\frac{F'_i-K'_i}{f'_i}a_{11}^{(i-1)}$$

$$+\frac{f_if'_i-F_iF'_i+K'_iF_i}{f'_i}a_{21}^{(i-1)}\ , \qquad (10)$$

$$a_{21}^{(i)}=-\frac{1}{f'_i}a_{11}^{(i-1)}+\frac{F_i}{f'_i}a_{21}^{(i-1)}\ . \qquad (11)$$

Substituting $a_{11}^{(i-1)}$ of Eq. (11) into Eq. (10), we obtain

$$a_{11}^{(i)}=-(F'_i-K'_i)a_{21}^{(i)}+f_ia_{21}^{(i-1)}. \qquad (12)$$

Replacing i by $i-1$,

$$a_{11}^{(i-1)}=-(F'_{i-1}-K'_{i-1})a_{21}^{(i-1)}+f_{i-1}a_{21}^{(i-2)}. \qquad (13)$$

Eliminating $a_{11}^{(i-1)}$ from Eqs. (11) and (13), we get

$$a_{21}^{(i)}=\frac{\Delta_{i-1}}{f'_i}a_{21}^{(i-1)}-\frac{f_{i-1}}{f'_i}a_{21}^{(i-2)}\ , \qquad (14)$$

where $\Delta_{i-1}=F'_{i-1}+F_i-K'_{i-1}\ .$ (15)

By Eq. (9), Eq. (14) becomes

$$\frac{f'_i}{f'^{(i)}}=\frac{\Delta_{i-1}}{f'^{(i-1)}}-\frac{f_{i-1}}{f'^{(i-2)}}\ . \qquad (16)$$

This is the recurrence formula for $f'^{(i)}$.

Expressing $f'^{(i)}$ by $f^{(i)}$ by Eq. (5), we obtain as the recurrence formula for $f^{(i)}$:

$$\frac{f_i}{f^{(i)}}=\frac{\Delta_{i-1}}{f^{(i-1)}}-\frac{f'_{i-1}}{f^{(i-2)}}\ . \qquad (17)$$

(b) *Recurrence formula for $F^{(i)}$ and $F'^{(i)}$*

By Eqs. (7) and (8), Eqs. (11) and (12) become

$$\frac{f'^{(i)}}{f'^{(i-1)}}=\frac{f'_i}{F'^{(i-1)}+F_i}\ ,$$

$$F'^{(i)}=F'_i-K'_i-f_i\frac{f'^{(i)}}{f'^{(i-1)}}\ .$$

Substituting the former equation into the latter one, we obtain the recurrence formula for $F'^{(i)}$:

$$F'^{(i)}=F'_i-K'_i-\frac{f_if'_i}{F'^{(i-1)}+F_i}\ . \qquad (18)$$

The above equation can also be written as follows:

$$F'^{(i)}=F'_i-K'_i-\frac{f_if'_i}{\Delta_{i-1}+F'^{(i-1)}-(F'_{i-1}-K'_{i-1})}$$

$$=F'_i-K'_i$$

$$-\frac{f_if'_i}{\Delta_{i-1}-\frac{f_{i-1}f'_{i-1}}{\Delta_{i-2}+F'^{(i-2)}-(F'_{i-2}-K'_{i\ 2})}}\ .$$

Therefore, $F'^{(i)}$ can be expressed finally as the following continued fraction:

$$F'^{(i)}=F'_i-K'_i-\frac{f_if'_i}{\Delta_{i-1}}\,\underset{-}{}\,\frac{f_{i-1}f'_{i-1}}{\Delta_{i-2}}\,\underset{-}{}$$

$$\cdots\cdots\underset{-}{}\,\frac{f_3f'_3}{\Delta_2}\,\underset{-}{}\,\frac{f_2f'_2}{\Delta_1}\ . \qquad (19)$$

Next, we consider $F^{(i)}$. From Eq. (6), the following equations are obtained:

$$a_{12}^{(i)}=\frac{F_i'-K_i'}{f_i'}a_{12}^{(i-1)}$$

$$+\frac{f_if_i'-F_iF_i'+K_i'F_i}{f_i'}a_{22}^{(i-1)}\ , \qquad (20)$$

$$a_{22}^{(i)}=-\frac{1}{f_i'}a_{12}^{(i-1)}+\frac{F_i}{f_i'}a_{22}^{(i-1)}\ . \qquad (21)$$

Replacing i by $i-1$ in Eq. (20) and substituting into Eq. (21), we obtain

$$a_{22}^{(i)}=\frac{1}{f_i'}\Big[F_i\,a_{22}^{(i-1)}-f_{i-1}\,a_{22}^{(i-2)}$$
$$-(F'_{i-1}-K'_{i-1})\Big(\frac{a_{12}^{(i-2)}}{f'_{i-1}}-\frac{F_{i-1}}{f'_{i-1}}a_{22}^{(i-2)}\Big)\Big]$$
$$=\frac{1}{f_i'}\Big[\Delta_{i-1}\,a_{22}^{(i-1)}-f_{i-1}\,a_{22}^{(i-2)}\Big]. \qquad (22)$$

By Eq. (9), this equation becomes

$$\frac{F^{(i)}}{f'^{(i)}}=\frac{1}{f_i'}\Big[\Delta_{i-1}\frac{F^{(i-1)}}{f'^{(i-1)}}-f_{i-1}\frac{F^{(i-2)}}{f'^{(i-2)}}\Big]. \qquad (23)$$

This is the recurrence formula for $F^{(i)}/f'^{(i)}$. As $f'^{(i)}$ can be obtained by the consecutive applications of Eq. (16), $F^{(i)}$ can easily be calculated from Eq. (23).

Furthermore, we put

$$\left.\begin{aligned}p^{(i)}&=f'_i f'_{i-1}\cdots f_1'\,a_{22}^{(i)}\,,\\ q^{(i)}&=f'_i f'_{i-1}\cdots f_1'\,a_{21}^{(i)}\,.\end{aligned}\right\} \qquad (24)$$

Substituting these equations into Eqs. (14) and (22), and cancelling denominators, we obtain

$$\left.\begin{aligned}p^{(i)}&=\Delta_{i-1}\,p^{(i-1)}-f'_{i-1}f_{i-1}\,p^{(i-2)}\,,\\ q^{(i)}&=\Delta_{i-1}\,q^{(i-1)}-f'_{i-1}f_{i-1}\,q^{(i-2)}\,.\end{aligned}\right\} \qquad (25)$$

By the theorem about the continued fraction, the above equations mean that $F^{(i)}$ can be expressed as the following continued fraction:

$$F^{(i)}=\frac{p^{(i)}}{q^{(i)}}=F_1-\frac{f_1f_1'}{\Delta_1}\;-\;\frac{f_2f_2'}{\Delta_2}\;-\;\cdots\;-\;\frac{f_{i-1}f'_{i-1}}{\Delta_{i-1}}\,. \qquad (26)$$

Eqs. (19) and (26) may be used to obtain directly the values of $F'^{(i)}$ and $F^{(i)}$.

(c) *Newton's formula*

If the number of accelerating stages is n, the relation between the source and image is given by the following Newton's formula:

$$(S-F^{(n)})\;(I-F'^{(n)})=f^{(n)}f'^{(n)} \qquad (27)$$

where S and I are the distance of source and image from the lens boundary respectively.

The magnification can be expressed as

$$M=-(I-F'^{(n)})/f'^{(n)}. \qquad (28)$$

It is necessary to make the value of M as small as possible, if a well-defined small spot of accelerated beam is required on a target.

§ 3. Applications

In order to calculate the ion optical characteristics of a multistage accelerator tube, the cardinal elements of individual accelerating lens must be known. However, there are very few experimental data except those by K. Spangenberg and L. M. Field[4], in which the cardinal elements of equidiameter cylinder lens are given against the voltage ratio N for several values of the gap spacing. These results show the considerable deviations especially for the cases of smaller voltage ratio and larger gap spacing from those calculated by the assumption that the electric field is uniform and protrudes by half the cylinder diameter into both electrodes. Therefore, we try to improve the approximation by the consecutive applications of our recurrence formulae obtained above.

At first, we assume that the potential distribution along the axis of the lens composed of two coaxial equidiameter cylinders is given by[5)]

$$V(z)=\frac{V_1+V_2}{2}+\frac{V_2-V_1}{2.6304\,S/R}\log\frac{1.3152\,(z+S/2)/R}{1.3152\,(z-S/2)/R}\,, \qquad (29)$$

where R is the cylinder diameter, S is the gap spacing between the two cylinders and the coordinate z is taken along the axis from the center of gap. The whole range of z is

Table I. The cardinal elements of the lens composed of two coaxial equidiameter cylinders for the case of $S=2R$.

Cardinal elements	N	Calculated by the recurrence formulae.	Calculated by the assumption of a single uniform field.	Experimental values.[4)]
f/R	4	7.3	7.1	13.6
	6	3.6	3.6	5.8
	8	2.6	2.4	3.0
	10	2.1	1.7	2.2
f'/R	4	14.5	14.2	25.0
	6	8.9	8.8	13.4
	8	7.3	6.7	8.9
	10	6.5	5.5	6.8
F/R	4	8.0	8.9	14.4*
	6	3.1	4.7	5.7*
	8	1.9	3.1	2.6*
	10	1.2	2.3	1.5*
F'/R	4	7.7	7.1	18.0*
	6	3.6	2.4	8.2*
	8	0.68	0.57	4.0*
	10	−0.84	−0.44	2.1*

* These are derived from the original values, assuming that the field boundaries are at the distance of $2R$ from the center of gap.

divided into a large number of small intervals, in which the field is taken to be uniform and the potential distribution given by Eq. (29) is replaced by a sequence of such uniform fields. The cardinal elements of each interval are calculated by Eq. (1). Then, the cardinal elements for the whole lens can be obtained by the consecutive applications of Eqs. (16), (17), (18) and (23), taking $K'=0$. The calculated results do not show any appreciable improvement as shown in Table I, in which the comparison for the case of $S=2R$ is given as an example. The situation can not be improved, even if the higher order terms[6] are taken into account. The reasons can not yet be well explained. The errors would, therefore, become large in calculating the cardinal elements of a multistage accelerator, unless the experimental values are used for each accelerating lens.

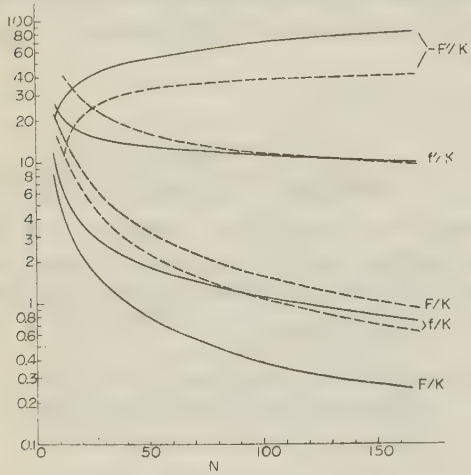

Fig. 3. Cardinal elements for our accelerator plotted against the ratio N of the energy of accelerated ions to that of incident ions. The accelerator consists of 12 coaxial equidiameter cylinders of 13.5 cm in length and 3 cm in inner diameter. The gap spacings are 2.5 cm. The case for a uniform acceleration is shown by the broken curves for the sake of comparison.

An example of the cardinal elements of a multistage accelerator tube is shown in Fig. 3, in which the calculated results for our 12-stage Cockcroft accelerator are given. As the applied accelerating voltage is assumed to be divided equally on each gap, the cardinal elements depend only on the ratio N of the energy of accelerated ions to that of incident ions. The broken curves in the figure represent the case in which a single uniform electric field is assumed in the accelerating system. Appreciable deviations are seen in f/K and f'/K for $N<50$, and in F/K and F'/K for the whole range of N. It is, therefore, clear that the calculation by the assumption of a uniform acceleration can not give satisfactorily accurate results in the case of such a multistage accelerator tube.

Transport Coefficients of Plasmas in a Magnetic Field

By Shobu KANEKO

Department of Physics, Faculty of Science,
University of Tokyo

(Received June 4, 1960)

The electric and the thermal conductivities, and the coefficient of the thermal diffusion of plasmas in a magnetic field are calculated under the assumption that the mass ratio m_2/m_1 is considerably smaller than unity, where m_1 and m_2 are masses of an ion and an electron, respectively. Thereby the terms of the order $(m_2/m_1)^{\frac{1}{2}}$ are retained considering the application to the deuterium plasma, but the higher order terms than those are neglected. For various strengths of the magnetic field, these coefficients are evaluated by the Chapman-Enskog method up to the 6th approximation, and the convergence of this method is examined. The probable error of our approximation varies from 0.1% to 10% with the strength of the magnetic field.

§ 1. Introduction

The investigation of the transport coefficients of plasmas is an important problem of the plasma physics. To calculate these coefficients we need, in general, the velocity distribution function which satisfies the Boltzmann equation. The electrical and thermal conductivites of plasmas have been calculated by many authors, i.e. Landshoff[1], Spitzer and Härm[2], and Schirmer and Friedrich[3] when there is no magnetic field. In the presence of a magnetic field, the calculations of these coefficients have been made by Cowling[4], Landshoff[5], Fradkin[6], Braginskii[7], Marshall[8], and Kihara, Midzuno, and Kaneko[9].

Using the Chapman-Enskog method[10] we calculate in this article these transport coefficients for various strengths of the magnetic field up to the 6th approximation, and examine the convergence of this method. In the absence of the magnetic field the calculation was also made by Landshoff[1] up to the 5th approximation under the same purpose.

The following assumptions have been made in carrying through the calculations.

(i) The plasma is composed of one type of ions as species *1* and electrons as species *2*. The particle mass, charge and number density of the ion will be denoted by m_1, $e_1=Ze$, and n_1 respectively and those of the electron by m_2, $e_2=-e$, and n_2.

(ii) The plasma is charge neutral as a whole, i.e. $Zn_1=n_2$.

(iii) Since the mass ratio, $m_2/m_1=M_2$, is considerably smaller than unity, we neglect the terms of the order M_2 or higher, but retain the terms of the order $M_2^{1/2}$ considering the practical application to the deuterium plasma.

(iv) The plasma is so hot that the Coulomb logarithm, $\ln\left(\frac{kTl_D}{e_1e_2}\right)$, is much larger than unity, where l_D is the Debye characteristic length and T the temperature of the plasma.

(v) The electric field $\boldsymbol{E}$, and the magnetic flux $\boldsymbol{B}$ are uniform in space. Both the field $\boldsymbol{E}$ and the temperature gradient $-\operatorname{grad} T$ are perpendicular to $\boldsymbol{B}$. By this assumption it is sufficient to consider only the transport coefficients across the magnetic field. The transport coefficients along the magnetic field are the same as in the absence of the magnetic field.

§ 2. Method of Calculation

Since the Chapman-Enskog method used in this paper has been explained in detail by many authors[10], only a short account will be given in this and the next section.

For the treatment of conduction phenomena it is sufficient to look for the stationary velocity distribution function. The velocity distribution function f_i for particles of species i, interacting with particles of species j is determined by the Boltzmann equation[10]

$$\boldsymbol{c}_i\frac{\partial f_i}{\partial \boldsymbol{r}}+\frac{e_i}{m_i}\left(\boldsymbol{E}+\frac{1}{c}\boldsymbol{c}_i\times\boldsymbol{B}\right)\cdot\frac{\partial f_i}{\partial \boldsymbol{c}_i}$$
$$=\sum_{j=1}^{2}\iiint d\boldsymbol{c}_j g_{ij} b\,db\,d\varepsilon\left[\,f_i(\boldsymbol{c}_i')f_j(\boldsymbol{c}_j')-f_i(\boldsymbol{c}_i)f_j(\boldsymbol{c}_j)\,\right], \tag{1}$$

where $\boldsymbol{c}_i$ and $\boldsymbol{c}_i'$ are the velocities of a particle of species i before and after the collision, $g_{ij}=|\boldsymbol{c}_i-\boldsymbol{c}_j|$ is the relative speed between particles i and j; b is the impact parameter, ε the azimuthal angle of the orbit of relative motion, and c the velocity of light.

Supposing that the electric field $\boldsymbol{E}$ and the temperature gradient $-\text{grad}\ T$ are small, the distribution functions f_i are expanded as

$$f_i=f_i^{(0)}[1+\varphi_i]\,, \tag{2}$$

where $f_i^{(0)}$ and φ_i are respectively the distribution functions in the equilibrium state and their distortion. The distribution functions $f_i^{(0)}$ are determined by

$$\begin{aligned}&\frac{e_i}{m_i c}\boldsymbol{c}_i\times\boldsymbol{B}\cdot\frac{\partial f_i^{(0)}}{\partial \boldsymbol{c}_i}\\&\quad=\sum_{j=1}^{2}\iiint d\boldsymbol{c}_j g_{ij} b\,db\,d\varepsilon\Big[f_i^{(0)}(\boldsymbol{c}_i')f_j^{(0)}(\boldsymbol{c}_j')-f_i^{(0)}(\boldsymbol{c}_i)f_j^{(0)}(\boldsymbol{c}_j)\Big]\,,\end{aligned} \tag{3}$$

and solutions of these equations are the well-known Maxwell distributions;

$$f_i^{(0)}=n_i\left(\frac{m_i}{2\pi kT}\right)^{3/2}\exp\left(-\frac{m_i c_i^2}{2kT}\right), \tag{4}$$

where k is the Boltzmann constant.

The distortions φ_i of the distribution functions which are of the order $\boldsymbol{E}$ and $-\text{grad}\ T$, are given as the solutions of following equations;

$$\begin{aligned}&-f_i^{(0)}\left(\frac{5}{2}-w_i^2\right)(\boldsymbol{c}_i\cdot\text{grad}\ln T)-f_i^{(0)}\frac{e_i}{kT}(\boldsymbol{c}_i\cdot\boldsymbol{E})=-f_i^{(0)}\frac{e_i}{m_i c}\boldsymbol{c}_i\times\boldsymbol{B}\cdot\frac{\partial\varphi_i}{\partial\boldsymbol{c}_i}\\&\quad+\sum_{j=1}^{2}\iiint d\boldsymbol{c}_j g_{ij} b\,db\,d\varepsilon\, f_i^{(0)}f_j^{(0)}\Big[\varphi_i(\boldsymbol{c}_i')+\varphi_j(\boldsymbol{c}_j')-\varphi_i(\boldsymbol{c}_i)-\varphi_j(\boldsymbol{c}_j)\Big]\,,\end{aligned} \tag{5}$$

where $\boldsymbol{w}_i$ are the non-dimensional velocities $\sqrt{\dfrac{m_i}{2kT}}\,\boldsymbol{c}_i$.

Because the left hand sides of the equations (5) have linear dependence on $\boldsymbol{E}$ and $-\text{grad}\ T$, the solutions φ_i may be written as

$$\varphi_i=-\boldsymbol{D}_i\cdot\boldsymbol{E}-\boldsymbol{A}_i\cdot\text{grad}\ln T\,, \tag{6}$$

where the quantities $\boldsymbol{D}_i$ and $\boldsymbol{A}_i$ are vectors which involve only the vectors $\boldsymbol{c}_i$ and $\boldsymbol{B}$ and scalars. Since $\boldsymbol{B}$ is a pseudo-vector, the independent true vectors which we need under the assumption (v) are $\boldsymbol{w}_i$ and $\boldsymbol{w}_i\times\boldsymbol{b}$ ($\boldsymbol{b}=\boldsymbol{B}/B$). Then the vectors $\boldsymbol{D}_i$ and $\boldsymbol{A}_i$ can be written as

$$\begin{aligned}\boldsymbol{A}_i&=A_i^{\mathrm{I}}\boldsymbol{w}_i+A_i^{\mathrm{II}}\boldsymbol{w}_i\times\boldsymbol{b}\,,\\\boldsymbol{D}_i&=D_i^{\mathrm{I}}\boldsymbol{w}_i+D_i^{\mathrm{II}}\boldsymbol{w}_i\times\boldsymbol{b}\,,\end{aligned} \tag{7}$$

where the coefficients A_i^{I}, etc. are scalar functions of w_i^2, B^2, and $(\boldsymbol{w}_i\cdot\boldsymbol{B})^2$.

Substituting the equations (6) and (7) into the equations (5), we obtain the equations for D and A as

$$\begin{aligned}&-f_i^{(0)}\frac{e_i}{kT}\boldsymbol{c}_i=i\omega_i D_i f_i^{(0)}\boldsymbol{w}_i\\&\quad-\sum_{j=1}^{2}\iiint d\boldsymbol{c}_j g_{ij} b\,db\,d\varepsilon\, f_i^{(0)}f_j^{(0)}\Big[(D_i\boldsymbol{w}_i)'+(D_j\boldsymbol{w}_j)'-(D_i\boldsymbol{w}_i)-(D_j\boldsymbol{w}_j)\Big]\,,\end{aligned} \tag{8}$$

$$\begin{aligned}&-f_i^{(0)}\left(\frac{5}{2}-w_i^2\right)\boldsymbol{c}_i=i\omega_i A_i f_i^{(0)}\boldsymbol{w}_i\\&\quad-\sum_{j=1}^{2}\iiint d\boldsymbol{c}_j g_{ij} b\,db\,d\varepsilon\, f_i^{(0)}f_j^{(0)}\Big[(A_i\boldsymbol{w}_i)'+(A_j\boldsymbol{w}_j)'-(A_i\boldsymbol{w}_i)-(A_j\boldsymbol{w}_j)\Big]\,,\end{aligned} \tag{9}$$

where we have used the complex notations, i.e.

$$D_i = D_i^{\mathrm{I}} + iD_i^{\mathrm{II}} \,,$$
$$A_i = A_i^{\mathrm{I}} + iA_i^{\mathrm{II}} \,, \tag{10}$$

and $\omega_i = e_iB/m_ic$ is the Larmer frequency of the species i.

First of all, we can derive a following relation between A and D from the equations (8) and (9)

$$\sum_i \frac{e_i}{kT}\int d\boldsymbol{c}_i(\boldsymbol{c}_i\cdot\boldsymbol{w}_i)\, f_i^{(0)} A_i = \sum_i \int d\boldsymbol{c}_i\left(\frac{5}{2} - w_i^2\right)(\boldsymbol{c}_i\cdot\boldsymbol{w}_i) f_i^{(0)} D_i . \tag{11}$$

Besides the equations (8) and (9), D_i and A_i, must satisfy a subsidiary condition that the plasma as a whole is at rest:

$$\sum_i m_i \int d\boldsymbol{c}_i\, f_i \boldsymbol{c}_i = 0 \,. \tag{12}$$

By substitution of the equations (2), (4), (6), and (7), this condition becomes

$$\sum_i n_i\sqrt{m_i}\int d\boldsymbol{w}_i e^{-w_i^2} w_i^2 D_i = 0 \,, \tag{12'}$$
$$\sum_i n_i\sqrt{m_i}\int d\boldsymbol{w}_i e^{-w_i^2} w_i^2 A_i = 0 \,.$$

For convenience in later work, we introduce a system of orthogonal functions;

$$S_1^{(0)} \equiv -\frac{n_2\sqrt{m_2}}{n_1\sqrt{m_1}} S^{(0)}{}_{3/2}(w_1^2) \,, \qquad S_2^{(0)} \equiv S^{(0)}{}_{3/2}(w_2^2) \,,$$

and for values of r greater than zero,

$$S_1^{(r)} \equiv S_{3/2}{}^{(r)}(w_1^2) \,, \qquad S_2^{(r)} \equiv 0 \,,$$
$$S_1^{(-r)} \equiv 0 \,, \qquad S_2^{(-r)} \equiv S^{(r)}{}_{3/2}(w_2^2) \,, \tag{13}$$

where $S_{3/2}{}^{(r)}(x)$ are Sonie's polynomials of the order ³⁄₂ whose orthogonal relation is

$$\int_0^\infty e^{-x} S_m{}^{(p)}(x) S_m{}^{(q)}(x) x^m dx = 0 \qquad \text{for } p \neq q \tag{14}$$
$$= \frac{1}{p!}\Gamma(m+p+1) \qquad \text{for } p = q \,.$$

By use of this system of orthogonal functions we expand D_i and A_i as

$$D_i = \sum_{m=-\infty}^{\infty} d^{(m)} S_i^{(m)} \,, \tag{15}$$
$$A_i = \sum_{m=-\infty}^{\infty} a^{(m)} S_i^{(m)} \,,$$

where

$$d^{(m)} = d^{\mathrm{I}(m)} + id^{\mathrm{II}(m)} \,, \tag{16}$$
$$a^{(m)} = a^{\mathrm{I}(m)} + ia^{\mathrm{II}(m)} \,.$$

The equality of the coefficients of $S_1^{(0)}$ and $S_2^{(0)}$ follows from the conditions (12′), which D and A must satisfy; it can easily be verified by substituting (15) and (16) into the equations (12′). The equations which determine the coefficients $d^{(m)}$ and $a^{(m)}$ are obtained from the equations (8) and (9) by substituting the equations (15) and operating $\sum_i \int d\boldsymbol{c}_i\boldsymbol{w}_i S_i^{(r)}$. The results are

$$\frac{3}{2}\frac{n_2 e}{kT}\left(\frac{2kT}{m_2}\right)^{1/2}\delta_{r,o}=\sum_{-\infty}^{\infty}\left[h^{(m)}\delta_{r,m}+\{\boldsymbol{w}S^{(r)},\boldsymbol{w}S^{(m)}\}\right]d^{(m)}\,,$$

$$\frac{15}{4}\left[n_1\left(\frac{2kT}{m_1}\right)^{1/2}\delta_{r,1}+n_2\left(\frac{2kT}{m_2}\right)^{1/2}\delta_{r,-1}\right] \tag{17}$$

$$=\sum_{-\infty}^{\infty}\left[h^{(m)}\delta_{r,m}+\{\boldsymbol{w}S^{(r)},\boldsymbol{w}S^{(m)}\}\right]a^{(m)}\,,$$

where

and

$$\{F,G\}=-\sum_{ij}\iiiint d\boldsymbol{c}_i d\boldsymbol{c}_j g_{ij} b\,db\,d\varepsilon\, f_i^{(0)}(c_i)\,f_j^{(0)}(c_j)F_i(\boldsymbol{c}_i)\cdot$$

$$\left[G_i(\boldsymbol{c}'_i)+G_j(\boldsymbol{c}'_j)-G_i(\boldsymbol{c}_i)-G_j(\boldsymbol{c}_j)\right]$$

$$=n_1^2[F,G]_1+n_2^2[F,G]_2+n_1n_2[F_1+F_2,\,G_1+G_2]_{12}\,, \tag{19}$$

$$[F,G]_i=-\frac{1}{n_i^2}\iiiint d\boldsymbol{c}_i d\bar{\boldsymbol{c}}_i g_{ii} b\,db\,d\varepsilon\, f_i^{(0)}(c_i)\,f_i^{(0)}(\bar{c}_i)F_i(\boldsymbol{c}_i)\,.$$

$$[G_i(\boldsymbol{c}_i')+G_i(\boldsymbol{c}_i')-G_i(\boldsymbol{c}_i)-G_i(\bar{\boldsymbol{c}}_i)]\,,$$

$$[F_1+F_2,\,G_1+G_2]_{12}$$

$$=-\frac{1}{n_1n_2}\iiiint d\boldsymbol{c}_1 d\boldsymbol{c}_2 g_{21} b\,db\,d\varepsilon\, f_1^{(0)}(c_1)\,f_2^{(0)}(c_2)\,[F_1(\boldsymbol{c}_1)+F_2(\boldsymbol{c}_2)]\,.$$

$$[G_1(\boldsymbol{c}_1')+G_2(\boldsymbol{c}_2')-G_1(\boldsymbol{c}_1)-G_2(\boldsymbol{c}_2)]\,,$$

$$\delta_{m,n}=\begin{cases}1 & \text{for } m=n \\ 0 & \text{for } m\neq n\,.\end{cases}$$

These equations (17) are infinite simultaneous linear equations, and can be solved approximately by taking r and m within some finite value.

§ 3. Transport Coefficients

Among the electric current $\boldsymbol{j}$, the reduced heat flow $\boldsymbol{q}$ due to conduction, the electric field $\boldsymbol{E}$, and the temperature gradient $-\text{grad}\ln T$ there exist the well-known linear relations[9]:

$$\boldsymbol{q}=-T\lambda\,\text{grad}\ln T+\alpha\boldsymbol{j}$$

$$\boldsymbol{E}=\ \alpha\,\text{grad}\ln T+\sigma^{-1}\boldsymbol{j}\,. \tag{20}$$

Here λ and σ are respectively the thermal and electric conductivities and α is the coefficient which represents the interference between the thermal and electric phenomena. These transport coefficients in a magnetic field are represented by tensors of the type,[9]

$$\lambda=\begin{pmatrix}\lambda^{\mathrm{I}} & -\lambda^{\mathrm{II}} \\ \lambda^{\mathrm{II}} & \lambda^{\mathrm{I}}\end{pmatrix}. \tag{21}$$

for example.

By definition, the electric current is written as

$$\begin{aligned} \boldsymbol{j} &\equiv \sum_i n_i e_i \overline{\boldsymbol{c}_i} = \sum_i e_i \int d\boldsymbol{c}_i f_i^{(0)} \varphi_i \boldsymbol{c}_i \\ &= -\frac{n_2 e_2}{2} \left(\frac{2kT}{m_2}\right)^{1/2} \left[d^{\mathrm{I}(0)} \boldsymbol{E} + d^{\mathrm{II}(0)} (\boldsymbol{b} \times \boldsymbol{E}) \right] \\ &\quad -\frac{n_2 e_2}{2} \left(\frac{2kT}{m_2}\right)^{1/2} \left[a^{\mathrm{I}(0)} \operatorname{grad} \ln T + a^{\mathrm{II}(0)} (\boldsymbol{b} \times \operatorname{grad} \ln T) \right], \end{aligned} \tag{22}$$

where we have used equations (6), (7), (15), and (16). Hence the electric conductivity σ and the coefficient of the thermal diffusion φ are expressed as follows

$$\sigma \equiv \sigma^{\mathrm{I}} + i \sigma^{\mathrm{II}} = -\frac{n_2 e_2}{2} \left(\frac{2kT}{m_2}\right)^{1/2} d^{(0)}, \tag{23}$$

$$\varphi \equiv \varphi^{\mathrm{I}} + i \varphi^{\mathrm{II}} = -\frac{n_2 e_2}{2T} \left(\frac{2kT}{m_2}\right)^{1/2} a^{(0)}, \tag{24}$$

where the assumption (iii) has been used.

In the same way the heat flow $\boldsymbol{q}^*$ can be calculated as

$$\begin{aligned} \boldsymbol{q}^* &\equiv \sum_i n_i \frac{1}{2} \overline{m_i c_i^2 \boldsymbol{c}_i} = \sum_i \frac{1}{2} m_i \int d\boldsymbol{c}_i c_i^2 \boldsymbol{c}_i f_i^{(0)} \varphi_i \\ &= \frac{n_2 e_2}{2} \left(\frac{2kT}{m_2}\right)^{1/2} \left[a^{\mathrm{I}(0)} \boldsymbol{E} + a^{\mathrm{II}(0)} (\boldsymbol{b} \times \boldsymbol{E}) \right] + \frac{5}{2} \frac{kT}{e_2} \boldsymbol{j} \\ &\quad + \frac{5}{4} n_1 kT \left(\frac{2kT}{m_1}\right)^{1/2} \left[a^{\mathrm{I}(1)} \operatorname{grad} \ln T + a^{\mathrm{II}(1)} (\boldsymbol{b} \times \operatorname{grad} \ln T) \right] \\ &\quad + \frac{5}{4} n_2 kT \left(\frac{2kT}{m_2}\right)^{1/2} \left[a^{\mathrm{I}(-1)} \operatorname{grad} \ln T + a^{\mathrm{II}(-1)} (\boldsymbol{b} \times \operatorname{grad} \ln T) \right]. \end{aligned}$$

In this calculation we have used the relation (11) and the assumption (iii). Hence the reduced heat flow $\boldsymbol{q} = \boldsymbol{q}^* - \frac{5}{2} \frac{kT}{e_2} \boldsymbol{j}$ may be written

$$\boldsymbol{q} = -T [\varphi^{\mathrm{I}} \boldsymbol{E} + \varphi^{\mathrm{II}} (\boldsymbol{b} \times \boldsymbol{E})] - T \lambda^{\mathrm{I}} \operatorname{grad} \ln T - T \lambda^{\mathrm{II}} (\boldsymbol{b} \times \operatorname{grad} \ln T),$$

where

$$\lambda \equiv \lambda^{\mathrm{I}} + i \lambda^{\mathrm{II}} = -\frac{5}{4} n_2 k \left(\frac{2kT}{m_2}\right)^{1/2} \left[a^{(-1)} + \frac{n_1}{n_2} \left(\frac{m_2}{m_1}\right)^{1/2} a^{(1)} \right]. \tag{25}$$

From these results we can see that only the coefficients $d^{(0)}$, $a^{(0)}$, $a^{(-1)}$ and $a^{(1)}$ are needed to calculate the transport coefficients and are determined by the equations (17). These equations can be simplified by use of the assumption (iii).

First of all we consider the collision integrals $\{wS^{(r)}, wS^{(m)}\}$. By use of the definitions (19) these collision integrals become

$$\{wS^{(r)}, wS^{(m)}\} = \begin{cases} n_1^2 [w_1 S_1^{(r)}, w_1 S_1^{(m)}]_1 + n_1 n_2 [w_1 S_1^{(r)}, w_1 S_1^{(m)} + w_2 S_2^{(m)}]_{12} & \text{for } r > 0 \\ n_1 n_2 \Big[-\frac{n_2 \sqrt{m_2}}{n_1 \sqrt{m_1}} \big\{ [w_1, w_1 S_1^{(m)}]_{12} + [w_1, w_2 S_2^{(m)}]_{12} \big\} & \\ \quad + [w_2, w_2 S_2^{(m)}]_{12} + [w_2, w_1 S_1^{(m)}]_{12} \Big] & \text{for } r = 0 \\ n_2^2 [w_2 S_2^{(r)}, w_2 S_2^{(m)}]_2 + n_1 n_2 [w_2 S_2^{(r)}, w_1 S_1^{(m)} + w_2 S_2^{(m)}]_{12} & \text{for } r < 0, \end{cases} \tag{26}$$

where we have used the conservation of the momentum:

$$[w_i, w_i S^{(m)}_{\frac{3}{2}} (w_i^2)]_i = 0 .$$

Various collision integrals which appeared in the above equation (26) are calculated in Appendix: the results are

$$
\begin{aligned}
&[w_1 S_{3/2}^{(r)}, w_1 S_{3/2}^{(m)}]_1 = M_2^{1/2}[w_2 S_{3/2}^{(r)}, w_2 S_{3/2}^{(m)}]_2 \ , \\
&[w_1 S_{3/2}^{(r)}, w_1 S_{3/2}^{(m)}]_{12} = O(M_2) \qquad , \\
&[w_1 S_{3/2}^{(r)}, w_2 S_{3/2}^{(m)}]_{12} = O(M_2^{r+1/2})
\end{aligned}
\tag{27}
$$

Using this mass ratio dependence in the equations (26) and (17), we get the equations for $d^{(0)}$, $a^{(0)}$, $a^{(-1)}$, and $a^{(1)}$ as follows

$$\frac{3}{2}\frac{n_2 e}{kT}\left(\frac{2kT}{m_2}\right)^{1/2}\delta_{r,o} = \sum_{m=-\infty}^{0}\{h^{(m)}\delta_{r,m} + n_2^2[w_2 S_2^{(r)}, w_2 S_2^{(m)}]_2 + n_1 n_2[w_2 S_2^{(r)}, w_2 S_2^{(m)}]_{12}\}\, d^{(m)} \qquad (r \leq 0)\ , \tag{28}$$

$$-\frac{15}{4} n_2\left(\frac{2kT}{m_2}\right)^{1/2}\delta_{r,-1} = \sum_{m=-\infty}^{0}\{h^{(m)}\delta_{r,m} + n_2^2[w_2 S_2^{(r)}, w_2 S_2^{(m)}]_2 + n_1 n_2[w_2 S_2^{(r)}, w_2 S_2^{(m)}]_{12}\} a^{(m)} \qquad (r \leq 0)\ , \tag{29}$$

$$-\frac{15}{4}\left(\frac{2kT}{m_2}\right)^{1/2}\delta_{r,1} = n_1 \sum_{m=1}^{\infty}[w_2 S_2^{(r)}, w_2 S_2^{(m)}]_2\, a^{(m)} \qquad (r \geq 1)\ . \tag{30}$$

In the equations (30) the influence of the magnetic field to the motion of ions is neglected. Because, as can be easily seen from the equations (18) and (27), it is higher order, at least, by $M_2^{1/2}$ compared with that of the ion-ion collisions and the contribution of the $a^{(1)}$ itself to the thermal conductivity λ is of the order $M_2^{1/2}$. The equations (28) and (29) were used by Landshoff[5] to calculate the transport coefficients.

For convenience we introduce the notations $e^{(m)}$ and $b^{(m)}$ by relations

$$
\begin{aligned}
d^{(m)} &= \frac{e}{kT}\left(\frac{2kT}{m_2}\right)^{1/2}\tau e^{(m)} \ , \\
a^{(m)} &= -\frac{5}{2}\left(\frac{2kT}{m_2}\right)^{1/2}\tau b^{(m)} \ ,
\end{aligned}
$$

where τ is the mean collision time for electrons and is defined by

$$\frac{1}{\tau} \equiv \frac{2}{3} n_1 [w_2, w_2]_{12} = \frac{16}{3} n_1 \left(\frac{2\pi kT}{m_2}\right)^{1/2}\left(\frac{Ze^2}{2kT}\right)^2 \ln\frac{kT\, l_D}{Ze^2}\ . \tag{31}$$

By use of these new notations transport coefficients are expressed by

$$\sigma = \frac{n^2 e^2}{m_2}\tau e^{(0)} \qquad , \tag{32}$$

$$\varphi = -\frac{5k}{2}\frac{n_2 e}{m_2}\tau b^{(0)} \qquad , \tag{33}$$

$$\lambda = \frac{25}{4}\frac{n_2 k^2 T}{m_2}\tau\left[b^{(-1)} + \frac{n_1}{n_2}\left(\frac{m_2}{m_1}\right)^{1/2} b^{(1)}\right] \qquad , \tag{34}$$

and $e^{(0)}$, $b^{(0)}$, $b^{(-1)}$ ane $b^{(1)}$ are determined by

$$\sum_{-\infty}^{0} E_{rm} e^{(m)} = \delta_{r,o} \qquad (r \leq 0) \qquad , \tag{35}$$

$$\sum_{-\infty}^{0} E_{rm} b^{(m)} = \delta_{r,-1} \qquad (r \leq 0) \qquad , \tag{36}$$

$$\sum_{1}^{\infty} F_{rm} b^{(m)} = \delta_{r,1} \qquad (r \geq 1) \qquad , \tag{37}$$

where

$$E_{rm}=\frac{4}{3}\,i\,\frac{\omega_2\tau}{\sqrt{\pi}}\,\frac{\Gamma\left(|r|+\frac{3}{2}\right)}{|r|!}\,\delta_{r,m}+\frac{n_2[w_2S_2^{(r)},\,w_2S_2^{(m)}]_2+n_1[w_2S_2^{(r)},\,w_2S_2^{(m)}]_{12}}{n_1[w_2,\,w_2]_{12}}, \tag{38}$$

$$F_{rm}=\frac{[w_2S^{(r)}{}_{3/2},\,w_2S^{(m)}{}_{3/2}]_2}{[w_2,\,w_2]_{12}}$$

The transport coefficient α, which is defined by the equation (20), is related to σ and φ by

$$\alpha=-T\sigma^{-1}\varphi \tag{39}$$

or

$$\alpha^{\mathrm{I}}=-T\frac{\varphi^{\mathrm{I}}\sigma^{\mathrm{I}}+\varphi^{\mathrm{II}}\sigma^{\mathrm{II}}}{(\sigma^{\mathrm{I}})^2+(\sigma^{\mathrm{II}})^2}=\frac{5}{2}\frac{kT}{e}c^{\mathrm{I}(0)},$$

$$\alpha^{\mathrm{II}}=-T\frac{\varphi^{\mathrm{II}}\sigma^{\mathrm{I}}-\varphi^{\mathrm{I}}\sigma^{\mathrm{II}}}{(\sigma^{\mathrm{I}})^2+(\sigma^{\mathrm{II}})^2}=\frac{5}{2}\frac{kT}{e}c^{\mathrm{II}(0)},$$

where

$$c^{\mathrm{I}(0)}=\frac{b^{\mathrm{I}(0)}e^{\mathrm{I}(0)}+b^{\mathrm{II}(0)}e^{\mathrm{II}(0)}}{\{e^{\mathrm{I}(0)}\}^2+\{e^{\mathrm{II}(0)}\}^2}, \tag{40}$$

$$c^{\mathrm{II}(0)}=\frac{b^{\mathrm{II}(0)}e^{\mathrm{I}(0)}-b^{\mathrm{I}(0)}e^{\mathrm{II}(0)}}{\{e^{\mathrm{I}(0)}\}^2+\{e^{\mathrm{II}(0)}\}^2}.$$

§ 4. Results

Following to Chapman and Enskog we cut off the matrices E_{rm} and F_{rm} beyond $|r|$, $|m|=M$ to solve the equations (35), (36), and (37) and examine the convergence of this method by taking $M=2, 3, 4, 5$, and 6. The simultaneous linear equations so obtained are solved by the Parametron Computor PC-1 at the University of Tokyo.

Considering the application to the deuterium or tritium plasma which plays an important role in the thermonuclear fusion devices, we

*) Value calculated by Spitzer and Härm, see reference 2).

have made calculations for the plasma with $Z=1$. The collision integrals which we need are calculated in Appendix. Computed values of $e^{(0)}$, $b^{(0)}$, $b^{(-1)}$ and $b^{(1)}$ for various strengths of the magnetic field are shown in Tables I through III. In the absence of the magnetic field Spitzer and Härm's values[2], which are obtained by solving the Fokker-Planck's equation, are also presented in these tables.

From these tables we see that, for all transport coefficients in a magnetic field of any strength, the values in the 6th approximation have accuracy of three decimal places. Especially our values of the 6th approximation coincide perfectly well with values of Spitzer and Härm.

The similar calculations with ours were also made by Landshoff for cases: (i) the 3rd approximation in the presence of the magnetic field[5], (ii) up to the 5th approximation in the absence of the magnetic field.[1]

For convenience of the practical uses, the $e^{(0)}$, $c^{(0)}$, and $b^{(-1)}$ in the 6th approximation have been computed in detail and presented in Table IV. The $b^{(1)}$ in this approximation has been already shown in Table III. For the deuterium plasma, for example, the $M_2^{1/2}$ is 0.0165 so the correction term $M_2^{1/2}b^{\mathrm{I}(1)}$ for λ^{I} is necessary to get values which are accurate to three places of decimals.

In conclusion the author wishes to express his sincere thanks to Prof. T. Kihara for his continual guidance and his kindness in reading the original manuscript. Thanks are also due to Mr. Y. Ishibashi for the permission to use his program for solving the simultaneous linear equations. The present work has been supported by the Asahi Fellowship for Nuclear Fusion Research.

Appendix

A part of the collision integrals which we need are treated by many authors[3][10], especially for the case of the Coulomb interaction, by Landshoff[5].

For convenience we introduce the velocities of the center of masses $\boldsymbol{G}$ and of the relative motion $\boldsymbol{g}_{21}$, instead of the velocities of two particles $\boldsymbol{c}_1$ and $\boldsymbol{c}_2$, i.e.

$$\boldsymbol{c}_1=\boldsymbol{G}-M_2\boldsymbol{g}_{21}\ , \qquad \boldsymbol{c}_2=\boldsymbol{G}+M_1\boldsymbol{g}_{21}\ , \tag{A·1}$$

or in a non-dimensional form

$$\begin{aligned} \boldsymbol{w}_1&=M_1{}^{1/2}\boldsymbol{X}-M_2{}^{1/2}\boldsymbol{g}\ , \\ \boldsymbol{w}_2&=M_2{}^{1/2}\boldsymbol{X}+M_1{}^{1/2}\boldsymbol{g}\ , \end{aligned} \tag{A·2}$$

where

$$M_1=\frac{m_1}{m_1+m_2}\ ; \qquad M_2=\frac{m_2}{m_1+m_2}\ ,$$

$$\boldsymbol{X}=\sqrt{\frac{m_1+m_2}{2kT}}\boldsymbol{G}\ , \quad \boldsymbol{g}=\sqrt{\frac{m_1m_2}{2(m_1+m_2)kT}}\boldsymbol{g}_{21}\ .$$

The Jacobian of this transformation is given by

$$\frac{\partial(\boldsymbol{X},\boldsymbol{g})}{\partial(\boldsymbol{c}_1,\boldsymbol{c}_2)}=\frac{(m_1m_2)^{3/2}}{(2kT)^3}\ . \tag{A·3}$$

The collision integral $[\boldsymbol{w}_1S_{3/2}{}^{(p)}(w_1{}^2),\ \boldsymbol{w}_2S_{3/2}{}^{(q)}(w_2{}^2)]_{12}$ is, by definition, equal to

$$\frac{1}{n_1n_2}\iiiint d\boldsymbol{c}_1d\boldsymbol{c}_2g_{21}bdbd\varepsilon\ f_1{}^{(0)}f_2{}^{(0)}\{\boldsymbol{w}_1S_{3/2}{}^{(p)}(w_1{}^2)-\boldsymbol{w}_1{}'S_{3/2}{}^{(p)}(w_1{}'^2)\}\cdot\boldsymbol{w}_2S_{3/2}{}^{(q)}(w_2{}^2).$$

Using the generating function of the Sonie polynomials

$$(1-s)^{-5/2}e^{-xs/1-s}=\sum s^pS_{3/2}{}^{(p)}(x)\ ,$$

we obtain the collision integral $[\boldsymbol{w}_1S_{3/2}{}^{(p)}(w_1{}^2),\ \boldsymbol{w}_2S_{3/2}{}^{(q)}(w_2{}^2)]_{12}$ as the coefficient of s^pt^q in the expansion of

$$(1-s)^{-5/2}(1-t)^{-5/2}\ \pi^{-3}\iiint\{H_{12}(0)-H_{12}(\chi)\}g_{21}\ bdbd\varepsilon\ d\boldsymbol{g} \tag{A·4}$$

in powers of s and t. Here $H_{12}(\chi)$ is defined by

$$H_{12}(\chi)=\int(\boldsymbol{w}_1{}'\cdot\boldsymbol{w}_2)\exp-(X^2+g^2+Sw_1{}'^2+Tw_2{}^2)d\boldsymbol{X}$$

where

$$S=\frac{s}{1-s}\ , \qquad T=\frac{t}{1-t}\ ,$$

and χ is the diffraction angle for the orbit of relative motion, i.e. $\boldsymbol{g}\cdot\boldsymbol{g}=g^2\cos\chi$.

The integral $H_{12}(\chi)$ becomes after straight forward calculations

$$\begin{aligned} &\pi^{-3/2}(1-s)^{-5/2}(1-t)^{-5/2}(M_1M_2)^{-1/2}H_{12}(\chi) \\ &\qquad=\exp(-j_{12}g^2)(1-M_2s-M_1t)^{-5/2}\{\frac{3}{2}+(1-j_{12}-\cos\chi)g^2\}\ , \end{aligned} \tag{A·5}$$

where $\qquad j_{12}=\{1-2M_1M_2st\,(1-\cos\chi)\}/(1-M_2s-M_1t)\ .$

Now we expand $\{H_{12}(0)-H_{12}(\chi)\}$ in terms of $(1-\cos\chi)$ and need only the linear term, because the Rutherford scattering cross section is proportional to $(1-\cos\chi)^{-2}$, so the contributions of large angle scattering are negligible. Then we get

$$\pi^{-3/2}(1-s)^{-5/2}(1-t)^{-5/2}(M_1M_2)^{-1/2}\{H_{12}(0)-H_{12}(\chi)\}=-(1-M_2s-M_1t)^{-5/2}\exp\left(-\frac{g^2}{1-M_2s-M_1t}\right)$$

$$\times g^2(1-\cos\chi)\left[1+\frac{5M_1M_2}{1-M_2s-M_1t}st-\frac{2M_1M_2st}{(1-M_2s-M_1t)^2}g^2\right].$$

Substituting this equation into the equation (A·4) we finally obtain

$$\sum_p\sum_q s^pt^q[w_1S_{3/2}{}^{(p)}(w_1{}^2),\, w_2S_{3/2}{}^{(q)}(w_2{}^2)]_{12}$$
$$=-8(M_1M_2)^{1/2}\left(\frac{2\pi kT}{m_{12}}\right)^{1/2}\left(\frac{Ze^2}{2kT}\right)^2\ln\left(\frac{kTl_D}{Ze^2}\right)$$
$$\times\frac{1}{(1-M_2s-M_1t)^{3/2}}\left[1+\frac{3M_1M_2st}{1-M_2s-M_1t}\right], \tag{A·6}$$

where m_{12} is the reduced mass.

We note here that M_1 and M_2 appear only in the combination M_1t, M_2s, so the collision integral $[w_1S_{3/2}{}^{(p)},\, w_2S_{3/2}{}^{(q)}]_{12}$ has $M_1{}^{q+1/2}\,M_2{}^{p+1/2}$ as a factor.

By similar method the collision integral $[w_1S_{3/2}{}^{(p)}(w_1{}^2),\, w_1S_{3/2}{}^{(q)}(w_1{}^2)]_{12}$ can be calculated and we write here only the results:

$$\sum_p\sum_q s^pt^q[w_1S_{3/2}{}^{(p)}(w_1{}^2),\, w_1S_{3/2}{}^{(q)}(w_1{}^2)]_{12}=$$
$$8M_2\left(\frac{2\pi kT}{m_{12}}\right)^{1/2}\left(\frac{Ze^2}{2kT}\right)^2\ln\left(\frac{kTl_D}{Ze^2}\right)$$
$$\times\frac{a^{-3/2}}{1-st}\left[1+\frac{5M_1{}^2}{a}st+\frac{2M_1M_2}{a}\frac{st(1-s)(1-t)}{1-st}\right], \tag{A·7}$$

where $a=1-M_2(s+t)+(M_2-M_1)st$.

From this we obtain

$$\sum_p\sum_q s^pt^q[w_1S_{3/2}{}^{(p)}(w_1{}^2),\, w_1S_{3/2}{}^{(q)}(w_1{}^2)]_{12}$$
$$=8M_2\left(\frac{2\pi kT}{m_2}\right)^{1/2}\left(\frac{Ze^2}{2kT}\right)^2\ln\left(\frac{kTl_D}{Ze^2}\right)\frac{1}{(1-st)^{5/2}}\left[1+\frac{5st}{1-st}\right]+O(M_2{}^2), \tag{A·8}$$

$$\sum_p\sum_q s^pt^q[w_2S_{3/2}{}^{(p)}(w_2{}^2),\, w_2S^{5/2(q)}(w_2{}^2)]_{12}$$
$$=8\left(\frac{2\pi kT}{m_2}\right)^{1/2}\left(\frac{Ze^2}{2kT}\right)^2\ln\left(\frac{kTl_D}{Ze^2}\right)\frac{1}{(1-s)^{3/2}(1-t)^{3/2}(1-st)}+O(M_2) \tag{A·9}$$

It is clear from the definition, the collision integrals $\sum\limits_p\sum\limits_q s^pt^q[w_2S_{3/2}{}^{(p)},\, w_2S_{3/2}{}^{(q)}]_2$ can be obtained from

$$\sum_p\sum_q s^pt^q\{w_2S_{3/2}{}^{(p)}(w_2{}^2),\, w_1S_{3/2}{}^{(q)}(w_1{}^2)]_{12}$$
$$+[w_2S_{3/2}{}^{(p)}(w_2{}^2),\, w_2S_{3/2}{}^{(q)}(w_2{}^2)]_{12}\}$$

by taking $M_1=M_2=\frac{1}{2}$, $m_{12}=\frac{m_2}{2}$, and $Z=1$.

Hence we get

$$\sum_p\sum_q s^pt^q[w_2S_{3/2}{}^{(p)}(w_2{}^2),\, w_2S_{3/2}{}^{(q)}(w_2{}^2)]_2=8\sqrt{2}\left(\frac{2\pi kT}{m_2}\right)^{1/2}\left(\frac{e^2}{2kT}\right)^2\ln\left(\frac{kTl_D}{e^2}\right)$$
$$\times\frac{st}{[1-\frac{1}{2}(s+t)]^{5/2}(1-st)^2}\left[1-\frac{1}{2}(s+t)-\frac{1}{8}st+\frac{1}{4}st(s+t)-\frac{3}{8}(st)^2\right]. \tag{A·10}$$

From the mass dependence of this equation we can deduce the relation

$$[w_1S_{3/2}{}^{(p)}(w_1{}^2),\, w_1S_{3/2}{}^{(q)}(w_1{}^2)]_1=M_2{}^{1/2}[w_2S_{3/2}{}^{(p)}(w_2{}^2),\, w_2S_{3/2}{}^{(q)}(w_2{}^2)]_2 . \tag{A·11}$$

The equations (A·9) and (A·10) are also obtained by Landshoff.[5]

Effect of Heat-Treatment upon Sintered Cadmium Sulphide Photoconductive Films

by Saburo KITAMURA

Central Research Laboratories, Matsushita Electric Industrial Co., Osaka

(Received June 23, 1960)

When the sintered CdS:Cl:Cu photoconductive films[1,2] prepared by the flux method using $CdCl_2$ as flux material were heated in vacuum or in inert gas, the relation between dark current and temperature became irreversible, the activation energy decreased, and the trap concentration increased, and it was found that there appeared a peak at room temperature in thermally stimulated current curve.

The sintered CdS:Cl:Cu photoconductive films were obtained by sintering on a base plate of fused quartz of 20 × 20 mm size. The material of electrodes was gold evaporated on the surface of fused quartz before sintering CdS layers. The distance between two electrodes was 0.5 mm and the length of electrodes was 20 mm. With evaporated gold electrodes, the contact between electrodes and CdS was nonohmic below 0.1 volt while ohmic above 0.1 volt. When the sintered films were heated at a rate of 1°C/min and the dark current was measured by applying a D. C. voltage of 100 volts, the relation between dark current and temperature was reversible below 90°C, but it became irreversible above 90°C.

The relations between conductivity and $1/T$(°K) of both untreated films and films treated at 160°C in vacuum are shown in Fig. 1. It is seen that by heat-treatment in vacuum, the activation energy of sintered films decreases to a value of one twentieth of the initial one. The results of the measurements on thermally stimulated current are plotted in Fig. 2. Sintered films cooled at liquid air temperature were irradiated by a light from an incandescent lamp and a D. C. voltage of 30 volts was applied in darkness, and then they were heated at a rate of about 1°C per second. The variation of current in heating process was recorded by an X–Y recorder. The trap concentration of sintered film heat-treated in vacuum is about twenty times that of the initial value, and there is a peak at about room temperature in thermally stimulated current curve of the sintered film heat-treated in vacuum.

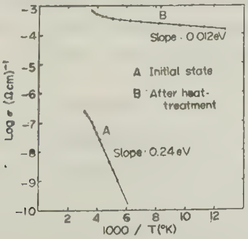

Fig. 1. Conductivity *versus* $1/T$(°K).

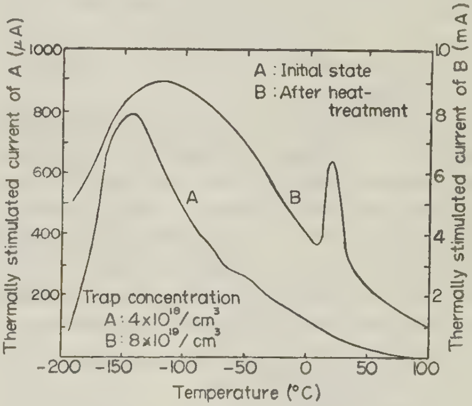

Fig. 2. Temperature dependence of thermally stimulated current; 30 volts D. C. was applied, heating rate about 1°C/sec.

Muscheid[3] and Woods[4] reported that CdS single crystal heated at 200∼300°C in vacuum had high conductivity due to sulphur vacancies. In sintered films these phenomena were found to appear above 90°C. By measuring the thermally stimulated current it is proved that the sintered films have large trap concentrations, but it is still unknown whether the peak at room temperature in thermally stimulated current curve of sintered films heated in vacuum is produced by sulphur vacancies or by other defects. Experiments are now carried on in order to investigate the peak at room temperature.

The author wishes to thank Professor K. Tanaka, Kyoto University, for his advice.

Ferroelectricity in The Potassium Ferrocyanide Group Ferroelectrics Substituted by Deuterium for Hydrogen

By Shigeru WAKU, Kunio MASUNO and Toshisuke TANAKA

Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Tokyo

(Received July 13, 1960)

In the previous papers,[1)2)] we reported the ferroelectric behavior in potassium ferrocyanide, $K_4Fe(CN)_6 \cdot 3H_2O$, and its isomorphous substances, $K_4Ru(CN)_6 \cdot 3H_2O$ and $K_4Os(CN)_6 \cdot 3H_2O$ and $K_4Mn(CN)_6 \cdot 3H_2O$. We attempted to substitute the water of crystallization of these cyano complexes by deuterium oxide.

After the dehydration of powdered samples of these cyano complexes by heating for 6 hours at 110°C, mother solutions were prepared by dissolving these dehydrated powders in heavy water containing 99.9% D_2O. Single crystals were grown by slow cooling of these mother solutions. In the case of $K_4Mn(CN)_6 \cdot 3D_2O$, as it was very unstable, we could not obtain deuterated compounds.

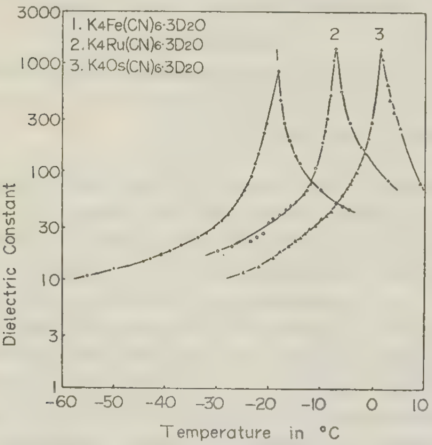

Fig. 1. Dielectric constant along [10$\bar{1}$] direction of deuterated potassium ferrocyanide group ferroelectrics.

Ferroelectric behavior of these deuterated cyano complexes were not significantly different from those of the normal cyano complexes except a little shifting of the Curie point toward the higher temperature side. Fig. 1 shows the temperature dependence of the small signal dielectric constant of these cyano complexes in [10$\bar{1}$] direction. Only one peak coresponding to the Curie point is shown in each curve. In [101] and [010] directions, no more than very weak anomaly is etected. Ferroelectric hysteresis loop appears only in [10$\bar{1}$] direction. Fig. 2 shows the temperature dependence of the spontaneous polarization P_s and coercive field E_c of these deuterated cyano complexes. The spontaneous polarization of the deuterated cyano complexes are somewhat larger than that of the normal cyano complexes. Table 1 shows the transition temperature of the normal and deuterated cyano complexes. Temperature sifting of the transition point by deuterium substitution is the smallest among the ready examined ferroelectrics.

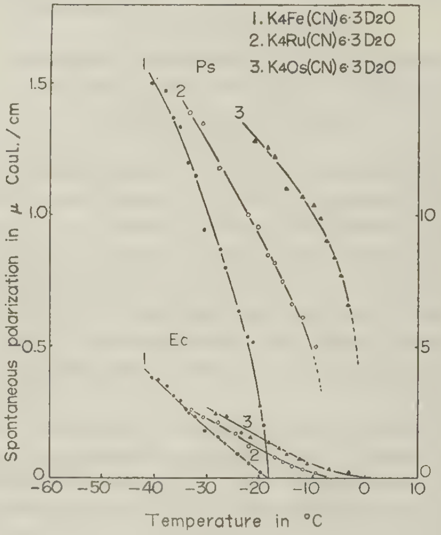

Fig. 2. Spontaneous polarization and coercive field along [10$\bar{1}$] direction of deuterated potassium ferrocyanide group ferroelectrics.

Table 1. The transition temperature of the normal and deuterated potassium ferrocyanide group ferroelectrics.

Impurity Shift of Pure Quadrupole Resonance Frequency

By Yoshiro IMAEDA

Faculty of Engineering, Tokushima University, Tokushima

(Received July 6, 1960)

It is well known that the line width of pure quadrupole resonances increases and its intensity decreases with the increase of impurity content in samples[1], but the frequency shift caused by the impurities has not been noticed except for a few cases[2,3] with exceptionally large shifts.

A careful measurement, however, revealed that an observable amount of the impurity shift exists in almost all cases. It is the purpose of this note to present the examples of these impurity shifts for bromates and chlorates.

In the present experiment, stable and sensitive regenerative spectrometers[4,5] operated at a low rf level are found to be essential in order to get faithful absorption curves without any dielectric heating of the samples which, if appreciable in magnitude, might result in a "temperature shift". And the temperature of the samples (0°C in the present experiment) ought to be kept constant with an accuracy of a few thousandths of a degree in every run in order to keep the temperature shift of the resonance frequency below the amount of the impurity shift.

Some of the experimental results are tabulated in Table I. The sign of the impurity shift is either positive or negative with respect to the frequency of pure specimen depending upon the kinds of the impurities. The general tendency is such that the larger size impurities than the original ions, when some of the latter ones are replaced by the former ones, decrease the frequency (−shift), and the smaller size impurities increase the frequency (+shift). The lines are always Gaussian, and no asymmetry in the line shape is observed for all specimens.

The dominant cause of the present impurity shift is believed to be due to a successive distortion of electronic wave functions about the impurities. And the change in the amplitude of the lattice vibrations due to impurities[3] would not be responsible for the present impurity shift, because the temperature dependence of the impurity shift for bromates is not noticed[6].

The details of the discussions as well as the experimental procedure will be published in the comming issue of the Journ. Sci. Hiroshima Univ. Ser. A.

It is a pleasure of the author to express his indebtedness to Professor H. Tazaki of Hiroshima University for the stimulating interest he has taken in the progress of this work and to Professor T. Kushida of the same University for the suggestion of the present investigation and his helpful advice and discussions and also to Professor Y. Kôi of Tokushima University for his valuable comments.

Table I. Impurity shift of P.Q.R. frequency. The observed shift in the resonance frequency caused by impurities in the lattice is shown in the fourth column, where a +sign and a −sign correspond to the increase and the decrease in the center frequency respectively. And the first column designates the host material whose halogen nuclei are observed.

Host material	Impurity	Impurity content (mol%)	Frequency shift (cps)	Halfwidth (cps)

Measurement of Temperature Dependence of T_1 of Proton in Some High Polymers by Pulsed NMR Technique

By Takao Kawai,* Masahumi Sasaki,**
Akira Hirai,** Tsuneo Hashi,**
and Akira Odajima***

**Yoshida College, Kyoto University*
***Department of Physics, Faculty of Science, Kyoto University*
****Research Institute of Applied Electricity, Hokkaido University*

(Received June 10, 1960)

In order to add to the information about the internal motion in high polymer, we have measured the spin-lattice relaxation time (T_1) of proton in some high polymers, in the temperature region from 20°C to 300°C, by 90°-90° pulse method at 25 Mc/sec. The description of the apparatus was already given.[1] The samples were poly-vinyle acetate (PVAc), poly-methyl acrylate (PMA), poly-methyl methacrylate (PMMA), etc. The error in the measurement was about ±10%.

The results obtained are shown in Fig. 1. For PVAc and PMA, the curves of log T_1 *versus* $1/T$ are simply V-shaped, and the dominant mechanism which determines T_1 is considered to the segmental motion. For PMMA, the curve is not V-shaped but has a tendency to have another minimum at lower temperature.

The correlation time of the internal motion in high polymer is distributed over a wide range, as well-known from the dielectric and mechanical relaxation experiments. Since simple analytic formulas relating T_1 with distributed correlation time are not available at present, we have tentatively used BPP theory for analysis, namely.

$$\frac{1}{T_1}=\frac{3}{10}\frac{\gamma^4\hbar^2}{b^6}\left\{\frac{\tau_c}{1+\omega^2\tau_c^2}+\frac{4\tau_c}{1+4\omega^2\tau_c^2}\right\},$$

$$\tau_c=\tau_0\exp\left(\frac{\Delta E}{RT}\right)$$

The results thus obtained are shown by the dashed curves in Fig. 1.

For further study, it is desirable to measure T_1 at lower temperature and at various resonance frequencies, and the spin-echo decay time. We are now proceeding along this line.

The authors express their sincere thanks to Prof. I. Takahashi for his continual interest and discussions. Their thanks are also due to the members of our laboratory for their assistances.

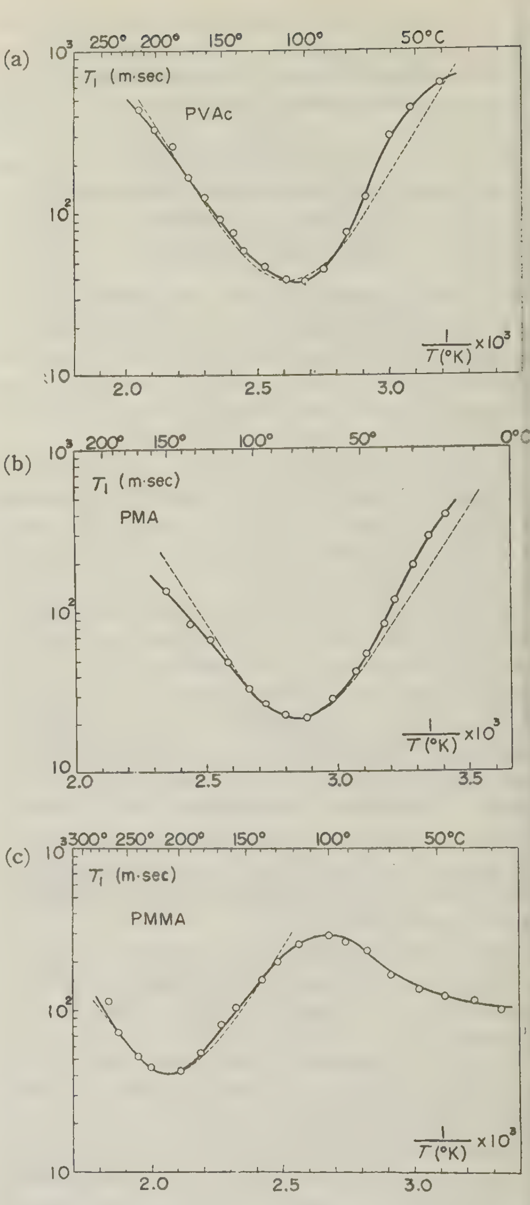

Fig. 1. Temperature dependence of T_1 of proton in some polymers. Solid curve represents the experimental results. Dashed curve represents the temperature dependence obtained by BPP theory, using following parameters.

(a) Sample; PVAc,
b=1.9Å, $\tau_0=6\times10^{-16}$ sec, ΔE=12 Kcal/mole.
(b) Sample; PMA,
b=1.8Å, $\tau_0=2\times10^{-16}$ sec, ΔE=11 Kcal/mole.
(c) Sample; PMMA,
b=1.9Å, $\tau_0=2\times10^{-14}$ sec, ΔE=12 Kcal/mole.

On the Mechanism of the Electrical Conduction in CdSe

By Hirosi Tubota, Hiromichi Suzuki
and Kazuyoshi Hirakawa

General Education Department, Kyushu University, Fukuoka

(Received June 28, 1960)

In order to study the mechanism of the electrical conduction in CdSe, the following experiments were performed. On the surface of single crystals of n-type CdSe obtained by slow cooling from the melt of stoichiometric composition, various elements of Group I, II, III, IV and VI were evaporated, and the crystals were heat-treated at various temperatures for various durations so that the elements diffused into the bulk material. These treatments were performed in vapor of the corresponding elements. The changes of resistivities of the treated specimens are shown in following figures.

Fig. 1 shows the behaviors of room-temperature resistivities of the specimens as functions of the duration of heat treatment at 350°C.

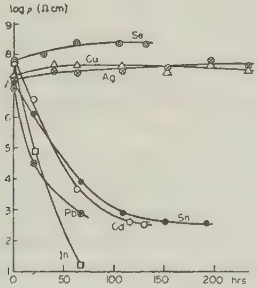

Fig. 1. Electrical resistivity against the duration of heat treatment for specimens treated at 350°C.

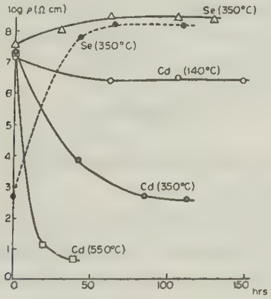

Fig. 2. Electrical resistivity of samples doped with Cd and Se.

Fig. 2 shows the effects of doping with Se and also with Cd at different temperatures. The result shown by the dashed curve in the figure was obtained for the specimen doped with Se after doping with Cd at 350°C.

It was found that resistivities of the heat-treated specimens changed toward the value of those of CdSe as grown when specimens were kept in air at room temperature.

Considering these results, we can conclude that the impurity centers contributing to the electrical conduction in CdSe may presumably be Se vacancies. Hence, if a specimen was treated with Se, its resistivity may increase because of the decrease of Se vacancies, whereas if treated with Cd the reverse is the case. As the doped atoms of Group III and IV may locate in the interstitial sites, resistivities decrease. In the case of Group I, resistivities increase slightly, This may be because these elements may substitute Cd atoms, but their diffusion constants are small. In the cases of foreign elements, it may be determined by consideration of atomic radii that whether they substitute the lattice atoms or locate in the interstitial sites. The atomic radii of the elements are given in Table I after Wyckoff. Since the atomic radii of Cu and Ag are smaller than that of Cd, they substitute Cd atoms. On the other hand, since the radii of In and Pb are larger than those of Cd and Se, they locate in the interstitial sites. As the diffusion through the interstitial sites are easier, it can be understood that in the cases of In and Pb the changes of resistivity are large. In the case of Sn, however, the result is difficult to understand from this consideration.

As seen above, the electrical conduction in CdSe might be due to the presence of Se vacancies. This implies that the CdSe crystals obtained from the melt of stoichiometric composition are excess in Cd. This is in agreement with the suggestion¹⁾ that in chalcogenides the compound contains the excess of the element with higher boiling point.

The authers wish to express their sincere thanks to Prof. T. Okada for his kind advice.

Table I. Atomic radii after Wyckoff (in Å)

I	II	III	IV	VI
Cu				Se
1.27				1.16

Characteristics of Krypton Counters

By Tatsusaburo Suzuki & Jiro Yuhara
Research & Development Institute, Japan
Tecchu Majima
Defence Agency, Tokyo
Japan Radio Company, Tokyo

(Received July 15, 1960)

In 1956 W. Parrish and T. R. Kohler⁽¹⁾ reported that they used a krypton counter (total pressure 500 mmHg) having 10% ethylene added to analyze the soft X-rays. But they did not describe the characteristics of the counter in detail. The authors experimented with the characteristics of krypton counter, since it seemed advantageous to use a krypton counter in order to analyze the soft X-rays because of high gas absorption obtained in the short length. The glass wall counters having gold sputtered cathodes and 0.05 mm.φ center wires were filled with 99.9% krypton gas made by Linde, and pure ethylene added as quenching gas. The partial pressures of krypton and ethylene were 150–500 mmHg and 2.5–52 mmHg, respectively. The counter out-puts were connected to the cathode-follower pre-amplifier plus Tracerlab pulse amplifier and counted by a Tracerlab super-scaler. The γ-ray 100 μc source of Cs^{137} was placed at the positions 10 cm, 20 cm, or 1 m distant from the counters.

The obtained discharging characteristics vs the partial pressures are shown in Fig. 1. It is evident from Fig. 1 that the characteristics of the counters depend mainly upon the partial pressures of ethylene, but not upon that of krypton. Because the counters having equal partial pressures of ethylene give similar plateau curves in spite of the differences of that of krypton, it seems possible to conclude that the characteristics of the counters are dependent upon only partial pressures, and not on the percentage of ethylene. At the partial pressures of ethylene which are lower than 8.5 mmHg the counters usually discharge continuously or semi-continuously at the voltages slightly higher than the starting voltages. At the partial pressure of ethylene higher than 45 mmHg they give only poor plateau curves. But at the partial pressures 17.5–35 mmHg of ethylene they give appreciable good plateau curves. The counting-rate of the counters giving good plateau curves was measured at the different sensitivities of the Tracerlab pulse amplifier from 1 mV to 100 mV. The counters out-puts were connected to the Tracerlab GM counter pre-amplifier and were counted. In this case the counts obtained agreed very well with the counts in the cases of pulse amplifier sensitivities 2–50 mV. Therefore it is evident that the counters experimented have Geiger-Müller counters properties. The counters containing mixtures of krypton and methane were also experimented. The partial pressures of methane were 10, 20, 30, 40, and 50 mmHg. They give poor plateau curves or discharge continuously. The counters containing mixtures of krypton and ethylene have good self-quenching properties. On the other hand the counters containing mixtures of krypton and methane have poor self-quenching properties. This fact can be accounted for by the fact that the ionization potential of the krypton is larger than that of the ethylene and less than that of the methane, and therefore the secondary emissions at the cathodes can be quenched in the krypton counter containing the ethylene and not in that containing the methane⁽²⁾. At the ethylene partial pressures which are less than 8.5 mmHg the counters discharge continuously, because the appreciable number of krypton ions can reach the cathodes after many collisions.

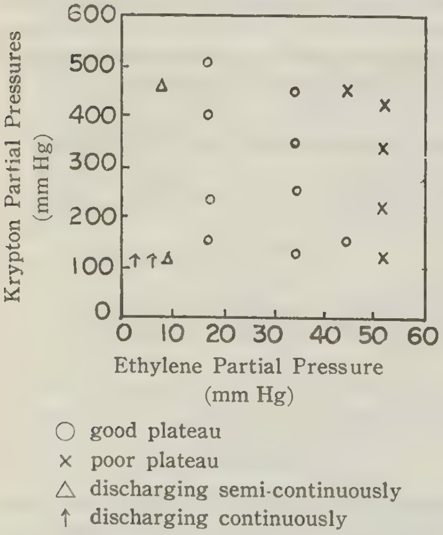

Fig. 1. Plotts of the krypton and ethylene partial pressures.

Magnetoresistance Effect in the Magnetization Reversal of Permalloy Films

By Eiji TATSUMOTO, Kaizo KUWAHARA and Mitita GOTO

Department of Physics, Faculty of Science, Hiroshima University, Hiroshima

(Received June 23, 1960)

In Permalloy films, it has been accepted that the magnetization reversal takes place by domain wall motion and rotation in low frequency fields parallel and perpendicular to the easy direction, respectively[1)2)]. In the present work, this was confirmed by measuring the magnetoresistance effect which is expressed as

$$\Delta R/R = A \sin^2\theta \qquad (1)$$

where A is a constant and θ is the angle between the magnetization vector and primary current[3)].

The specimens used were two kinds of rectangular films of 80 Ni Permalloy (10 mm × 20 mm) which will be denoted by (//) and (⊥) depending on whether the lengthwise direction is parallel or perpendicular to the easy direction, respectively. They were made on glass substrates heated at 200°C by depositing in the presence of fields in vacuum and their thickness is about 2×10^3 A.

While the anisotropy field H_k has usually been determined by measuring the linear relation between B and H in low driving fields perpendicular to the easy direction[1)], it can also be determined by measuring the relation of $\Delta R/R$ and H in that case, because Eq. (1) can be rewritten as $\Delta R/R = A(1-H^2/H^2_k)$, since $\cos\theta = H/H_k$. Both linear relations, B–H and $\Delta R/R$–H^2, were found to be equally applicable, and the H_k obtained is 4.0 oe in the (//) specimen and 4.5 oe. in the (⊥) specimen.

Figs. 1 and 2 show B–H, dB/dt–H and $\Delta R/R$–H curves from the top to the bottom which were measured on the (//) and (⊥) specimens in a 60 cps field of 10 oe. peak. The observed B, dB/dt and $\Delta R/R$ and H are all parallel to the long side direction of the specimens.

In the (//) specimen, according to the B–H and dB/dt–H curves in Fig. 1, the magnetization reversal is interpreted as due to nucleation of reverse domains and their growth, as is commonly accepted. This interpretation is confirmed by the $\Delta R/R$–H curve in Fig. 1 (c), because it indicates the fact that very little rotation occurs. In detail, however, a small variation in $\Delta R/R$ is observed near the coercive force H_c as seen faintly in the figure. We suspect that it may be attributed not to a small coherent rotation but to local rotation on account of the fluctuation of H_k in direction and magnitude. The local rotation would presumably be responsible for nucleation of the reverse domains.

In the (⊥) specimen, it has been assumed that the B–H and dB/dt–H curves in Fig. 2 are due to coherent rotation. This is also confirmed by the $\Delta R/R$–H curve in Fig. 2 (c) which illustrates that there occurs almost coherent and continuous rotation with the variation of fields. In detail, however, the rotation does not seem to be perfectly coherent, because the maximum variation of $\Delta R/R$ is slightly smaller than A which is the maximum in the coherent rotation corresponding to the value at 90° in Eq. (1). We also suspect that, as in case of the (//) specimen, it may be attributed to the local fluctuation of H_k. In this magnetization process, the clockwise and anti-clockwise rotations must start simultaneously in different regions so that the boundaries would be fuzzy in the initial process but probably be converted abruptly to the distinct ordinary walls. Then, we suspect that the Barkhausen discontinuities observed near H_c in Fig. 2 (b) would be due to the abrupt conversion.

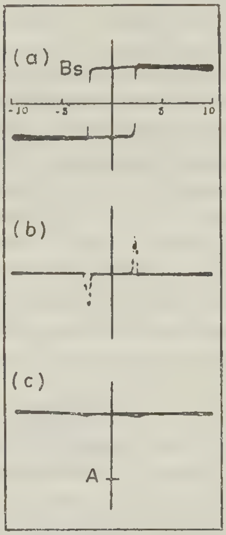

Fig. 1. The (//) specimen: (a) is B–H curve, (b) dB/dt–H curve and (c) $\Delta R/R$–H curve.

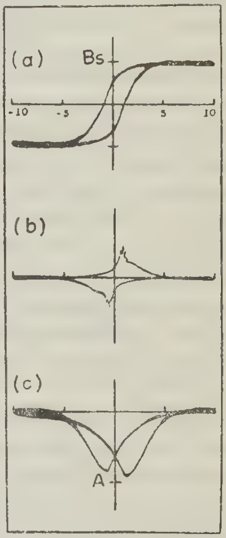

Fig. 2. The (⊥) specimen: (a) is B–H curve, (b) dB/dt–H curve and (c) $\Delta R/R$–H curve.

Magnetostriction of Yttrium Iron Garnet

By Akira NAKAMURA and Yoshikazu SUGIURA
Electrotechnical Laboratory, Nagatacho,
Tokyo, Japan

(Received July 25, 1960)

The magnetostriction of polycrystalline Y.I.G. was measured by the method using the adhesive strain gauge. In order to measure the rather small change in length, the output signal of the strain gauge bridge was amplified by the chopper amplifier. The over-all sensitivity of the relative change in length reached nearly 2×10^{-8}. Somewhat modified method using coaxial cavity[1] was also used for checking the sign of the magnetostriction. Although the sensitivity is in the vicinity of 1×10^{-7}, the same sign for pure nickel metal was observed.

The sample was prepared from 99.9% Y_2O_3 and 99.99% Fe_2O_3 by sintering in air at 1350°C. The X-ray diffraction patterns showed no extra lines. The sample was placed in a Dewar vessel to avoid temperature fluctuation. The saturation magnetostriction of polycrystalline material is expressed as

$$\frac{\delta l}{l}=\frac{3}{2}\lambda_s(\cos^2\theta-1/3)$$

where θ is the angle between the magnetic field and the measured direction of length.

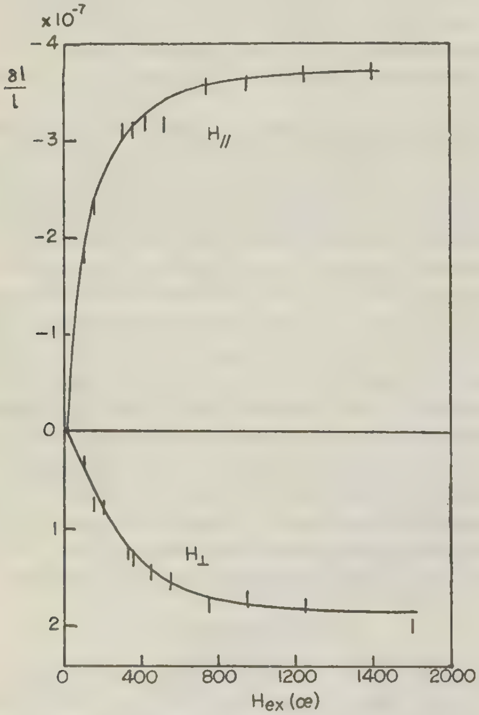

Fig. 1. The fractional change in length of polycrystalline Y.I.G. vs external magnetic field at room temperature.
The dimension of the sample: $6.9\times2.4\times0.9$ (mm).

The relative change in length is plotted against the applied magnetic field in Fig. 1. From this curve we obtain the saturation magnetostriction constant $\lambda_s=-(3.7\pm0.5)\times10^{-7}$. This rather small value seems to be explained by the dipolar interaction.[2] Since Tsuya[3] has explained the magnetostriction of Mn-ferrite by the dipolar interaction.

In the case of the dipolar interaction the magnetostriction constants for Y.I.G. is expressed as follows,

$$\lambda_{100}=2U/(C_{11}-C_{12}),\quad \lambda_{111}=-2U/3c_{44}$$
$$U=(2S_{AA}+3S_{BB}-4S_{AB})\cdot32M^2$$

where c_{ij} is the elastic constants and M is the saturation magnetization per cc. The values of S_{lk} are calculated by the lattice sum method as follows;

$$S_{AA}=0.046,\quad S_{BB}=0.094,\quad S_{AB}=-0.099.$$

As the elastic constants for Y.I.G. has not been obtained, we substitute the values for Ni-ferrite.[4] Taking $M=138$ gauss and

$$c_{11}=21.99\times10^{11},\quad c_{12}=10.94\times10^{11},\quad c_{44}=8.12\times10^{11}$$

(dyne cm^{-2}), the calculated value are

$$\lambda_{100}=8.4\times10^{-7},\quad \lambda_{111}=-3.8\times10^{-7}$$
$$\lambda_s=1/5(2\lambda_{100}+3\lambda_{111})=1.1\times10^{-7}$$

If we take as c_{ij} the value of magnetite or Co-Zn ferrite[5] λ_s becomes 0.2×10^{-7} or 0.8×10^{-7}.

The order of magnitude of the calculated value for λ_s is not so far apart from the experimental value, but its sign is different from the measured one. The shape effect[6] and the magneto-caloric effect may be smaller than 0.2×10^{-7}. Thus we may probably have to consider some other effect originating from the higher order perturbation relating to the L-S coupling, in order to explain the measured negative λ_s.

The authors express their sincere thanks to Drs. M. Tachiki, E. Sawaguchi, and N. Sakamoto K. Matsuura for their kind discussions.

The Influence of Aging Treatment on the Temperature Dependence of the Electric Resistance in Alnico 5 Magnet

By Tatsuo Fujiwara and Tetsuo Kato
Daido Steel Co., Research Lab. Nagoya

(Received July 22, 1960)

In Alnico 5 Magnet, it has been believed that its magnetic anisotropy and high coercivity are principally founded on the shape anisotropy of elongated fine precipitates oriented to the direction of magnetic field which is applied during heat-treatment. However, the reversibility discovered recently in its magnetic properties during aging process has brought out a certain presumption that some other mechanisms except the precipitation may affect them, too.1)2) It was pointed out by Clegg and co-workers3) that the perfect separation of phases would not take place in the structure of Alnico 5 magnet which gives best magnetic properties. Its best magnetic properties brought out by aging treatment at about 600°C may also depend upon another mechanism, except the growth of precipitates. In order to interpret its phenomenon, the present authors investigated first the influence of aging treatment on the temperature dependence of the electric resistance associated with its magnetic properties. The heating-rate in measurement is about 4.5°C/min. In Fig. 1, the curvatures as indicated by AB, BC, and CD can be noticed on the curves of the specimens aged at and under 600°C, and in aging at 625°C the curvature as indicated by AB vanishes. This phenomenon suggests that there is a transformation which starts at about 300°C and finishes at about 600°C.

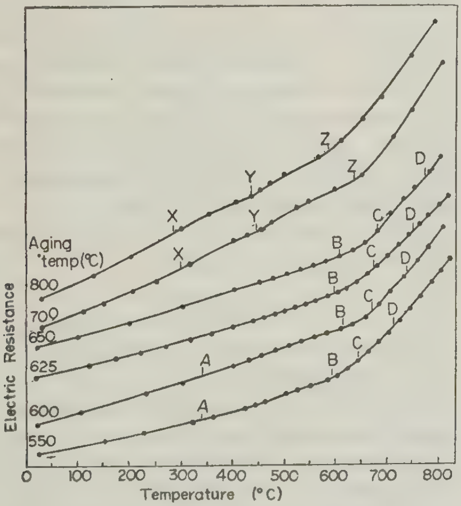

Fig. 1. Electric resistance-temperature curves in Alnico 5 aged 4 hrs. at each temperature from 550 to 800°C after solution heating and subsequent cooling at about 1.5°C/sec.

Moreover points C and curvatures CD on the curves correspond to the decreases of reversibility of its magnetic properties originated from aging treatment at about 650°C.4) This fact suggests the perfect separation to two phases to be commenced from this temperature. At the specimens aged at above 700°C, each curve shows a kink point at 450°C as indicated by Y. This change corresponds to the change at the temperature dependence of the saturated induction.3)

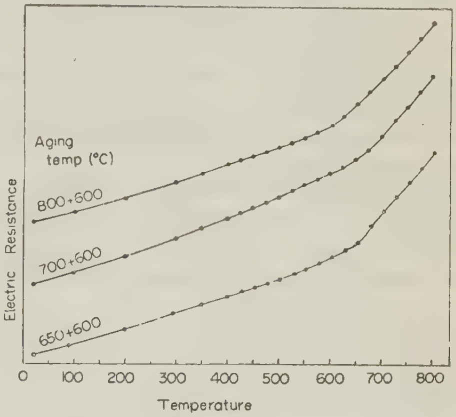

Fig. 2. Electric resistance-temperature curves in Alnico 5 aged 4 hrs. at each temperature from 650 to 800°C after solution heating and subsequent cooling at about 1.5°C/sec, and re-aged 4 hrs. at 600°C.

Fig. 2. shows the curves for the case reaged for 4 hours at 600°C. These curves do not show the curvature and the kink point like AB and Y indicated in Fig. 1, respectively. From this fact, it is suggested that the nature of the transformation caused by aging treatment at 600°C differs from one caused by aging treatment above 650°C.

From these experimental results, it is concluded that there are two different mechanisms during aging process of Alnico 5 magnet. One will occur during aging process at about 600°C that gives the best magnetic properties, and may be something like order-disorder transformation. And the other will be lapped over the former mechanism during aging process above 650°C, which is precipitation.

Preparation of Ferromagnetic Chromium Dioxide

By Buichi KUBOTA

Technical Research Department, Wireless Division,
Matsushita Electric Industrial Co., Ltd.
Kadoma, Osaka, Japan

(Received June 14, 1960)

Since it has been reported[1][2][3][4] that ferromagnetic chromium dioxide, CrO_2, was formed by the thermal decomposition of chromium trioxide CrO_3, an increasing interest is being shown in the magnetic properties of chromium dioxide.[5] The present paper describes a new preparation method based on the thermal decomposition of CrO_3 under a high oxygen pressure resulting from the oxygen liberated from CrO_3 itself.

Chemically pure CrO_3 containing 0.059% of sulfate ion and 0.2% of absorbed water was used as a starting material. Various amounts of dry CrO_3 were charged in the high pressure bomb which was made of stainless steel and whose inner volume was about 36 cm³ (30 mmϕ, 50 mm height), and then heated at a constant rate of 10°C per hour in an electric furnace. The temperature was measured at the top and bottom of the bomb, and the temperature difference between them was controlled within 1°C. The high oxygen pressure in the bomb was caused by the oxygen liberated from CrO_3 itself and increased with the temperature. The pressure was measured with a Bourdon gauge set in the bomb. The relations between the temperature and oxygen pressure are shown in Fig. 1. by solid lines. The lines show that the pressure increases by step with the temperature. It will be concluded that the decomposition promotes remarkably in the temperature regions of the vertical parts of these curves and does not occur in those of the horizontal parts.

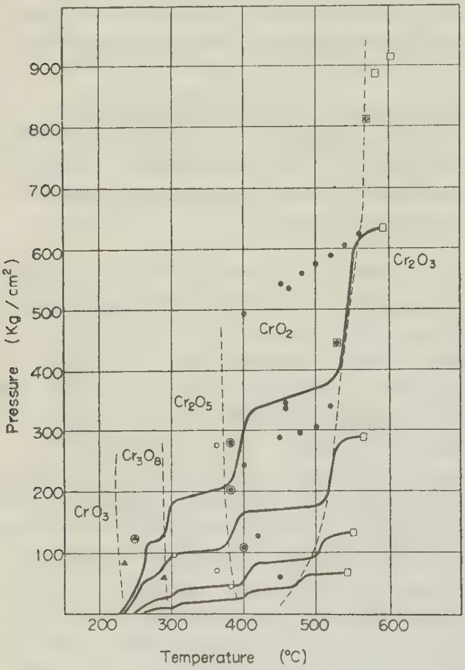

Fig. 1. The relation between the heating temperature and oxygen pressure in the thermal decomposition of chromium anhydride, CrO_3. ▲, ○, ● and □ show the results of isothermal heat treatments, indicating that the crystal structure are Cr_3O_8, Cr_2O_5, CrO_2 and Cr_2O_3, respectively.

Dotted lines show roughly the boundaries among the various oxides.

In order to confirm this conclusion, isothermal heat treatments were also carried out. As above mentioned, dry CrO_3 in the bomb was heated up to the various temperatures and kept for several hours at each temperature and quenched in air. The X-ray powder patterns of the products were observed. The results are shown in Fig. 1, indicating that their crystal structures were either one or two of Cr_3O_8, Cr_2O_5, CrO_2 and Cr_2O_3. From decomposition losses of the samples heated at 1000°C for 2 hours, the ratios of the oxygen to chromium ion were determined. From the available data, it was found that their chemical formula were $CrO_{2.6\sim2.7}$, $CrO_{2.4\sim2.5}$, $CrO_{1.9\sim2.1}$ and $CrO_{1.5}$, respectively.

The magnetic properties of the chromium dioxide prepared by heating CrO_3 at 480°C for 4 hours under the oxygen pressure of about 560 kg/cm², were measured with a magnetic balance in the temperature range from 77°K to 500°K. The ratio of the oxygen to chromium ion was 1.997, as a result of the thermogravimetric analysis. The Curie temperature was 117°C and the saturation magnetization at O°K was 133.7±2 gausses/gram, from which the Bohr magneton number of a Cr^{4+} ion was calculated to be 2.01±0.03.

The author wishes to thank Mr. F. Kanamaru and Mr. H. Chiba for their help.

A New Method to Determine Hydration Energy of Ion

By Yoshio ISHIDA

Department of Physics, Faculty of Education Shimane Univerity, Matsue

(Received June 10, 1960)

The method reported here is based upon the double-shell model for hydration of ion and the idea was got from the following experimental facts. The molal volume of the hydration sphere can be obtained by measurement of either of the compressibility and the dielectric constant versus the concentration of the aqueous solution of metallic salt. The molal volume Φ_β which can be obtained from the compressibility measurement, is represented by

$$\Phi_\beta=-\frac{1000A}{\beta_1}-\frac{1000B}{\beta_1}C^{1/2} \tag{1}$$

assuming that the sphere is imcompressible. A and B are the constants in the relation $\beta=\beta_1+Ac+Bc^{3/2}$, where β and β_1 are the compressibilities of the solution and the pure water respectively, and C the molal concentration. The molal volume $\Phi_{\varepsilon 0}$ which can be obtained from the dielectric measurement, is given by

$$\varepsilon=\varepsilon_1-\frac{C}{1000}\Phi_{\varepsilon 0}(\mathcal{E}_1-\mu^2)\frac{1+2\varepsilon_1}{\mu^2+2\varepsilon_1}, \tag{2}$$

assuming that the dielectric constant of the sphere reduces to its optical value. In the expression, ε and ε_1 are the dielectric constants and μ the refractive index of pure water. The values of $\Phi_{\beta 0}$ (Φ_β at infinite dilution C→O) of several salts were calculated from the data of Bachem,[1] Yasunaga[2] and the present author, and those of $\Phi_{\varepsilon 0}$ from the data of Hasted, Ritson and Collie.[3] We find that $\Phi_{\beta 0}$ is nearly equal to $\Phi_{\beta 0}$ for NaCl and KCl, but greater than $\Phi_{\beta 0}$ for $MgCl_2$ and $BaCl_2$. Therefore, it is reasonable to assume the double-shell structure for hydration sphere. The first shell which is conceived referring to $\Phi_{\beta 0}$ responds to neither the change of the mechanical pressure nor of the electric field. The second shell which is referring to $\Phi_{\varepsilon 0}-\Phi_{\beta 0}$, however, does respond to the change of the mechanical pressure but not of the electric field. In order to discuss matters about separate ion, we divided $\Phi_{\beta 0}$ and $\Phi_{\varepsilon 0}$ into the values of respective ions according to ionic mobilities and then obtained the coordination numbers n_1 and n_2 constituting the first and the second shell. The effective radius R_{eff} of the shell was also obtained. Referring to Bernal-Fowler's study,[4] we have attained the formula to calculate the hydration energy U_h as follows:

$$U_h=\frac{\varepsilon_1-1}{2\varepsilon_1}\frac{Z^2e^2}{R_{eff}}+n_1P_1+n_2P_2-(n_1+n_2)u_w, \tag{3}$$

where the first term gives the change of the free energy outside the shell, P_1 is a mutual potential energy between a water molecule in the first shell and the ion, P_2 that between a water molecule in the second shell and the ion, and u_w energy which a water molecule in the shell had in pure water. From Fig. 1, we can get

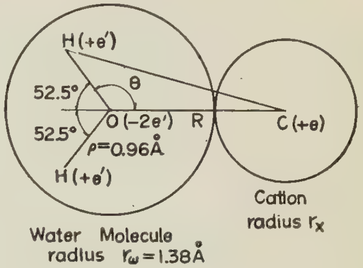

Fig. 1. A water molecule attaching to a univalent cation.

$$P_1=\frac{2e'e}{R}-\frac{2e'e}{\sqrt{R^2+\rho^2+2R\rho\cos\theta}}-\frac{b}{R^9}, \tag{4}$$

where e', effective charge of H, is approximately equal to $e/2$. The last term gives the quantum mechanical repulsive potential, in which b can be obtained by $\partial P_1/\partial R=0$. As to P_2 we can calculate it, assuming that the radius of ion becomes r_x+2r_w. We can evaluate u_w as 8.3 [kcal/mol] from the definition. Thus, we calculated the values of U_h of several ions, which are tabulated in Table I with other related values. They coincide roughly with the values given by different researchers and in different ways.

Table I. Hydration energy U_h calculated and other related values

Ion	n_1	n_2	R_{eff} [Å]	U_h[kcal/g.ion]
Na^+	4	0	3.38	121
K^+	3	0	2.92	81.1
Mg^{2+}	8	8	4.99	455
Ba^{2+}	10	4	4.82	429
Cl^-	2	0	2.51	67.4

The author wishes to thank Professor I. Takahashi of Kyoto University for his continual encouragement and valuable discussion.

On the Stripe Pattern during Rolling of Viscous Materials

Toshimaro Sone, Masayoshi Fukushima
Research Laboratory, Snow Brand Milk Products Co. Ltd. Higashi-Sinagawa Tokyo
Eiichi Fukada
Kobayashi Institute of Physical Research Kokubunji, Tokyo

(Received July 11, 1960)

A regular pattern of stripe has been observed in a number of viscous materials during rolling on the roll mill. The photograph shows the stripe pattern that appeared in the butter during rolling. The roll mill employed is the ordinary type of two duplicate cylinders which is originally designed for the calendering of synthetic resins at high temperature. The length and diameter of roll are 17.5 cm and 7.6 cm respectively and the speed of rotation can be varied from 18 to 45 r.p.m.

As is seen in the photograph, the pattern appears on both surfaces of rolls, parallel to the direction of rotation and with the same distances between successive peaks. The distance between peaks in the stripe is closely associated with the viscosity of the material on roll. Fig. 1. depicts the relation between the distance between peaks D and the viscosity η of the butter during rolling. a is the clearance between two rollers. The experimental formula derived for the relation is $\eta=\eta_0 \exp C/(D_0-D)$, where C and D_0 are constants which are determined by experiments. The viscosity η has been measured at 600 c/s by an oscillation-plate viscometer. Some results for the condensed milk is also plotted in the same curve.

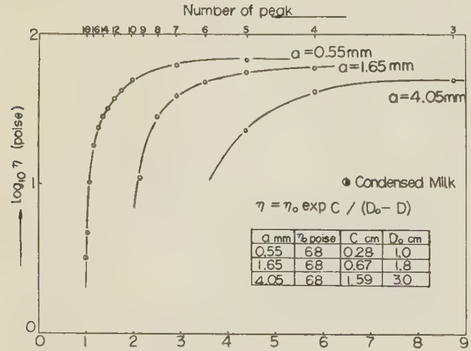

Fig. 1.

When the butter is subjected to working by the roll mill, the viscosity of butter decreases gradually with the rolling time. The number of peaks in stripe increases, in another words, the distance between peaks decreases with the decrease of viscosity. When the effective length of roller is varied by moving the two spacers located in both ends of roll, the distance between peaks is never changed, although the number of peak is inevitably altered.

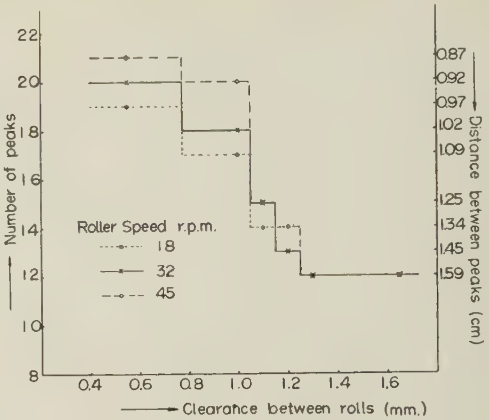

Fig. 2.

The generation of the stripe pattern is quite stable. Even if the pattern is broken by stirring the butter mechanically, it reappears again directly after passing of material through the clearance of rolls. The stripe with a certain number of peaks is stable for a certain range of viscosity. If the viscosity decreases further, the alignment of peaks becomes unstable and fluctuating, then a new peak adds the stripe and makes the pattern stable again. Therefore, the correlation curve between the viscosity and the distance between peaks is not continuous but discontinuous one with the zig-zag breaks.

The similar behaviour during rolling has been observed in many materials other than butter, for example, honey, syrup, grease, silicone oil etc. Fig. 2. illustrates the relation between the clearance of rolls and the distance between peaks in the stripe observed in a printing ink on the roll mill. The apparent viscosity of printing ink decreases with the increase of shear rate of flow, which is determined by the roller speed and the clearance between rolls. Fig. 2. reflects, therefore, the close correlation between the distance between peaks and the apparent viscosity of printing ink.

α-Trapping Centers in n-Type Silicon

By Jun'ichi OKADA and Tetsuro SUZUKI
Matsuda Research Laboratory
Tokyo Shibaura Electric Co., Ltd.,
Kawasaki Japan

(Received July 26, 1960)

It has been known that there are several kinds of trapping centers1),2) in a silicon crystal which is pulled from a melt in a fused silica crucible. Kaiser, Frisch and Reiss3) have suggested that these trapping centers would correspond to the electrically active complexes containing two or three oxygen atoms. They have also shown that the complexes containing four oxygen atoms are ascribed to the thermal donors formed during heat treatment at 450°C, and have postulated that these electrically active complexes are generated by the successive reactions from atomically dispersed oxygen atoms. And the density of these dispersed oxygen atoms can be assumed to remain nearly constant3),4) in the initial stage of the annealing process. According to this assumption, it can be shown that the increase of these electrically active complexes is monotonous against the annealing time. In order to see whether this expected behavior of the complexes is in accordance with that of the density of α-trapping centers or not, we have investigated the rate of formation of α-trapping centers and thermal donors in n-type silicon crystals grown from quartz crucible due to annealing at 450°C.

Our experimental procedure and results are as follows. In the first step, the etched specimen was heated on a molybdenum boat in a purified hydrogen atomosphere for 30 minutes at 1350°C. Then, it was quenched by sliding the molybdenum boat to room temperature part of the furnace. In the succeeding steps, the specimen was heated in the same furnace for definite time intervals at 450°C, repeatedly. After each step of the heat treatments, the densities of added electrons and α-trapping centers were measured. The former was estimated from the resistivity, and the latter was estimated from the time dependence of the photoconductivity. An example of our experimental results is shown in Fig. 1. The increase of electron densities is monotonous in the initial stage of annealing. However the density of α-trapping centers is zero after quenching from 1350°C and shows maximum for annealing time of about 30 minutes at 450°C. Thus, this result indicates that α-trpping centers in n-type silicon cannot be described as the complexes containing two or three oxygen atoms. On the other hand, it has been confirmed that an oxygen-free silicon crystal which is grown by floating-zone technique contains no trapping center. This fact indicates that a trapping center has something to do with the presence of oxygen atoms dispersed in a silicon crystal. Accordingly, it may be predicted that α-trapping centers would correspond to the complexes which contain not only oxygen atoms but also other impurity atoms or crystal defects, i.e. vacancies, interstitials or dislocations.

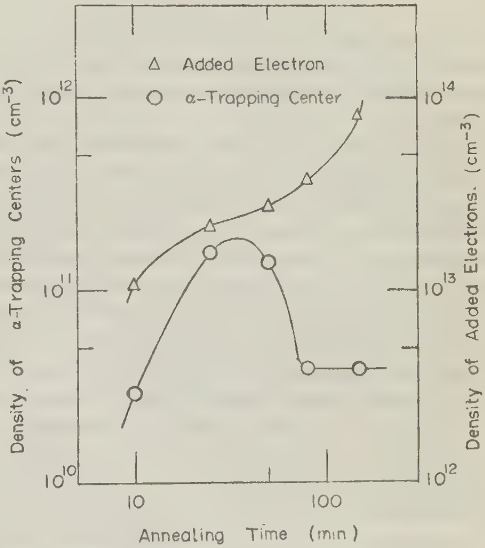

Fig. 1. Densities of α-trapping centers and added electrons *versus* annealing time at 450°C.

The behavior of trapping center is now being investigated against the following conditions: (1) speed of quenching from 1350°C (2) dislocation density (3) concentration of dissolved oxygen atoms.

We are indebted to Mr. Toshio Abe and Mr. Teruo Kobayashi for their kind advices and discussions.

Die Schwankung der Zündstelle eines brennbaren Gemisches bei der Selbst-Zündung in Stosswellen

von Kunio TERAO

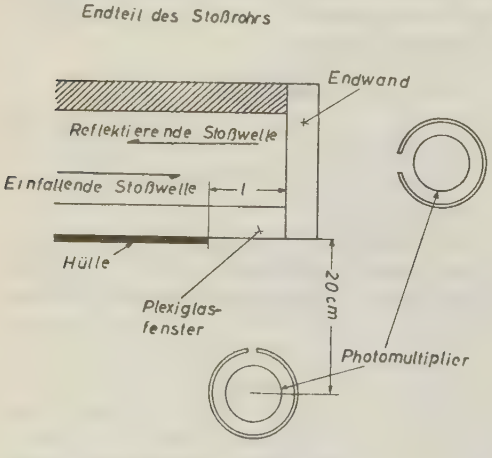
Institut für physikalische Chemie der Universität Göttingen

(Received July 9, 1960)

Die Induktionszeit der Selbstzündung eines brennbaren Gemisches hat allgemein eine Schwankung(1), die aus physikalischen Gründen unvermeidlich ist.

Um diese Schwankung der Zündstelle zu messen, wurde ein Stoßrohr von 4 m Länge und 3 cm × 3 cm Querschnitt benutzt, und der Versuch wurde genau so wie bei der Messung(1) der Induktionszeit der Selbstzündung durchgeführt, nämlich das Rohr wurde mit einer Membrane aus Aluminiumfolien in zwei Teile getrennt. In den ersten Teil wurde Hochdrucktreibluft eingeführt und in den andern wurde das Gemisch eingeführt. Wenn die Versuchsbedingungen erfüllt waren, wurde die Membrane mit einer Stechnadel zerbrochen, so daß die Stoßwelle in das Gemisch läuft. Die Entzündung entsteht in der reflektierenden Stoßwelle an der Endwand.

Als Endwand wurde eine Plexiglasplatte eingesetzt, so daß man von draußen mit einem Photomultiplier die Entzündung im ganzen Stoßrohr messen kann. An einer Seite des Endteils des Stoßrohrs wurde ein Fenster aus Plexiglas angebracht, so daß man von dieser Seite mit einem andern Photomultiplier die Entzündung im Raum des Stoßrohrs hinter dem Fenster messen kann.

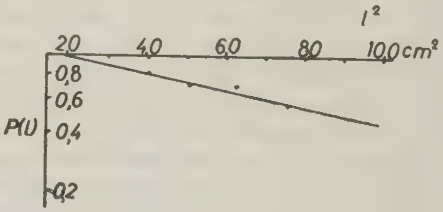


Die beiden Photomultiplier* wurden an einen Zweistrahloszillographen angeschlossen, so daß sie gleichzeitig gemessen werden konnten. Wenn die Entzündung im Raum direkt hinter dem Fenster losgeht, muß die Induktionszeit, die mit dem Photomultiplier von der Seite gemessen wird, gleich der Induktionszeit sein, die mit dem andern Photomultiplier vor der Endwand gemessen wird. Wenn die Entzündung im andern Raum losgeht, muß die Induktionszeit, die mit dem Photomultiplier von der Seite gemessen wird, länger sein, als die mit dem andern Photomultiplier gemessene.

Wenn man die Breite des Fenster ändert und mehrere Male denselben Versuch macht, bekommt man eine Verteilungskurve der Zündstelle. Bei diesem Experiment wurde der Versuch bei Verschiedenen Fensterbreirte ausgeführt. Die Breite des Fensters betrug: 20,0 mm, 22,5 mm, 25,0 mm, 27,5 mm und 30,0 mm von der Endwand. Bei jeder Breite des Fensters wurde 20 Mal unter derselben Bedingungen gemessen.

Von dieser Verteilungskurve der Zündstelle kann man die Wahrscheinlichkeit der Entzündung in einer Volumeneinheit bekommen, aber dabei muß die Zeitänderung berücksichtigt werden, genau so wie bei der Messung der Wahrscheinlichkeit der Entzündung in einer Zeiteinheit die Volumänderung berücksichtigt wurde. Wenn man Folgende darstellt:

$P(l)$: die Wahrscheinlichkeit dafür, daß im Abstand l von der Endwand des Stoßrohrs keine Entzündung und in größeren Abstand Entzündung auftritt; $\mu(l)$: die Wahrscheinlichkeit der Entzündung in einem Mol und in einer Millisekunde an einer Stelle l; t:Zeit nach der Reflektion der Stoßwelle an der Endwand; l: Abstand von der Endwand; D_2: Geschwindigkeit der reflektierenden Stoßwelle; A: Querschnittsfläche des Stoßrohrs dann(1)(2) folgt



$$\mu(l) = -\frac{\{2 \cdot D_2 \ln P(l) - \ln P(l_2)\}}{A \cdot (l_1^2 - l_2^2)},$$

Bild 2 zeigt das Versuchsergebnis eines Methan-Luftgemisches (Konzentration 5,5%) und die Kurve ist wirklich eine Gerade. Daraus erhält man

$\mu(l) = 140 \times 10^2/\text{Mol}\cdot\text{msec.}$, $\mu(l)$ wirklich von l unabhängig.

Dabei konnte man nur das Druckverhältnis Treibdruck zu Unterdruck messen.

$$\frac{P_T}{P_0} = \frac{21{,}0at}{0{,}15at} = 140$$

Von der Schwankung der Induktionszeit wurde die Wahrscheinlichkeit der Entzündung in einer Millisekunde und in einem Mol unter ähnlichen

Bedingungen ($\frac{P_T}{P_0}=152$, die Temperatur der Rückwelle 773°K) berechnet. Sie ergibt sich $\mu(t)=50\times10^2$/Mol·msec. Eigentlich ist $\mu(t)$ nicht anders als $\mu(l)$, und sie müssen miteinander übereinstimmen, wenn die Bedingungen gleich sind. Das Resultat des Experiments zeigt, daß sie miteinander ziemlich gut übereinstimmen, wenn man Versuchsfehler berücksichtigt.

Damit wurde bewiesen, daß die Zündstelle der Selbstzündung eines brennbaren Gemisches eine Schwankung hat, und daß auch die Menge des Gemisches auf die Entzündung großen Einfluß hat.

Electron Spin Resonance of Manganese in Ammonium Chloride

By Hidetaro ABE and Hiroko SHIRAI
The Institute for Solid State Physics, University of Tokyo

(Received July 11, 1960)

Recently, divalent manganese ion incorporated into cubic crystals of monovalent alkali halides has been extensively investigated with the electron spin resonance techniques[1)2)] which give us detailed informations about the electronic structure of the ion and its environments.

The crystal structure of alkali halides belongs to the NaCl type, one of the simplest lattices. In the present report, ammonium chloride, NH_4Cl, is used as the host crystal which belongs to the CsCl type, another of the simplest crystal lattices. It is known that ammonium chloride has three crystal modifications. The β modification is stable at a temperature range from 184.3°C to −30.5°C (the λ temperature) and has the crystal structure of CsCl type, if an ammonium group, NH_4^+, is treated as a monovalent positive ion.[3)4)]

The sample crystals were grown from the mixed aqueous solution of ammonium chloride and manganese chloride, $MnCl_2\cdot4H_2O$, with a weight ratio about 100: 1. The ESR spectra were observed at room temperature (about 20°C) with the static magnetic field rotated within the (001) and the (110) plane. The spectrometer works at about 23,110 Mc which was used to study the copper butylate monohydrate.[5)]

In our preveous study[6)] with 9000 Mc spectrometer, the observed spectra could not been analyzed because the influence of crystalline field was much larger than the Zeeman energy. With our 24,000 Mc spectrometer, the Zeeman energy just exceeds the former. The ESR spectrum consists of many lines which spread over a wide range of magnetic field, e.g. at the [100] direction they appear from 1,705 oer, to 14,940 oer. The results are fairly well expressed with a spin-Hamiltonian:

$$\mathscr{H}=g\beta\vec{H}\vec{S}+DS_z^2+A\vec{I}\vec{S} \qquad (1)$$

with parameters of $g=1.984$ (isotropic), $D=1600\pm25$ oer., and $A=93\pm4$ oer. The crystalline field seems to have no rhombic part ($E\approx0$). There are three equivalent choices in direction of z-axis which are three cubic axes of the crystal: [100], [010], and [001] axes. This suggests the manganese ion substitutes an ammonium group (NH_4^+) and one of the six nearest neighbour ammonium ions becomes vacant to secure the requirement of charge neutrality. This model satisfies the axially symmetric field by a consideration on atomic arrangements.

The crystalline field parameter, D, in the present case is anomalously large compared with the case of manganese ion in some hydrated crystals[7)] (100∼200 oer.) or in NaCl[1)] (130 oer.).

Results at reduced temperatures, in bromide crystals, and further discussions will be published in a forthcoming paper.

A Note on the Magnetic Resonance in Metals

By Ko SUGIHARA
Technical Research Department, Wireless Division,
Matsushita Electric Industrial Co.,
Kadoma, Osaka

(Received June 13, 1960)

The effect of the normal skin effect on the line shape of the magnetic resonance of the localized spins was studied by Bloembergen[1]. For a pure metal at liquid helium temperatures, the free path of the conduction electrons is large compared to the skin depth in the radio-frequency range, actually typical values of the free path are $l \gtrsim 10^{-3}$ cm and the penetration depth δ for angular frequency $\omega \sim 10^8$ sec^{-1} is 10^{-4} cm. In this note we shall derive the absorption curve in N M R in the anomalous skin effect region.[*]

The theories of the anomalous skin effect in the presence of a static magnetic field have been given by Heine,[4] Azbel'-Kaner[5] and Mattis-Dresselhaus[6] in connection with the cyclotron resonance in metals.

A semi-infinite sample is considered with its boundary in the $z=0$ plane and positive z direction is towards the interrior of the metal. The oscillating field $H_1 \exp(i\omega t)$ and the static field are parallel to the y-axis and to the z-axis respectivelly. The absorption rate is given by

$$P=(c/4\pi)^2 H_1^2 (R_e Z) \qquad (1)$$

where Z represents the surface impedance. Taking into the consideration of the permeability μ, Z is written in the form

$$Z=-4\pi i\omega\mu c^{-2}\, E_x(0)/E'_x(0), \qquad (2)$$

where $E_x(0)$ stands for the x-component of the electric field and $E'_x(0)$ its derivative at $z=0$. Neglecting the displacement current, $E_x(0)/E'_x(0)$ can be written as

$$\frac{E_x(0)}{E'_x(0)}=-\frac{2}{3}\left(1-\frac{i}{\sqrt{3}}\right)\left(\frac{c^2 l}{3\pi^2\sigma\mu\omega}\right)^{1/3} \times \tanh^{1/3}\left[\frac{\pi}{\omega_c\tau}(1+i\omega\tau)\right], \qquad (3)^{\dagger)}$$

where σ is the D. C. conductivity, ω_c the cyclotron frequency and τ is the time of relaxation of the conduction electrons. As $\omega\tau$, ω/ω_0 and $|\chi|$ are very small, the real peal part of Z becomes

$$R_e Z=R_0\left\{1+\frac{8\pi}{3}\left(\frac{\chi'}{\sqrt{3}}+\chi''\right)\right\}, \qquad (4)$$

$$R_0=\frac{8}{9}\left(\frac{\sqrt{3}\,\pi\omega^2 l}{c^4\sigma}\right)^{1/3}\left[\frac{\sinh(\pi/\omega_c\tau)}{\cosh(\pi/\omega_c\tau)}\right]^{1/3}. \qquad (4)'$$

If the electron's orbit are not quantized, (4)′ reduces to the result given by Reuter-Sondheimer.[7] From Eq. (4) it is concluded that the absorption rate by the spin system is proportional to $(\chi'/\sqrt{3}+\chi'')$ in the anomalous region, on the other hand to $(\chi'+\chi'')$ in the normal region. For simplicity, we assume that the line shape is given by the Bloch-type and far from saturation, then the ratios of the absorption maximum and minimum and their positions are easily obtained and they are summarized in the following table.

	position of max	position of min.	ratio of absorption max. and min.
Normal	$\Delta\omega T_2=\sqrt{2}-1$	$\Delta\omega T_2=-(1+\sqrt{2})$	14: -1
Anomalous	$\Delta\omega T_2=2-\sqrt{3}$	$\Delta\omega T_2=-(2+\sqrt{3})$	5.8: -1

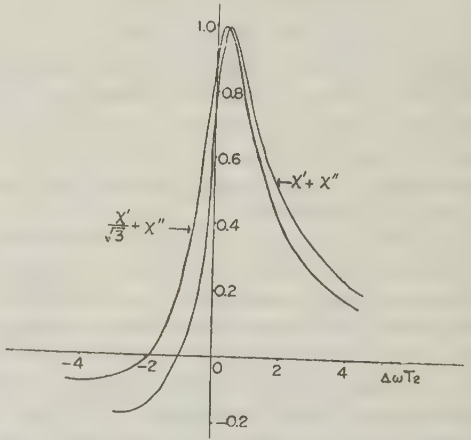

Fig. 1. Absorption curves in the normal and the anomalous region.

Absorption curve in which the maximum values are normalized to 1 are shown in Fig. 1. Unitil now, we limit our discussion to the semiinfinite sample but it is desirable to analize the relation between the dimension of the sample and the absorption curve. Particularly, it seems to be interesting to us to investigate the problem in the region $l>d>\delta$, where d is the thickness of the sample.

---

[*] The extension of the Dyson's theory[2] of paramagnetic resonance by the conduction electrons in the normal region was carried out by Kittel[3], but his theory can not be applicable to the problem of the localized spin system.

†) Putting $\mu=1$, we obtain the Eq. (27) given by Mattis-Dresselhaus.

$1/f$ Noise and Channel in Ge PN Junction

By Kiichi Komatsubara*, Yoshio Inuishi, Hiroshi Edagawa* and Tsutomu Shibaike

College of Engineering, Osaka Uuiversity.
**Kobe Kogyo Co..*

(Received June 25, 1960)

We have been studying the mechanism of $1/f$ noise in semiconductor pn junctions,⁽¹⁾⁽²⁾ and suggested that the channel is a predominant source of the $1/f$ noise in reversely biased pn junctions. Now some direct evidence of this suggestion have been found in our measurement of "field effect" on excess noise. Ge grown pn junctions were placed like Fig. 1, where surface field electrode of conducting glass were attached to the cleaned junction surface through a thin mica separator. The glass tubes containing the specimen were evacuated at 10^{-6} mm Hg for several hours and sealed. Ge pn junction thus prepared were reversely biased at the voltage V_c and various surface fields were applied on the junction by the voltage V_F on the field electrode as shown in Fig. 1. The mean reverse current I through the junction and the mean square short-circuit noise current $\langle \Delta i^2\rangle$ at 1 kc were measured at various values of V_F and V_c.

As an example, Fig. 2 shows the noise $\langle \Delta i^2\rangle$ and current I in n^+p junctions as function of surface field voltage V_F. For $V_F>0$, inversion layer or channel grows in the high resistivity (p) side and for $V_F<0$ accumulation layer grows in the high resistivity side as will be mentioned later. Now we can see in Fig. 2 that the channel produces the remarkable increase both in excess current and in excess noise. Judging from the frequency spectrum of the noise as shown in Fig. 3, the channel noise is mainly $1/f$ type. Similar data for p^+n junction are shown in Fig. 4, which also show that the channel formation in high resistivity n side at $V_F<0$ produces large $1/f$ noise accompanied by the increase in excess current.

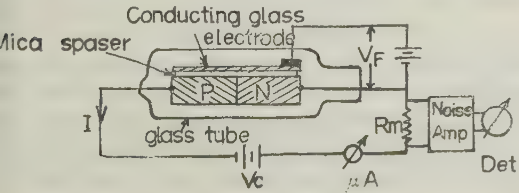

Fig. 1.

This channel formation was confirmed by illuminating the reversely biased junction surface by fine beam of chopped light through conducting glass electrode at various voltage V_F and examin-

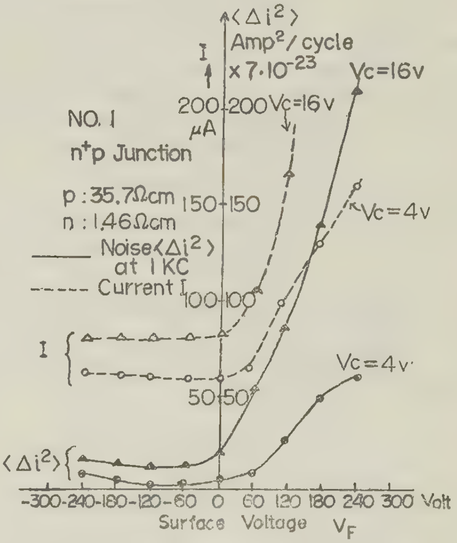

Fig. 2.

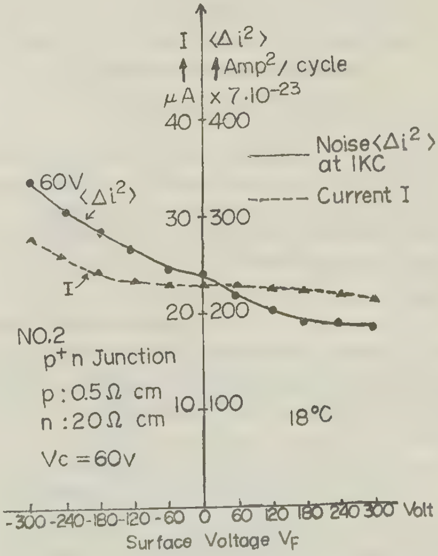

Fig. 3.

ing the photo-current as the function of beam position. The details of these experiment will be published in a full paper soon.

Spin Wave Resonance in Ni Films

By Hiroshi NOSÉ

Department of Physics, Faculty of Science,
Tokyo Metropolitan University

(Received June 14, 1960)

The "*Spin Wave Resonance*" (*S.W.R.*) proposed by Kittel[1] was confirmed from the observation in 80 Ni-Fe film by Seavey and Tannenwald.[2] The present report shows that it was confirmed also in Ni film provided that a certain condition was satisfied.

In the thin film, it was suggested by Macdonald[3] that the usual expressions of ferromagnetic resonance condition had to be modified. When an external magnetic field $H_{\parallel}$ is applied parallel to the film plane,

$$\left(\frac{\omega}{\gamma}\right)^2=\left(H_{\parallel}+4\pi M+\frac{3\lambda\sigma}{M}+\frac{3\lambda\sigma_u}{M}\cos^2\theta\right)\times\left(H_{\parallel}+\frac{3\lambda\sigma_u}{M}\cos 2\theta\right),$$

where M and λ are the saturation magnetizatio and magnetostriction constant of the bulk, respec tively; σ is a planer stress isotropic in the fil plane; σ_u is a uniaxial stress lying in the film plan at an angle θ out of the direction of M. Th stresses are positive for tension, and negative fo compression as usual. The uniaxial stress ha been introduced in place of the uniaxial anisotropy though the latter is commonly used.

Similarly in the case of the magnetic field H perpendicular to the film plane,

$$\left(\frac{\omega}{\gamma}\right)^2=\left(H_{\perp}-4\pi M-\frac{3\lambda\sigma}{M}-\frac{3\lambda\sigma_u}{M}+\frac{2A}{M}k^2\right)\times\left(H_{\perp}-4\pi M-\frac{3\lambda\sigma}{M}+\frac{2A}{M}k^2\right),$$

where the term $2Ak^2/M$ expresses the *S.W.R.*; th exchange coupling constant $A=4JS^2/a$ (a: th lattice constant for f.c.c., J: the exchange energy S: the spin angular momentum); the magnitude o the wave number $k=p\pi/L$ (p: an odd integer, L the film thickness).

Ni films in the present work were prepared b evaporating on the mica- and glass-substrates heate at 15~320°C in vacuum (4×10^{-5} mmHg). The film thicknesses measured by the multiple beam inter ferometer were 1000~3000Å. The presence of magnetic field about 50 Oe in the course of th evaporation or annealing affected hardly the *S.W.R* in these films.

Some of the results obtained by the ferro magnetic resonance at 9,300 Mc/s, and the crystal line structures examined by the electron diffractio are briefly reported.

i) The films evaporated on the mica heated a 320°C had $\sigma=5.3\times10^9$ and $\sigma_u=-1.9\times10^8$ dyne/cm in agreement with the observation by Macdonal carried out only in the case of the parallel field a 23,000 Mc/s. These values did not remarkably depend on the substrate temperature. This is pre sumably due to the fact that the cleavage surface of mica is fairly clean and smooth. The *S.W.R* in these films was not clearly observed.

ii) In the films evaporated on the glass main tained at room temperature, magnitudes of stresses considerably fluctuated: that is $\sigma=(6\sim12)\times10^9$ and $\sigma_u=-(1\sim5)\times10^8$ dyne/cm². This fluctuation as well as these magnitudes, however, decreased with the rising substrate temperature, for example at 320°C $\sigma=(4.0\sim4.5)\times10^9$ and $\sigma_u=-(0.2\sim0.5)\times10^8$ dyne/cm². These results are quite different from the films on the mica and somewhat attributable to inhomogenities on the surface structure of glass substrate. The *S.W.R.* in these films could be definitely observed provided that the films prepared at room temperature had not only larger stresses but also sharper absorption line. They had $L=$ 2000~2500Å, $p=4\sim7$, and $A=(0.47\sim0.59)\times10^{-6}$

erg/cm. Even if they were annealed at 100～300°C for one hour in vacuum immediately following the evaporation, the definite *S.W.R.* disappeared.

iii) While the half-widths (ΔH between maximum slopes) were about $\Delta H_{\parallel}=300\sim600$ and $\Delta H_{\perp}=250$ Oe in the films prepared on the mica at any substrate temperature they were $\Delta H_{\parallel}=200\sim600$ and $\Delta H_{\perp}=180\sim300$ Oe, and $\Delta H_{\parallel}=250\sim350$ and $\Delta H_{\perp}=180\sim280$ Oe in the films prepared on the glass at room temperature and at 320°C, respectively. They also depend on the condition of substrate surface as described above. Though its fine structure of absorption line could not be made clear, the *S.W.R.* seems to exist also in parallel field taking account of the skewed absorption line and $\Delta H_{\parallel}\geqq\Delta H_{\perp}$.

iv) By investigations with the electron diffraction, it was found that the preparation of the single crystal films on the mica by socalled *Epitaxy* failed at any substrate temperature. On the other hand, the films prepared on the glass maintained at lower temperatures had the fibre textures whose axes were [110] and/or [111] normal to the films, but the ones prepared at the temperature higher than 200°C had no fibre texture and the sharper diffraction lines. According to the results obtained, these fibre textures are presumed to have no relation with the excitation of the *S.W.R.* and the magnitude of stresses.

The author wishes to express his thanks to Prof. R. Kimura for his continued encouragement and to Dr. M. Kuriyama for his cooperation.

Magnetic Property of Cr_2O_5

By Eiichi HIROTA and Buichi KUBOTA

Research Division, Wireless Department,
Matsushita Electric Industrial Co., Ltd.
Osaka, Japan

(Received July 4, 1960)

Various intermediate chromium oxides between CrO and Cr_2O_3 are obtained by heating CrO_3 under high oxygenic pressure. These oxides are Cr_3O_8, Gr_2O_5 and CrO_2. Of these oxides, chromium dioxide, CrO_2, is ferromagnetic. A number of investigations on this dioxide have been reported, but there are few reports of the other oxides. In the present note the result of magnetic measurements on Cr_2O_5 is reported.

The specimen was prepared by heating CrO_3 up to 305°C under an oxygenic pressure of 95 Kg/cm² for 12 hours. The X-ray powder pattern of the specimen showed only the Cr_2O_5 phase, but the background was remarkable. The oxygen content of the specimen was determined from the ignition loss at 1,000°C for 1 hour, and the result showed that the specimen was $CrO_{2.41}$. From thermogravimetric and differential thermal analysis, it was found that the oxide was stable up to about 380°C in air. The density was about 3.24. Impurities of the specimen were also examined by spectroscopic analysis and traces of Ca, Cu, Fe, Mg, Na, Pb and Si were detected.

Magnetic measurements were carried out with the use of an automatic recording magnetic balance in the temperature range between 77°K and 500 K. The paramagnetic susceptibility of Cr_2O_5 at room temperature was obtained as

$$\chi=(19.4\pm0.5)\times10^{-6}\ \text{e.m.u./g},$$

where an aqueous solution of Ni Cl_2 was used as the standardizing solution.

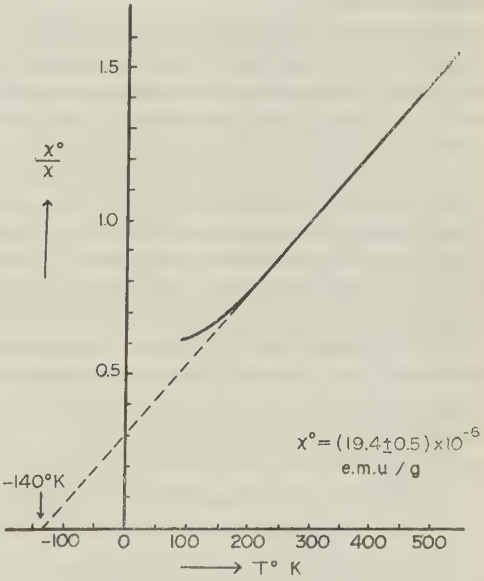

Fig. 1. Inverse susceptibility versus temperature curve for Cr_2O_5.

From thermomagnetic measurements the $1/\chi$–T curve was obtained. The result is shown in Fig. 1. In the high temperature range the $1/\chi$–T curve is well described by the Curie-Weiss law, $\chi=C/(T+\theta$, where $C=8.44\times10^{-3}$ e.m.u./g-deg, $\theta=140$°K. It seems resonable to conclude that Cr_2O is antiferromagnetic. To make this conclusion more definite, measurements below 77°K are desirable.

Thermal Bleaching of F-Centers of Gamma-Irradiated KCl at Low Temperatures

By Noriaki ITOH, and Tokuo SUITA

Department of Nuclear Engineering, College of Engineering, Osaka University.

(Received July 29, 1960)

In order to investigate the nature of color centers in KCl formed by gamma-irradiation at low temperatures and the mechanism of their formation, the thermal bleaching curve of F-centers was measured.

The specimens which were obtained from the ingot purchased from Harshaw Chemical Co. were kept in the cryostat with quartz window set in the Co^{60} 10,000 Curie cave in Japan Atomic Energy Research Institute (JAERI). After irradiation the change in the optical absorption was measured by the Cary spectrophotometer. The coloration of the quartz window is small as compared with that of KCl crystals in the interesting wave length range and can be subtracted without causing substantial error.

The irradiated specimens were warmed at a rate of about 1°C/min and during that the absorption coefficient of the specimen was measured intermittently by sweeping the spectrometer at the speed of 5 mμ/sec. The temperature dependence of the band width of the F-band was obtained by measuring the temperature dependence of the peak value of the F-band of gamma-irradiated KCl at room temperature, in which case, the change of the absorption coefficient with temperature was reversible showing that the absorption intencity is constant. The dependence of the band width on the temperature thus obtained is nearly the same as that obtained by Russel and Klick[1], and used to calculate the concentration of F-centers from the peak value of the F-band at various temperatures during warming up.

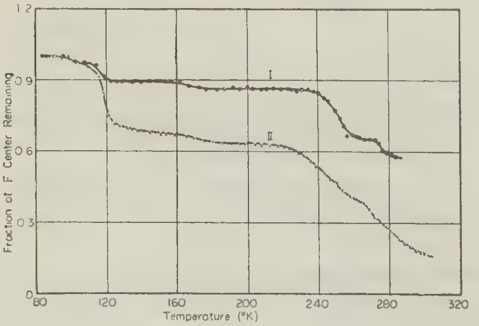

Fig. 1. Annealing curve of F-centers of KCl gamma-irradiated at liquid nitrogen temperature. I; 9.4×10^4 r, n_0 (initial F center concentration) $= 3.8 \times 10^{15}$/cc, II; 1.7×10^6 r, $n_0 = 4.6 \times 10^{16}$/cc.

Fig. 1 shows the bleaching curue of F centers of KCl irradiated at liquid nitrogen temperature by various gamma dose. It is clear that the sharp decrease of F centers occur at the temperatures of 98°K, 116°K, 172°K, 250°K and 278°K. It should also be noted that the gradual decrease of the concentration of F centers can be observed besides the sharp decreases especially when the crystal was heavily colored. This is more clearly seen in the bleaching curve of KCl irradiated at dry ice temperatures.

As F centers are stable thermally in these temperature range[2], the decrease shown in Fig. 1 seems to be due to the thermal decomposition of V centers. Measurements were also done on the change of V bands during warming up. In the temperature range in which the first decrease of F centers occur, most of V_1 centers disappeared, showing that this decrease is due to the decomposition of V_1 centers. From the results of Delbecq et al[3], the second stage seems to be related to the V_K centers. The forth and fifth stage were observed to correspond to the V_2 band and the band having the peak near 270 mμ, respectively.

The decrease of the concentration of F centers in each stage seems to be a measure of the concentration of each V centers formed by gamma-irradiation. It is interesting to know that the concentration of V_1 centers is nearly proportional to the initial concentrations of F centers, whereas the concentration of V_K centers increased superlinearly with increasing gamma ray dose. Corresponding to the superlinear incaease of V_K centers, the concentration of F centers which remain stable after warming up to room temperature saturates in the case when irradiated at liquid nitrogen temperature.

The gradual decrease of the F center concentration during warming up may occur if some clustering of V type centers lowers their activation energy for thermal decomposition. In this connection it is interesting to note that Markham et al have shown[4] that the distribution of F centers are not so uniform in KBr irradiated at room temperature, from their bleaching experiments at liquid helium temperature. In order to clear these points and effects of impurity on the annealing curve more experiments are now in progress.

Most parts of this work was done while Nuclear Engineering one of the authors (N. I.) was in the course of School of JAERI. The authors would like to express our gratitude to Prof. Y. Takagi, Dr. K. Kubo and other staffs of the Solid State Physics Division of JAERI and

also to the members of solid state group of Suita's Laboratory.

Oscillatory Magnetoresistance in N-Type PbTe

By Yasuo KANAI, Riro NII and Naozo WATANABE

Electrical Communication Laboratory, Musashinoshi, Tokyo

(Received July 5, 1960)

As is well known[1)], the mobilities of electrons and holes in PbS, PbSe and PbTe become very large at liquid helium temperature. This fact suggests us that the oscillatory galvanomagnetic effects could be observed in these semiconductors at very low temperatures.

Hall effect and megnetoresistance of n-type PbTe were measured at 4.2°K in a pulsive strong (over 100 KG) magnetic field. The transverse magnetoresistance *versus* magnetic field strength curve of one of our samples is shown in Fig. 1. This sample had the following character at 4.2°K; electrical resistivity $\rho_0=2.15\times10^{-5}$ ohm-cm, Hall coefficient $R_H=-35.6$ cm^3/Coul., hence Hall mobility $\mu_H\equiv|R_H|/\rho_0=1.65\times10^6$ cm^2/V. sec. As we can see in Fig. 1, it is quite clear that there are some oscillatory parts in the magnetoresistance effect in n-type PbTe. But we could not find any anomaly in the Hall effect of the same sample.

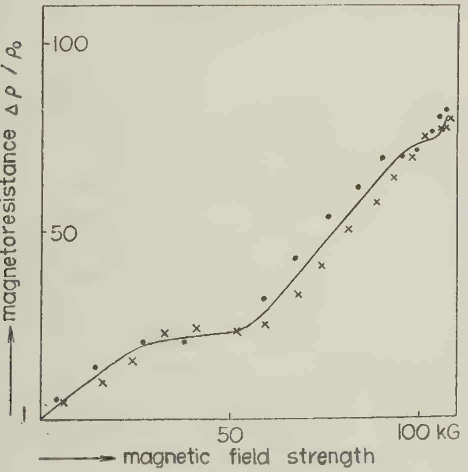

Fig. 1. The transverse magnetoresistance *versus* magnetic field strength curve of an n-type PbTe crystal at 4.2°K. The symbols · and × show the values obtained when the magnetic field increased and decreased respectively.

Further systematic investigations on the oscillatory galvanomagnetic effects in PbTe are now in progress and the results will be reported in this Journal.

Sign Reversal of Hall Coefficients at Low Temperatures in Heavily Compensated *p*-type Germanium

Hiroo YONEMITSU, Hajime MAEDA, and Hisao MIYAZAWA

Matsuda Research Laboratory, Toshiba Electric Co., Kawasaki

(Received July 8, 1960)

Impurity center conduction in germanium has been well examined by Fritzsche et al[1] and other authors[2]. However, no one has successfully observed sign reversal of Hall coefficients even in deliberately compensated specimens. According to the two carrier model[1] of free holes and acceptor electrons, there might be the sign reversal provided the mobility and the concentration of free holes are very small while those of acceptor electrons are quite large. These conditions will be realized if the crystal is quite heavily compensated, as illustrated in Fig. 1.

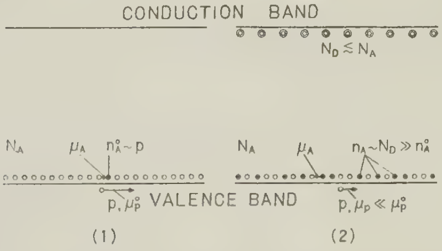

Fig. 1. Comparison between (1) uncompensated and (2) heavily compensated p-type Ge. Note that $n_A \gg n^0_A$ and $\mu_p \ll \mu_p^0$ because of added donors.

The present authors, therefore, prepared such a crystal in which the ingot initially containing $\sim 2\times 10^{16}$ Ga cm^{-3} and having resistivity of 0.2 ohm·cm was heavily compensated with Sb. The resultant specimens cut from this crystal indicate resistivity of ~0.32 ohm-cm and p-type Hall coefficient of ~740 cm^3 coul^{-1}. at room temperature, suggesting ~40% compensation. When the measurements were carried out at low temperatures, The Hall coefficients at 5,000 gauss, as plotted in Fig. 2, indicated a maximum at 10°K, then decreased as usual with decreasing temperature, and eventually the sign reversal occurred nearly at 5°K. Thereafter the Hall coefficients flattened off, showing temperature insensitive behaviors. Meanwhile, the resistivity showed typical characteristics of impurity conduction below 10°K. Similar results have been obtained on several specimens.

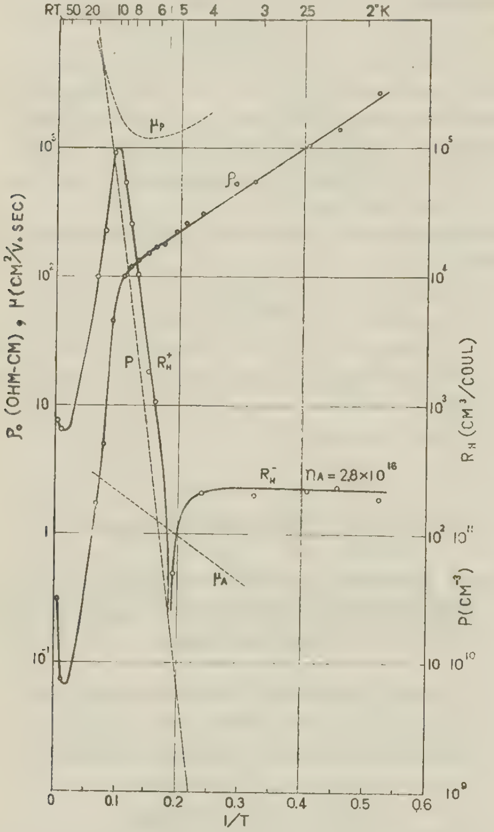

Fig. 2. An example of behaviors of Hall coefficient and resistivity for a heavily compensated p-type Ge.

The data were analysed by the two carrier model, which is expressed by

$$R_H = \frac{1}{e}\frac{r_p p \mu_p{}^2 - r_A \mu n_A{}^2{}_A}{(p\mu_p + n\mu_A)^2}, \quad \rho_0 - e^{-1}(p\mu_p + n_A\mu_A)^{-}$$

where r_p and r_A are assumed to be unity in the present case. Some quantities thus determined are presented in Fig. 2. The values of μ_p and μ_A seem reasonable[3,4] except n_A slightly exceeds N_A.

Energy Dependence of Angular Distributions of the Reaction $Al^{27}(p, \alpha)Mg^{24}$ in the Energy Region between 10.5 and 14.5 Mev*

By Hiroshi OGATA, Hidehiko ITOH,
Department of Nuclear Science, Faculty of Science, Kyoto University
Yoshiko MASUDA, Kunio TAKAMATSU, Maumi KAWASHIMA,
Akira MASAIKE and Isao KUMABE
Department of Physics, Faculty of Science, Kyoto University

(Received June 13, 1960)

The angular distributions of the reactions $Al^{27}(p, \alpha)Mg^{24}$ resulting in the ground and first excited states of Mg^{24} were measured at 37 energies between 10.5 and 14.5 Mev, making use of proportional counters.

Similar behaviour was obtained for both reactions. The variation of the shape of the angular distributions with the bombarding energy is rather smooth in the higher energy region, but becomes rapid with decreasing the bombarding energy. There appear some resonance-like peaks and valleys in the excitation curves at laboratory angles of 50°, 90° and 130° but their positions are not coincident with one another and in the higher energy region these peaks disappear in the excitation curves for the total cross sections.

The variations of the excitation curves for the total cross sections and of the shape of the angular distributions with energy in the lower energy region may be due to the fluctuations in the number or properties of the compound nucleus levels and to the interference between the compound nucleus and direct interaction processes. The smoothing-outs of the excitation curves for the total cross sections and of the variation of the shape of the angular distributions in the higher energy region seem to be due to the effects of decreasing level spacing in the compound nucleus and of increasing contribution from the direct interaction process. However, in the entire energy region, the interference between the compound nucleus and direct interaction processes and some contribution from the heavy particle stripping process cannot be neglected.

§1. Introduction

The sharp energy dependence of the differential cross sections for the (p, α) and (p, p') reactions in the medium weight nuclei was reported by several authors. Fischer *et al.*[1] have measured the angular distributions of the reactions $Al^{27}(p, \alpha_0)Mg^{24}$ and $Al^{27}(p, \alpha_1)Mg^{24*}$ resulting in the ground and first excited states of Mg^{24}, respectively, at 10.87 and 10.97 Mev, as well as the excitation curves for these reactions in the energy region between 9.6 and 11 Mev. It has been found that these excitation curves show a sharp energy dependence which is not expected from the view-point of direct interaction theories.

In a previous paper,[2] we have reported the excitation curves at a laboratory angle of 50° with respect to the bombarding beam, from 12.7 to 14.1 Mev and the angular distributions at 14.1, 13.0 and 12.8 Mev for the reactions $Al^{27}(p, \alpha_0)Mg^{24}$ and $Al^{27}(p, \alpha_1)Mg^{24*}$. It has been found that the excitation curves show a sharp energy dependence, and some angular distributions show strong backward peaking, although the $Al^{27}(p, \alpha_0)Mg^{24}$ data can be partially fitted by $[j_2(Qr_0)]^2$ of Butler's theory.[3]

For Ni and Si^{28} targets, the dependence of the yield of the inelastic scattering resulting in the first excited state on the bombarding energy has been measured in detail by Hu *et al.*[4] by changing the incident proton energy finely at intervals of about 50 kev. They have recognized that there were resonance-like behaviours with spacing of about several hundred kev. In order to interpret such sharp energy dependence, Igarasi *et al.*[5] have proposed a nuclear model based on some kind of partial heating of the nucleus.

---

* This experiment was performed using a 160 cm variable energy cyclotron at the Institute for Nuclear Study, University of Tokyo.

Numerical data obtained in this experiment will be published in Memoirs of the College of Science, University of Kyoto.

In this situation the accumulation of more detailed experimental data is desirable for further development. In this paper the results of measurements on the angular distributions of the reactions $Al^{27}(p, \alpha_0)Mg^{24}$ and $Al^{27}(p, \alpha_1)Mg^{24*}$ at 37 energies between 10.5 and 14.5 Mev are reported as a part of our extensive investigations on the (p, α) reaction.

§ 2. Experimental Procedure

Proton beam was obtained from a 160 cm variable energy cyclotron[6] at the Institute for Nuclear Study, University of Tokyo. The detector[7] is a proportional counter, as shown in Fig. 1, filled with argon and 5% CO_2 at such pressures that the fast alpha particles from the individual (p, α) reaction lose their energies completely inside the sensitive volume of the counter. In this way alpha particle groups were easily separated from proton and deuteron groups. Two proportional counters making an angle of 40° to each other were placed on the turn table in the scattering chamber to save the time of the observation. In order to stop completely the alpha particles resulting in the ground state of Mg^{24}, the counters were filled with $A\text{-}CO_2$ at pressures of 75.0, 64.4, 60.1, 51.0 and 45.3 cmHg for 14.55∼14.28, 14.16∼13.31, 13.16∼12.25, 12.17∼11.70 and 11.53∼10.65 Mev respectively. The counter pressures could be easily varied from the outside of the scattering chamber.

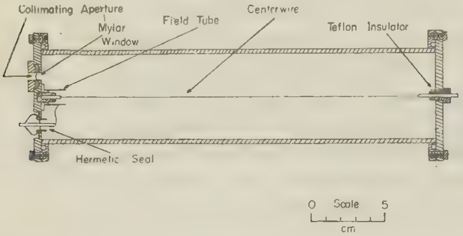

Fig. 1. Proportional counter used for the detection of the alpha particles.

As a target a foil of aluminium of 0.668 mg/cm² in thickness was used which was placed at 45° with respect to the bombarding beam, and corresponds to the energy loss of about 30 kev at 14 Mev proton energy. The beam current was measured by a Faraday cup and a beam current integrator, and furthermore monitored by a CsI(Tl) scintillation counter located at one of the side windows of the scattering chamber making an angle of 75° with the beam direction. The detector bias was chosen to count only the pulses due to the protons scattered elastically by aluminium.

The beam energy was varied at intervals of about 100 kev by varying the magnetic field and the frequency of the cyclotron. The energy of protons was measured carefully at the beginning and the end of each measurement of the angular distributions by the combination of aluminium absorbers and a shallow ionization chamber. Using the range energy relation obtained by Bichsel *et al.*,[8] the absolute value of beam energy was determined within the experimental error of 100 kev, and the relative value is considered to be much more accurate. The energy spread of the incident beam was not determined precisely but it seems to be less than 50 kev.

A typical pulse height distribution of the alpha particles from the reaction $Al^{27}(p,\alpha)\cdot Mg^{24}$ is shown in Fig. 2. Two peaks in Fig. 2 correspond to the reaction $Al^{27}(p, \alpha_0)\cdot Mg^{24}$ ($Q=+1.595$ Mev[9]) resulting in the ground state and the reaction $Al^{27}(p, \alpha_1)Mg^{24*}$
